62 •• How many time constants must elapse before the current in an *RL* circuit (Figure 28-54) that is initially zero reaches (*a*) 90 percent, (*b*) 99 percent, and (*c*) 99.9 percent of its steady-state value?

63 •• A circuit consists of a 4.00-mH coil, a 150-Ω resistor, a 12.0-V ideal battery, and an open switch—all connected in series. After the switch is closed: (*a*) What is the initial rate of increase of the current? (*b*) What is the rate of increase of the current when the current is equal to half its steady-state value? (*c*) What is the steady-state value of the current? (*d*) How long does it take for the current to reach 99 percent of its steady state value? SSM

64 •• A circuit consists of a large electromagnet that has an inductance of 50.0 H and a resistance of 8.00 Ω, a dc 250-V power source, and an open switch—all connected in series. How long after the switch is closed is the current equal to (*a*) 10 A and (*b*) 30 A.

65 •• **SPREADSHEET** Given the circuit shown in Figure 28-55, assume that the inductor has negligible internal resistance and that the switch S has been closed for a long time so that a steady current exists in the inductor. (*a*) Find the battery current, the current in the 100 Ω resistor, and the current in the inductor. (*b*) Find the potential drop across the inductor immediately after the switch S is opened. (*c*) Using a spreadsheet program, make graphs of the current in the inductor and the potential drop across the inductor as functions of time, for the period during which the switch is open. SSM

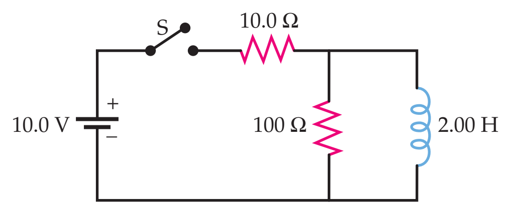

FIGURE 28-55 Problem 65

66 •• Given the circuit shown in Figure 28-56, the inductor has negligible internal resistance and the switch *S* has been open for a long time. The switch is then closed. (*a*) Find the current in the battery, the current in the 100-Ω resistor, and the current in the inductor immediately after the switch is closed. (*b*) Find the current in the battery, the current in the 100-Ω resistor, and the current in the inductor a long time after the switch is closed. After being closed for a long time the switch is now opened. (*c*) Find the current in the battery, the current in the 100-Ω resistor, and the current in the inductor immediately after the switch is opened. (*d*) Find the current in the battery, the current in the 100-Ω resistor, and the current in the inductor after the switch is opened for a long time.

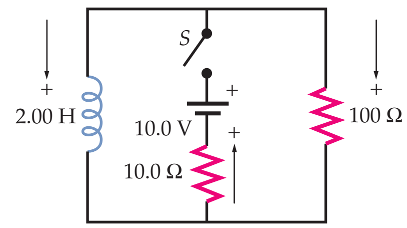

FIGURE 28-56 Problem 66

67 •• An inductor, two resistors, a make-before-break switch, and a battery are connected as shown in Figure 28-57. The switch throw has been at contact *e* for a long time and the current in the inductor is 2.5 A. Then, at $t = 0$, the throw is quickly moved to contact *f*. During the next 45 ms the current in the inductor drops to 1.5 A. (*a*) What is the time constant for this circuit? (*b*) If the resistance *R* is equal to 0.40 Ω, what is the value of the inductance *L*?

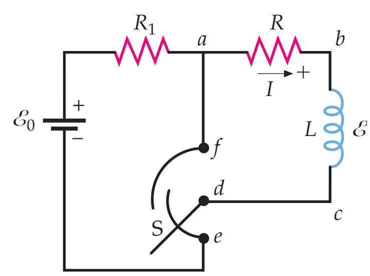

FIGURE 28-57 Problem 67

68 •• A circuit consists of a coil that has a self-inductance equal to 5.00 mH and an internal resistance equal to 15.0 Ω, an ideal 12.0-V battery, and an open switch—all connected in series (Figure 28-58). At $t = 0$ the switch is closed. Find the time when the rate at which energy is dissipated in the coil equals the rate at which magnetic energy is stored in the coil.

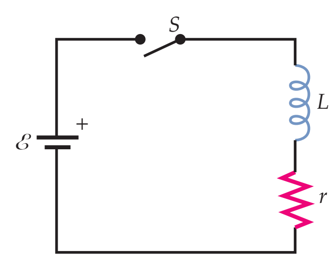

FIGURE 28-58 Problem 68

69 ••• In the circuit shown in Figure 28-54, let $\mathcal{E}_0 = 12.0$ V, $R = 3.00\ \Omega$, and $L = 0.600$ H. The switch is closed at time $t = 0$. During the time from $t = 0$ to $t = L/R$, find (*a*) the amount of energy supplied by the battery, (*b*) the amount of energy dissipated in the resistor, and (*c*) the amount of energy delivered to the inductor. *Hint: Find the energy transfer rates as functions of time and integrate.* SSM

GENERAL PROBLEMS

70 • A 100-turn coil has a radius of 4.00 cm and a resistance of 25.0 Ω. (*a*) The coil is in a uniform magnetic field that is perpendicular to the plane of the coil. What rate of change of the magnetic field strength will induce a current of 4.00 A in the coil? (*b*) What rate of change of the magnetic field strength is required if the magnetic field makes an angle of 20° with the normal to the plane of the coil?

71 •• **ENGINEERING APPLICATION** Figure 28-59 shows a schematic drawing of an *ac generator*. The basic generator consists of a rectangular loop of dimensions *a* and *b* and has *N* turns connected to *slip rings*. The loop rotates (driven by a gasoline engine) at an angular speed of ω in a uniform magnetic field $\vec{B}$. (*a*) Show that the induced potential difference between the two slip rings is given by $\mathcal{E} = NBab\omega \sin \omega t$. (*b*) If $a = 2.00$ cm, $b = 4.00$ cm, $N = 250$, and $B = 0.200$ T, at what angular frequency ω must the coil rotate to generate an emf whose maximum value is 100 V? SSM

72 •• **ENGINEERING APPLICATION** Prior to 1960, magnetic field strengths were usually measured by a *rotating coil gaussmeter*. The device uses a small multiturn coil rotating at a high speed on an axis perpendicular to the magnetic field. The coil is connected to an ac voltmeter by means of slip rings, like those shown in Figure 28-59. In one specific design, the rotating coil has 400 turns and an area of 1.40 cm^2. The coil rotates at 180 rev/min. If the magnetic field strength is 0.450 T, find the maximum induced emf in the coil and the orientation of the normal to the plane of the coil relative to the field for which the maximum induced emf occurs.

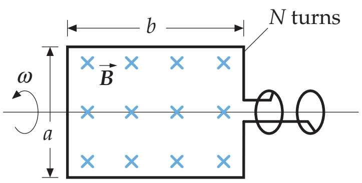

FIGURE 28-59 Problems 71 and 72

73 •• Show that the equivalent self-inductance for two inductors that have self-inductances L_1 and L_2 and are connected in series is given by $L_{eq} = L_1 + L_2$ if there is no flux linkage between the two inductors. (Saying there is no flux linkage between them is equivalent to saying that the mutual inductance between them is zero.)

74 •• Show that the equivalent self-inductance for two in ductors that have self-inductances L_1 and L_2 and are connected in parallel is given by $\frac{1}{L_{eq}} = \frac{1}{L_1} + \frac{1}{L_2}$ if there is no flux linkage between the two inductors. (Saying there is no flux linkage between them is equivalent to saying that the mutual inductance between them is equal to zero.)

75 •• A circuit consists of a 12-V battery, a switch, and a lightbulb—all connected in series. It is known that the lightbulb requires a minimum current of 0.10 A in order to produce a visible glow. In the circuit, that particular bulb draws 2.0 W when the switch has been closed for a long time. Now, an inductor is put in series with the bulb and the rest of the circuit. If the lightbulb begins to glow 3.5 ms after the switch is closed, how large is the self-inductance of the inductor? Ignore any heating time of the filament and assume the glow is observed as soon as the current in the filament reaches the 0.10-A threshold.

76 •• Your friend decides to generate electrical power by rotating a 100 000-turn coil of wire around an axis in the plane of the coil and through its center. The coil is perpendicular to Earth's magnetic field in a region where the field strength is equal to 0.300 G. The loops of the coil have a radius of 25.0 cm, and the coil has negligible resistance. (*a*) If your friend turns the coil at a rate of 150 rev/s, what peak current will exist in a 1500-Ω resistor that is connected across the terminals of the coil? (*b*) The average of the square of the current will equal half of the square of the peak current. What will be the average power delivered to the resistor? Is this an economical way to generate power? *Hint: Energy has to be expended to keep the coil rotating.*

77 •• Figure 28-60*a* shows an experiment designed to measure the acceleration due to gravity. A large plastic tube is encircled by a wire, which is arranged in single loops separated by a distance of 10 cm. A strong magnet is dropped through the top of the loop. As the magnet falls through each loop the voltage rises; then the voltage rapidly falls through zero to a large negative value and then returns to zero. The shape of the voltage signal is shown in Figure 28-60*b*. (*a*) Explain the basic physics behind the generation of this voltage pulse. (*b*) Explain why the tube cannot be made of a conductive material. (*c*) Qualitatively explain the *shape* of the voltage signal in Figure 28-60*b*. (*d*) The times at which the voltage crosses zero as the magnet falls through each loop in succession are given in the table on the next page. Use these data to calculate a value for *g*. SSM

78 •• The rectangular coil shown in Figure 28-61 has 80 turns, is 25 cm wide, is 30 cm long, and is located in a magnetic field of 0.14 T directed out of the page, as shown. Only half of the coil is in the region of the magnetic field. The resistance of the coil is 24 Ω. Find the magnitude and the direction of the induced current if the coil is moving with a velocity of 2.0 m/s (*a*) to the right, (*b*) up the page, (*c*) to the left, and (*d*) down the page.

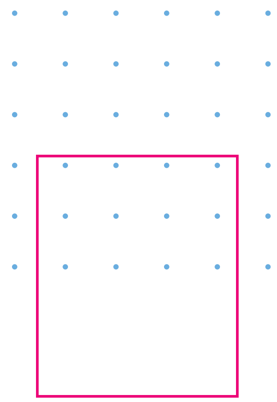

FIGURE 28-61 Problem 78

79 •• A long solenoid has n turns per unit length and carries a current that varies with time according to $I = I_0 \sin \omega t$. The solenoid has a circular cross section of radius R. Find the induced electric field, at points near the plane equidistant from the ends of the solenoid, as a function of both the time t and the perpendicular distance r from the axis of the solenoid for (*a*) $r < R$ and (*b*) $r > R$. SSM

80 ••• A coaxial cable consists of two very thin-walled conducting cylinders of radii r_1 and r_2 (Figure 28-62). The currents in the inner and outer cylinders are equal in magnitude but opposite in direction. (*a*) Use Ampère's law to find the magnetic field as a function of the perpendicular distance r from the central axis of the cable for (1) $0 < r < r_1$, (2) $r_1 < r < r_2$, and (3) $r > r_2$. (*b*) Show that the magnetic energy density in the region between the cylinders is given by $u_m = \frac{1}{2}(\mu_0/4\pi)I^2/(\pi r^2)$. (*c*) Show that the total magnetic energy in a cable volume of length ℓ is given by $U_m = (\mu_0/4\pi)I^2\ell \ln(r_2/r_1)$. (*d*) Use the result in Part (*c*) and the relationship between magnetic energy, current, and inductance to show that the self-inductance per unit length of the cable arrangement is given by $L/\ell = (\mu_0/2\pi)\ln(r_2/r_1)$.

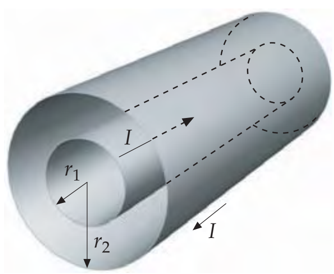

FIGURE 28-62 Problem 80

81 ••• A coaxial cable consists of two very thin-walled conducting cylinders of radii r_1 and r_2 (Figure 28-63). The currents in the inner and outer cylinders are equal in magnitude but opposite in direction. Compute the flux through a rectangular area of sides ℓ and $r_2 - r_1$ between the conductors shown in Figure 28-63. Use the relationship between flux and current ($\phi_m = LI$) to show that the self-inductance per unit length of the cable is given by $L/\ell = (\mu_0/2\pi)\ln(r_2/r_1)$.

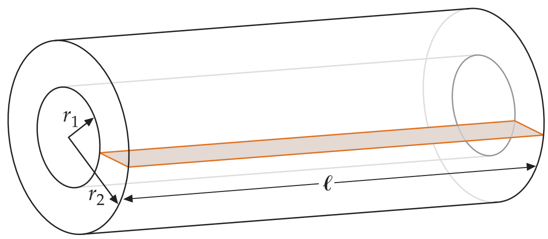

FIGURE 28-63 Problem 81

82 ••• **SPREADSHEET** Figure 28-64 shows a rectangular loop of wire that is 0.300 m wide, is 1.50 m long, and lies in the vertical plane which is perpendicular to a region that has a uniform magnetic field. The magnitude of the uniform magnetic field is 0.400 T and the direction of the magnetic field is into the page. The portion of the loop not in the magnetic field is 0.100 m long. The resistance of the loop is 0.200 Ω and its mass is 50.0 g. The loop is released from rest at $t = 0$. (*a*) What are the magnitude and direction of the induced current when the loop has a downward speed v? (*b*) What is the force that acts on the loop as a result of the current? (*c*) What is the net force acting on the loop? (*d*) Write out Newton's second law for the loop. (*e*) Obtain an expression for the speed of the loop as a function of time. (*f*) Integrate the expression obtained in Part (*e*) to find the distance the loop falls as a function of time. (*g*) Using a spreadsheet program, make a graph of the position of the loop as a function of time (letting $t = 0$ at the start) for values of y between 0 m and 1.40 m (i.e., when the loop leaves the magnetic field). (*h*) At what time does the loop completely leave the field region? Compare this to the time it would have taken if there were no field.

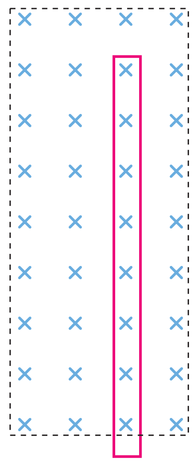

FIGURE 28-64 Problem 82

83 ••• A coil that has N turns and an area A is suspended from the ceiling by a wire that provides a linear restoring torque that has a torsion constant κ. The two ends of the coil are connected to each other, the coil has resistance R, and the moment of inertia of the coil is I. The plane of the coil is vertical and parallel to a uniform horizontal magnetic field $\vec{B}$ when the wire is not twisted (i.e., $\theta = 0$). The coil is twisted about a vertical axis through its center by a small angle θ_0 and released. The coil then undergoes damped harmonic oscillation. Show that its angle with its equilibrium position will vary with time according to $\theta(t) = \theta_0 e^{-t/2\tau}\cos\omega' t$, where $\tau = RI/(NBA)^2$, $\omega = \sqrt{\kappa/I}$ and $\omega' = \omega_0\sqrt{1 - (2\omega_0\tau)^{-2}}$.

CHAPTER 29

THIS LISTENER DIALS IN HER FAVORITE RADIO STATION. THIS CHANGES THE RESONANT FREQUENCY OF AN OSCILLATING ELECTRIC CIRCUIT WITHIN THE TUNER, SO ONLY THE STATION SHE SELECTS IS AMPLIFIED. *(© Roger Ressmeyer/Corbis.)*

Alternating-Current Circuits

? What component of the circuit is modified as she turns the dial? (See Example 29-11.)

More than 99 percent of the electrical energy used today is produced by electrical generators in the form of alternating current, which has a great advantage over direct current. Electrical energy can be distributed over large regions at very high voltages and low currents to reduce energy losses due to Joule heating. With alternating current, electrical energy can then be transformed, with almost no energy loss, to lower and safer voltages and correspondingly higher currents for local distribution and use.* The transformer that accomplishes these changes in potential difference and current works on the basis of magnetic induction. In North America, power is delivered by a sinusoidal current that has a frequency equal to 60 Hz. Devices such as radios, television sets, and microwave ovens detect or generate alternating currents of much higher frequencies.

Alternating current is produced by motional emf or by magnetic induction in an ac generator, which is designed to provide a sinusoidal emf.

* High voltage direct current is sometimes used to transmit electrical power between one point and another distant point. However, alternating current is always used to transmit power from one point to two or more distant points.

In this chapter, we will see that when the generator output is sinusoidal, the current in an inductor, a capacitor, or a resistor is also sinusoidal, although it is generally not in phase with the generator's emf. When the emf and current are both sinusoidal, their maximum values are proportional. The study of sinusoidal currents is particularly important because even currents that are not sinusoidal can be analyzed in terms of sinusoidal components using Fourier analysis.

29-1 ALTERNATING CURRENT IN A RESISTOR

Figure 29-1 shows a simple **ac generator.** An analysis of such a generator is presented in Chapter 28. The emf of such a generator is given by the equation immediately following Equation 28-10:

$$\mathcal{E} = \mathcal{E}_{\text{peak}} \cos \omega t \qquad \text{29-1}$$

where ω is the angular speed of the coil. (Equation 28-10 has the emf proportional to $\sin \omega t$ rather than $\cos \omega t$. The distinction between the two is the choice of when $t = 0$.) If the N-turn coil has area A, and if the magnetic field is uniform and has magnitude B, the peak emf is given by ωNBA. Although practical generators are considerably more complicated, they all produce a sinusoidal emf either by induction or by motional emf. In circuit diagrams, an ac generator is represented by the symbol ~ (circled).

Figure 29-2 shows a simple ac circuit that consists of an ideal generator and a resistor. (A generator is ideal if its internal resistance, its self-inductance, and its capacitance are negligible.) The voltage drop across the resistor V_R is equal to the emf $\mathcal{E}$ of the generator. If the generator produces an emf given by Equation 29-1, we have

$$V_R = V_{R\,\text{peak}} \cos \omega t$$

Applying Ohm's law, we have

$$V_R = IR \qquad \text{29-2}$$

Thus,

$$V_{R\,\text{peak}} \cos \omega t = IR \qquad \text{29-3}$$

so the current in the resistor is

$$I = \frac{V_{R\,\text{peak}}}{R} \cos \omega t = I_{\text{peak}} \cos \omega t \qquad \text{29-4}$$

where

$$I_{\text{peak}} = \frac{V_{R\,\text{peak}}}{R} \qquad \text{29-5}$$

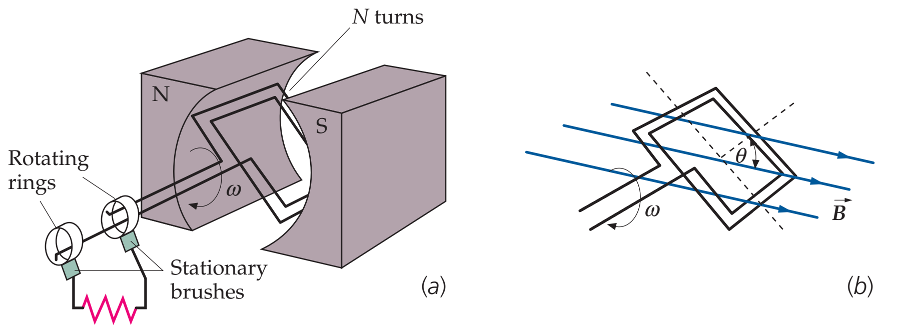

FIGURE 29-1 (*a*) An ac generator. A coil rotating with constant angular frequency ω in a static magnetic field $\vec{B}$ generates a sinusoidal emf. Energy from falling water or from a steam turbine is used to rotate the coil to produce electrical energy. The emf is supplied to an external circuit by the brushes that are in contact with the rings. (*b*) At this instant, the normal to the plane of the coil makes an angle θ with the magnetic field, and the flux through the each turn of the coil is $BA \cos \theta$.

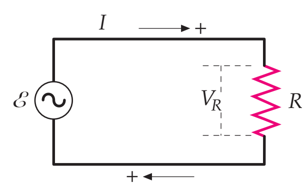

FIGURE 29-2 An ac generator in series with a resistor R.

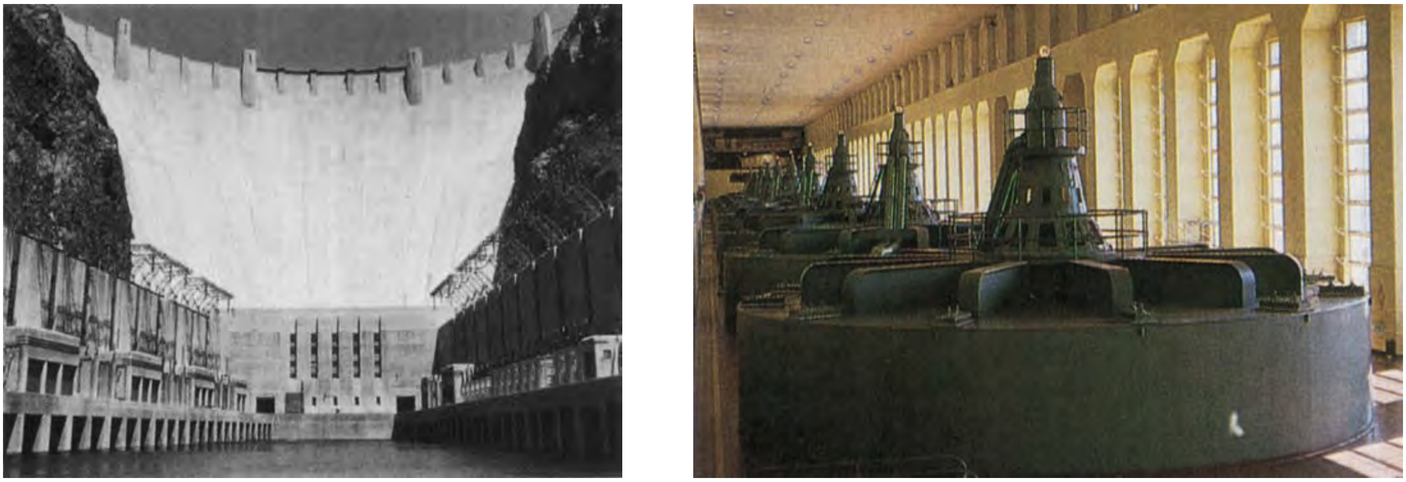

(a) (b)

Note that the current through the resistor is in phase with the potential drop across the resistor, as shown in Figure 29-3.

The power delivered to the resistor varies with time. Its instantaneous value is

$$P = I^2R = (I_{\text{peak}} \cos \omega t)^2 R = I^2_{\text{peak}} R \cos^2 \omega t \qquad 29\text{-}6$$

Figure 29-4 shows the power as a function of time. The power varies from zero to its peak value I^2_{peak}, as shown. We are usually interested in the average power over one or more complete cycles:

$$P_{\text{av}} = (I^2R)_{\text{av}} = I^2_{\text{peak}} R(\cos^2 \omega t)_{\text{av}}$$

The average value of $\cos^2 \omega t$ over one or more complete periods is $\frac{1}{2}$. This result can be seen from the identity $\cos^2 \omega t + \sin^2 \omega t = 1$. A plot of $\sin^2 \omega t$ looks the same as a plot of $\cos^2 \omega t$ except that the plot is shifted by 90°. Both have the same average value over one or more complete periods, and because their sum is 1, the average value of each must be $\frac{1}{2}$. The average power dissipated in the resistor is thus

$$P_{\text{av}} = (I^2R)_{\text{av}} = \frac{1}{2} I^2_{\text{peak}} R \qquad 29\text{-}7$$

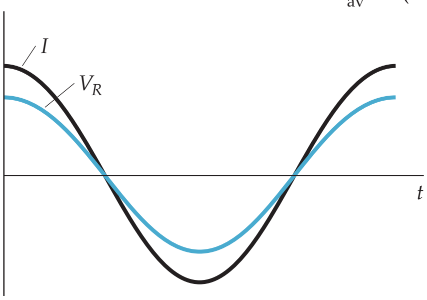

FIGURE 29-3 The voltage drop across a resistor is in phase with the current.

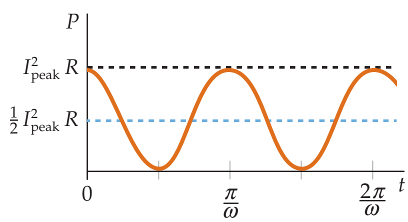

FIGURE 29-4 Plot of the power delivered to the resistor shown in Figure 29-2 versus time. The power varies from zero to a peak value $I^2_{\text{peak}}R$. The average power is half the peak power.

ROOT-MEAN-SQUARE VALUES

Most ac ammeters and voltmeters are designed to measure the **root-mean-square (rms) values** of current and potential difference. The rms value I_{rms} of a current is defined by

$$I_{\text{rms}} = \sqrt{(I^2)_{\text{av}}} \qquad 29\text{-}8$$

DEFINITION—RMS CURRENT

For a sinusoidal current, the average value of I^2 is

$$(I^2)_{\text{av}} = \left[(I_{\text{peak}} \cos \omega t)^2\right]_{\text{av}} = \frac{1}{2} I_{\text{peak}}^2$$

Substituting $\frac{1}{2}I_{\text{peak}}^2$ for $(I^2)_{\text{av}}$ in Equation 29-8, we obtain

$$I_{\text{rms}} = \frac{1}{\sqrt{2}} I_{\text{peak}} \approx 0.707 I_{\text{peak}} \qquad 29\text{-}9$$

RMS VALUE RELATED TO PEAK VALUE

The rms value of *any quantity* that varies sinusoidally with time is equal to the peak value of that quantity divided by $\sqrt{2}$.

Substituting $(I_{\text{rms}})^2$ for $\frac{1}{2}I_{\text{peak}}^2$ in Equation 29-7, we obtain for the average power delivered to the resistor

$$P_{\text{av}} = (I_{\text{rms}})^2 R \qquad 29\text{-}10$$

The rms current equals the steady dc current that would produce the same Joule heating as the actual ac current.

For the simple circuit in Figure 29-2, the average power delivered by the generator is

$$P_{\text{av}} = (\mathcal{E} I)_{\text{av}} = \left[\left(\mathcal{E}_{\text{peak}} \cos \omega t\right)\left(I_{\text{peak}} \cos \omega t\right)\right]_{\text{av}} = \mathcal{E}_{\text{peak}} I_{\text{peak}} (\cos^2 \omega t)_{\text{av}}$$

or

$$P_{\text{av}} = \tfrac{1}{2} \mathcal{E}_{\text{peak}} I_{\text{peak}}$$

Using $I_{\text{rms}} = I_{\text{peak}}/\sqrt{2}$ and $\mathcal{E}_{\text{rms}} = \mathcal{E}_{\text{peak}}/\sqrt{2}$, this can be written

$$P_{\text{av}} = \mathcal{E}_{\text{rms}} I_{\text{rms}} \qquad 29\text{-}11$$

AVERAGE POWER DELIVERED BY A GENERATOR

> ! The rms current equals the steady dc current that would produce the same Joule heating as the actual ac current.

The rms current is related to the rms potential drop in the same way that the peak current is related to the peak potential drop. We can see this by dividing each side of Equation 29-5 by $\sqrt{2}$ and substituting for I_{peak} and $V_{R\,\text{rms}}$ using $I_{\text{rms}} = I_{\text{peak}}/\sqrt{2}$ and $V_{R\,\text{rms}} = V_{R\,\text{peak}}/\sqrt{2}$.

$$I_{\text{rms}} = \frac{V_{R\,\text{rms}}}{R} \qquad 29\text{-}12$$

Equations 29-10, 29-11, and 29-12 are of the same form as the corresponding equations for direct-current circuits; however, I is replaced by I_{rms} and V_R is replaced by $V_{R\,\text{rms}}$. We can therefore calculate the power input and the heat generated using the same equations that we used for direct current, if we use rms values for the current and potential drop.

PRACTICE PROBLEM 29-1

The sinusoidal potential drop across a 12–Ω resistor has a peak value of 48 V. Find (*a*) the rms current, (*b*) the average power, and (*c*) the maximum power delivered to the resistor.

The ac power supplied to domestic wall outlets and light fixtures in the United States has an rms potential difference of 120 V at a frequency of 60 Hz. This potential difference is maintained, independent of the current. If you plug a 1600-W space heater into a wall outlet it will draw a current of

$$I_{\text{rms}} = \frac{P_{\text{av}}}{V_{\text{rms}}} = \frac{1600\text{ W}}{120\text{ V}} = 13.3\text{ A}$$

All appliances plugged into the outlets of a single 120-V circuit are connected in parallel. If you plug a 500-W toaster into another outlet of the same circuit, it will draw a current of 500 W/120 V = 4.17 A, and the total current through the parallel combination will be 17.5 A. Typical household wall outlets are rated at 15 A and are part of a circuit using wires rated at either 15 A or 20 A, with each circuit having several outlets. A total current greater than the rated current for the wiring is likely to overheat the wiring and is a fire hazard. Each circuit is therefore equipped with a circuit breaker (or a fuse in older houses) that trips (or blows) when the total current exceeds the 15-A or 20-A rating.

High-power domestic appliances, such as electric clothes dryers, kitchen ranges, and hot water heaters, typically require power delivered at 240 V rms. For a given power requirement, only half as much current is required at 240 V as at 120 V, but 240 V is more likely to deliver a fatal shock or to start a fire than 120 V.

Example 29-1 Sawtooth Waveform

Find (*a*) the average current and (*b*) the rms current for the sawtooth waveform shown in Figure 29-5. In the region $0 < t < T$, the current is given by $I = (I_0/T)t$.

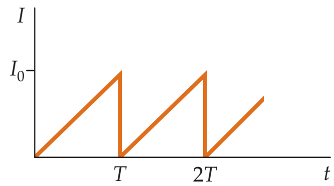

FIGURE 29-5

PICTURE The average of any quantity over a time interval T is the integral of the quantity over the interval divided by T. We use this to find both the average current, I_{av}, and the average of the square of the current, $(I^2)_{av}$.

SOLVE

(*a*) Calculate I_{av} by integrating I from $t = 0$ to $t = T$ and dividing by T:

$$I_{av} = \frac{1}{T}\int_0^T I\,dt = \frac{1}{T}\int_0^T \frac{I_0}{T}t\,dt = \frac{I_0}{T^2}\frac{T^2}{2} = \boxed{\frac{1}{2}I_0}$$

(*b*) 1. Find $(I^2)_{av}$ by integrating I^2:

$$(I^2)_{av} = \frac{1}{T}\int_0^T I^2\,dt = \frac{1}{T}\left(\frac{I_0}{T}\right)^2\int_0^T t^2\,dt = \frac{I_0^2}{T^3}\frac{T^3}{3} = \frac{1}{3}I_0^2$$

2. The rms current is the square root of $(I^2)_{av}$:

$$I_{rms} = \sqrt{(I^2)_{av}} = \boxed{\frac{I_0}{\sqrt{3}}}$$

CHECK Both the average current and the rms current are less than I_0, as expected.

29-2 ALTERNATING-CURRENT CIRCUITS

Alternating current behaves differently than direct current in inductors and capacitors. When a capacitor becomes fully charged in a dc circuit, the capacitor blocks the current; that is, the capacitor acts like an open circuit. However, if the current alternates, charge continually flows onto the plates and off of the plates of the capacitor. We will see that at high frequencies, a capacitor hardly impedes the current at all. That is, the capacitor acts like a short circuit. Conversely, an induction coil that has a low internal resistance is essentially a short circuit for direct current; however, when the current is changing, a back emf is generated in an inductor that is proportional to dI/dt. At high frequencies, the back emf is large and the inductor acts like an open circuit.

INDUCTORS IN ALTERNATING-CURRENT CIRCUITS

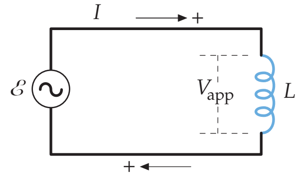

FIGURE 29-6 An ac generator in series with an inductor L. The arrow indicates the positive direction along the wire. Note that for a positive value of dI/dt, the potential drop V_L across the inductor is positive.

Figure 29-6 shows an induction coil in series with an ac generator. When the current changes in the inductor, a back emf equal to $L\,dI/dt$ is generated due to the changing flux. Usually this back emf is much greater than the Ir drop due to the resistance r of the coil, so we normally neglect the resistance of the coil.

The potential drop across the inductor V_L is then given by

$$V_L = L\frac{dI}{dt} \qquad \text{29-13}$$

POTENTIAL DROP ACROSS AN IDEAL INDUCTOR

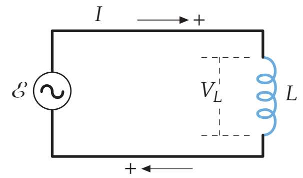

FIGURE 29-6 *(repeated)*
An ac generator in series with an inductor L. The arrow indicates the positive direction along the wire. Note that for a positive value of dI/dt, the potential drop V_L across the inductor is positive.

In this circuit, the potential drop V_L across the inductor equals the emf $\mathcal{E}$ of the generator. That is,

$$V_L = \mathcal{E} = \mathcal{E}_{\max}\cos\omega t = V_{L\,\text{peak}}\cos\omega t$$

where $V_{L\,\text{peak}} = \mathcal{E}_{\text{peak}}$. Substituting for V_L in Equation 29-13 gives

$$V_{L\,\text{peak}}\cos\omega t = L\frac{dI}{dt} \qquad \text{29-14}$$

Rearranging, we obtain

$$dI = \frac{V_{L\,\text{peak}}}{L}\cos\omega t\, dt \qquad \text{29-15}$$

We solve for the current I by integrating both sides of the equation:

$$I = \frac{V_{L\,\text{peak}}}{L}\int\cos\omega t\, dt = \frac{V_{L\,\text{peak}}}{\omega L}\sin\omega t + C \qquad \text{29-16}$$

where the constant of integration C is the dc component of the current. Setting the dc component of the current to be zero, we have

$$I = \frac{V_{L\,\text{peak}}}{\omega L}\sin\omega t = I_{\text{peak}}\sin\omega t \qquad \text{29-17}$$

where

$$I_{\text{peak}} = \frac{V_{L\,\text{peak}}}{\omega L} \qquad \text{29-18}$$

The potential drop $V_L = V_{L\,\text{peak}}\cos\omega t$ across the inductor is 90° out of phase with the current $I = I_{\text{peak}}\sin\omega t$. From Figure 29-7, which shows I and V_L as functions of time, we can see that the peak value of the potential drop occurs $\frac{1}{4}T$ earlier in time than the corresponding peak value of the current, where T is the period. The potential drop across an inductor is said to *lead the current by* 90°. We can also conceptually understand this result. The potential drop across the inductor its equal to the emf induced in it. When I is zero but decreasing, dI/dt is at its minimum, which is negative, so the emf induced in the inductor is at its maximum. One-quarter cycle later, I is maximum. At this time, dI/dt is zero, so V_L is zero. Using the trigonometric identity $\sin\theta = \cos(\theta - \frac{\pi}{2})$, Equation 29-17 for the current can be written

$$I = I_{\text{peak}}\cos(\omega t - \tfrac{\pi}{2}) \qquad \text{29-19}$$

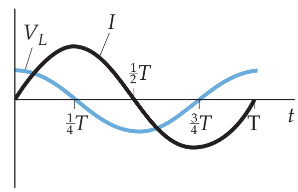

FIGURE 29-7 Current and potential drop across the inductor shown in Figure 29-6 as functions of time. The maximum potential drop occurs one-fourth period before the maximum current. Thus, the potential drop is said to lead the current by one-fourth period or 90°.

The relation between the peak current and the peak potential drop (or between the rms current and rms potential drop) for an inductor can be written in a form similar to $I_{\text{rms}} = V_{R\,\text{rms}}/R$ (Equation 29-12). From Equation 29-18, we have

$$I_{\text{peak}} = \frac{V_{L\,\text{peak}}}{\omega L} = \frac{V_{L\,\text{peak}}}{X_L} \qquad \text{29-20}$$

where

$$X_L = \omega L \qquad \text{29-21}$$

DEFINITION—INDUCTIVE REACTANCE

is called the **inductive reactance.** Because $I_{rms} = I_{peak}/\sqrt{2}$ and $V_{L\,rms} = V_{L\,peak}/\sqrt{2}$, the rms current is given by

$$I_{rms} = \frac{V_{L\,rms}}{X_L} \qquad 29\text{-}22$$

Like resistance, inductive reactance has units of ohms. As we can see from Equation 29-22, the larger the reactance for a given rms potential drop, the smaller the rms current. Unlike resistance, the inductive reactance depends on the frequency—the greater the frequency, the greater the reactance.

The *instantaneous* power delivered to the inductor is

$$P = V_L I = (V_{L\,peak} \cos \omega t)(I_{peak} \sin \omega t) = V_{L\,peak} I_{peak} \cos \omega t \sin \omega t$$

The *average* power delivered to the inductor is zero. We can see this by using the trigonometric identity

$$2 \cos \omega t \sin \omega t = \sin 2\omega t$$

The value of $\sin 2\omega t$ oscillates twice during each cycle of the current, and so is negative as often as it is positive. Thus, when averaged over an integral number of cycles, no energy is delivered to an inductor. (If the internal resistance r of the inductor is not negligible, then the average power delivered is equal to $(I_{rms})^2 r$.)

Example 29-2 Inductive Reactance

The potential drop across a 40.0-mH inductor is sinusoidal and has an rms potential drop of 120 V. Find the inductive reactance and the rms current when the frequency is (*a*) 60.0 Hz and (*b*) 2000 Hz.

PICTURE We calculate the inductive reactance at each frequency and use Equation 29-20 to find the peak current.

SOLVE

(*a*) 1. The peak current equals the rms potential drop divided by the inductive reactance:

$$I_{rms} = \frac{V_{L\,rms}}{X_L}$$

2. Compute the inductive reactance at 60.0 Hz:

$$X_{L1} = \omega_1 L = 2\pi f_1 L$$
$$= (2\pi)(60.0\text{ Hz})(40.0 \times 10^{-3}\text{ H})$$
$$= \boxed{15.1\ \Omega}$$

3. Use this value of X_L to compute the rms current at 60.0 Hz:

$$I_{1\,rms} = \frac{120\text{ V}}{15.1\ \Omega} = \boxed{7.95\text{ A}}$$

(*b*) 1. Compute the inductive reactance at 2000 Hz:

$$X_{L2} = \omega_2 L = 2\pi f_2 L$$
$$= (2\pi)(2000\text{ Hz})(40.0 \times 10^{-3}\text{ H}) = \boxed{503\ \Omega}$$

2. Use this value of X_L to compute the rms current at 2000 Hz:

$$I_{2\,rms} = \frac{120\text{ V}}{503\ \Omega} = \boxed{0.239\text{ A}}$$

CHECK The rms current at 2000 Hz is about 3 percent of the rms current at 60.0 Hz. This result is expected because we expect the inductor to behave more and more like an open circuit as the frequency increases.

CAPACITORS IN ALTERNATING-CURRENT CIRCUITS

When a capacitor is connected across the terminals of an ac generator (Figure 29-8), the voltage drop across the capacitor is

$$V_C = \frac{Q}{C} \tag{29-23}$$

where Q is the charge on the upper plate of the capacitor.

In this circuit, the potential drop V_C across the capacitor equals the emf $\mathcal{E}$ of the generator. That is,

$$V_C = \mathcal{E}_{\text{peak}} \cos \omega t = V_{C\,\text{peak}} \cos \omega t$$

where $V_{C\,\text{peak}} = \mathcal{E}_{\text{peak}}$. Substituting for V_C in Equation 29-23 and solving for Q gives

$$Q = V_C C = V_{C\,\text{peak}} C \cos \omega t = Q_{\text{peak}} \cos \omega t$$

The current is

$$I = \frac{dQ}{dt} = -\omega Q_{\text{peak}} \sin \omega t = -I_{\text{peak}} \sin \omega t$$

where

$$I_{\text{peak}} = \omega Q_{\text{peak}} \tag{29-24}$$

Using the trigonometric identity $\sin\theta = -\cos(\theta + \frac{\pi}{2})$, where $\theta = \omega t$, we obtain

$$I = -\omega Q_{\text{peak}} \sin \omega t = I_{\text{peak}} \cos(\omega t + \tfrac{\pi}{2}) \tag{29-25}$$

The voltage drop V_C across the capacitor is in phase with the charge Q (Equation 29-23), so as with the inductor, the voltage drop across the capacitor is 90° out of phase with the current in the circuit. From Figure 29-9, we see that the maximum value of the potential drop occurs 90° or one-fourth period later in time than the maximum value of the current. Thus, *the potential drop across a capacitor lags the current by* 90°. We can also understand this result in another way. The charge Q is proportional to the potential drop V_C, so the maximum value of $dQ/dt = I$ occurs when the charge Q, and therefore V_C, is zero. As the charge on the capacitor plate increases the current decreases, until one-fourth period later the charge Q, and therefore V_C, is a maximum and the current is zero. The current then becomes negative as the charge Q decreases.

We can relate the current to the potential drop in a form similar to $I_{\text{rms}} = V_{R\,\text{rms}}/R$ (Equation 29-5) for a resistor. From Equation 29-24, we have

$$I_{\text{peak}} = \omega Q_{\text{peak}} = \omega C V_{C\,\text{peak}} = \frac{V_{C\,\text{peak}}}{1/(\omega C)} = \frac{V_{C\,\text{peak}}}{X_C}$$

and, similarly,

$$I_{\text{rms}} = \frac{V_{C\,\text{rms}}}{X_C} \tag{29-26}$$

where

$$X_C = \frac{1}{\omega C} \tag{29-27}$$

DEFINITION—CAPACITIVE REACTANCE

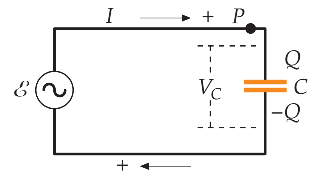

FIGURE 29-8 An ac generator in series with a capacitor C. The positive direction along the circuit is such that when the current is positive the charge Q on the upper capacitor plate is increasing, so the current is related to the charge by $I = +dQ/dt$.

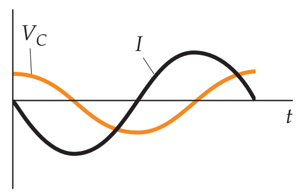

FIGURE 29-9 Current and potential drop across the capacitor shown in Figure 29-8 versus time. The maximum potential drop occurs one-fourth period after the maximum current. Thus, the potential drop is said to lag the current by 90°.

is called the **capacitive reactance** of the circuit. Like resistance and inductive reactance, capacitive reactance has units of ohms and, like inductive reactance, capacitive reactance depends on the frequency of the current. In this case, the greater the frequency, the smaller the reactance. The average power delivered to a capacitor in an ac circuit is zero, as it is for an inductor. This is so because the potential drop is proportional to $\cos \omega t$ and the current is proportional to $\sin \omega t$, and $(\cos \omega t \sin \omega t)_{av} = 0$. Thus, like inductors with no resistance, capacitors dissipate no energy.

Because charge cannot pass across the space between the plates of a capacitor, it may seem strange that there is a continuing alternating current in the circuit shown in Figure 29-8. Suppose we choose the time to be zero at the instant that the voltage drop V_C across the capacitor is both zero and increasing. (At this same instant, the charge Q on the upper plate of the capacitor is also both zero and increasing.) As V_C then increases, positive charge flows off the lower plate and onto the upper plate, and Q reaches its maximum value Q_{peak} a quarter period later. After Q reaches its maximum value Q continues to change, reaching zero at the half-period point, $-Q_{peak}$ at the three-quarter-period point, and zero (again) at the completion of the cycle at the full-period point. The charge Q_{peak} flows past point P (see Figure 29-8) on the wire each quarter period. If we double the frequency, we halve the period. Thus, if we double the frequency we halve the time for the charge Q_{peak} to flow past point P on the wire, so we have doubled the current amplitude I_{peak}. Hence, the greater the frequency, the less the capacitor impedes the flow of charge.

Example 29-3 Capacitive Reactance

A 20.0-μF capacitor is placed across an ac generator that applies a potential drop which has an amplitude (peak value) of 100 V. Find the capacitive reactance and the current amplitude when the frequency is (*a*) 60.0 Hz and (*b*) 6000 Hz.

PICTURE The capacitive reactance is $X_C = 1/(\omega C)$ and the peak current is $I_{peak} = V_{C\,peak}/X_C$.

SOLVE

(*a*) Calculate the capacitive reactance at 60.0 Hz and use this value to find the peak current at 60.0 Hz:

$$X_{C1} = \frac{1}{\omega_1 C} = \frac{1}{2\pi f_1 C}$$

$$= \frac{1}{2\pi(60.0\ \text{Hz})(20.0 \times 10^{-6}\ \text{F})} = \boxed{133\ \Omega}$$

$$I_{1\,peak} = \frac{V_{C\,peak}}{X_{C1}} = \frac{100\ \text{V}}{133\ \Omega} = \boxed{0.752\ \text{A}}$$

(*b*) Calculate the capacitive reactance at 6000 Hz and use this value to find the peak current at 6000 Hz:

$$X_{C2} = \frac{1}{\omega_2 C} = \frac{1}{2\pi f_2 C}$$

$$= \frac{1}{2\pi(6000\ \text{Hz})(20.0 \times 10^{-6}\ \text{F})} = \boxed{1.33\ \Omega}$$

$$I_{2\,peak} = \frac{V_{C\,peak}}{X_{C2}} = \frac{100\ \text{V}}{1.33\ \Omega} = \boxed{75.2\ \text{A}}$$

CHECK The current at 60.0 Hz is about 1 percent of the current at 6000 Hz. This result is expected because we expect the capacitor to be more like an open circuit at lower frequencies.

TAKING IT FURTHER Note that the capacitive reactance is inversely proportional to the frequency, so increasing the frequency by two orders of magnitude decreases the reactance by two orders of magnitude. The current is directly proportional to the frequency, as expected.

* 29-3 THE TRANSFORMER

A transformer is a device used to increase or decrease the voltage in a circuit without an appreciable loss of power. Figure 29-10 shows a simple transformer consisting of two wire coils around a common iron core. The coil carrying the input power is called the primary, and the other coil is called the secondary. Either coil of a transformer can be used for the **primary** or **secondary.** The transformer operates on the principle that an alternating current in one circuit induces an alternating emf in a nearby circuit due to the mutual inductance of the two circuits. The iron core increases the magnetic field for a given current and guides its direction so that the flux linkage between the coils approaches 100%. (At 100% flux linkage, all the magnetic field lines through one coil also go through the other coil.) If no power were lost, the product of the potential drop across and the current in the secondary windings would equal the product of the potential drop across and the current in the primary windings. Thus, if the potential difference across the secondary coil is larger than the potential difference across the primary coil, the current in the secondary coil is smaller than the current in the primary coil, and vice versa. Power losses arise because of Joule heating, both in the two coils and in the iron core currents,* and from hysteresis in the iron core. We will neglect those losses and consider an ideal transformer of 100 percent efficiency, for which all of the power supplied to the primary coil appears in the secondary coil. Actual power distribution transformers often have efficiencies of 98 percent or more.

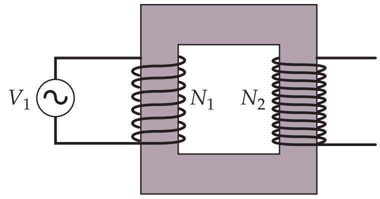

FIGURE 29-10 A transformer that has N_1 turns in the primary and N_2 turns in the secondary.

Consider a transformer with a potential drop V_1 across the primary coil of N_1 turns; the secondary coil of N_2 turns is an open circuit. Because of the iron core, there is a large flux through each coil even when the magnetizing current I_m in the primary circuit is very small. (The magnetizing current is the current in the primary when the secondary circuit is open.) We can ignore the resistances of the coils, which are negligible in comparison with their inductive reactances. The primary circuit is then a simple circuit consisting of an ac generator and a pure inductance, like that discussed in Section 29-2. The magnetizing current in the primary coil and the voltage drop across the primary coil are out of phase by 90°, and the average power dissipated in the primary coil is zero. If ϕ_{turn} is the magnetic flux per turn of the primary coil, the potential drop across the primary coil is equal to the back emf, so

$$V_1 = N_1\frac{d\phi_{\text{turn}}}{dt} \qquad \text{29-28}$$

If there is no flux leakage out of the iron core, the flux through each turn is the same for both coils. Thus, the total flux through the secondary coil is $N_2\phi_{\text{turn}}$, and the potential difference across the secondary coil is

$$V_2 = N_2\frac{d\phi_{\text{turn}}}{dt} \qquad \text{29-29}$$

Comparing Equations 29-28 and 29-29, we can see that

$$V_2 = \frac{N_2}{N_1}V_1 \qquad \text{29-30}$$

If N_2 is greater than N_1, the potential difference across the secondary coil is greater than the potential drop across the primary coil, and the transformer is called a *step-up transformer*. If N_2 is less than N_1, the potential difference across the secondary coil is less than the potential drop across the primary coil, and the transformer is called a *step-down transformer*.

(*a*)
(*b*)
(*c*)

(*b*) A suburban power substation where transformers step down voltage from high-voltage transmission lines. (*c*) A 9-volt ac plug-in transformer. *((a) Yaov/Phototake. (b) Daniel S. Brody/Stock Boston. (c) Ramòn Rivera Moret.)*

* The induced currents, called eddy currents, can be greatly reduced by using a core of laminated metal to break up current paths.

When we put a resistance R, called a *load resistance*, across the secondary coil, there will then be a current I_2 in the secondary circuit that is in phase with the potential drop V_2 across the resistance. This current sets up an additional flux ϕ'_{turn} through each turn that is proportional to $N_2 I_2$. This flux opposes the original flux set up by the original magnetizing current I_m in the primary. However, the potential drop across the primary coil is determined by the generator emf, which is unaffected by the secondary circuit. According to Equation 29-29, the flux in the iron core must change at the original rate; that is, the total flux in the iron core must be the same as when no load exists across the secondary. The primary coil thus draws an additional current I_1 to maintain the original flux ϕ_{turn}. The flux through each turn produced by this additional current is proportional to $N_1 I_1$. Because this flux equals $-\phi'_{\text{turn}}$, the additional current I_1 in the primary is related to the current I_2 in the secondary by

$$N_1 I_1 = -N_2 I_2 \qquad \text{29-31}$$

The currents are 180° out of phase and produce counteracting fluxes. Because I_2 is in phase with V_2, the additional current I_1 is in phase with the potential drop across the primary circuit. The power input from the generator is $V_{1\,\text{rms}} I_{1\,\text{rms}}$, and the power output is $V_{2\,\text{rms}} I_{2\,\text{rms}}$. (The magnetizing current does not contribute to the power input because it is 90° out of phase with the generator voltage.) If there are no losses,

$$V_{1\,\text{rms}} I_{1\,\text{rms}} = V_{2\,\text{rms}} I_{2\,\text{rms}} \qquad \text{29-32}$$

In most cases, the additional current in the primary I_1 is much greater than the original magnetizing current I_m that is drawn from the generator when no load exists. This can be demonstrated by putting a lightbulb in series with the primary coil. The lightbulb is much brighter when there is a load across the secondary circuit than when the secondary circuit is open. If I_m can be neglected, Equation 29-32 relates the total currents in the primary and secondary circuits.

Example 29-4 Doorbell Transformer

A doorbell requires 0.40 A rms of alternating current at 6.0 V rms. It is connected to a transformer whose primary has 2000 turns and is connected to a 120-V-rms ac line. (*a*) How many turns should there be in the secondary? (*b*) What is the current in the primary?

PICTURE We can find the number of turns from the turns ratio, which equals the voltage ratio. The primary current can be found by equating the power out to the power in.

SOLVE

(*a*) The turns ratio can be obtained from Equation 29-30. Solve for the number of turns in the secondary, N_2:

$$\frac{N_2}{N_1} = \frac{V_2}{V_1}$$

so

$$N_2 = \frac{V_{2\,\text{rms}}}{V_{1\,\text{rms}}} N_1 = \frac{6.0\text{ V}}{120\text{ V}} 2000\text{ turns} = \boxed{100\text{ turns}}$$

(*b*) Because we are assuming 100 percent efficiency in power transmission, the input and output currents are related by Equation 29-32. Solve for the current in the primary, I_1:

$$V_{2\,\text{rms}} I_{2\,\text{rms}} = V_{1\,\text{rms}} I_{1\,\text{rms}}$$

so

$$I_{1\,\text{rms}} = \frac{V_{2\,\text{rms}}}{V_{1\,\text{rms}}} I_{2\,\text{rms}} = \frac{6.0\text{ V}}{120\text{ V}}(0.40\text{ A}) = \boxed{0.020\text{ A}}$$

CHECK To step-down the voltage requires fewer turns in the secondary than in the primary. In addition, a transformer that steps down the voltage steps up the current. Our results reflect both of these attributes.

An important use of transformers is in the transmission and distribution of electrical power. To minimize the I^2R heat loss (Joule heating) in transmission lines, it is economical to use a high voltage and a low current. On the other hand, safety and other considerations require that power be delivered to consumers at lower voltages and therefore with higher currents. Suppose, for example, that each person in a city with a population of 50 000 uses consumes electrical energy at a rate of 1.2 kW. (The per capita rate of consumption of electrical energy in the United States is actually somewhat higher than this value.) At 120 V, the current required for each person would be

$$I = \frac{1200\text{ W}}{120\text{ V}} = 10\text{ A}$$

The total current for 50 000 people would then be 500 000 A. The transport of such a current from a power-plant generator to a city many kilometers away would require conductors of enormous thickness, and the I^2R power loss would be substantial. Rather than transmit the power at 120 V, step-up transformers are used at power plants to step up the voltage to values as great as 600 000 V. For this voltage, the current needed is only

$$I = \frac{120\text{ V}}{600\ 000\text{ V}}(500\ 000\text{ A}) = 100\text{ A}$$

To reduce the voltage to a safer level for transport within a city, power substations are located just outside the city to step down the voltage to a safer value, such as 10 000 V. Transformers in boxes attached to the power poles outside each house again step down the voltage to 120 V (or 240 V) for distribution to the house. Because of the ease of stepping the voltage up or down with transformers, alternating current rather than direct current is in common use.

Example 29-5 Transmission Losses

A transmission line has a resistance of 0.020 Ω/km. Calculate the power loss due to Joule heating if 200 kW of power is transmitted from a power generator to a city 10 km away at (*a*) 240 V rms and (*b*) 4.4 kV rms.

PICTURE First, note that the total resistance of 10 km of wire is $R = (0.020\ \Omega/\text{km})(10\text{ km}) = 0.20\ \Omega$. In each case, begin by finding the current needed to transmit 200 kW using $P = IV$, then find the power loss using $(I_{\text{rms}})^2R$. In the solution, the voltages and currents are rms values and the power is the average power.

SOLVE

(*a*) 1. Find the current needed to transmit 200 kW of power at 240 V: $I = \frac{P}{V} = \frac{200\text{ kW}}{240\text{ V}} = 833\text{ A}$

2. Calculate the power loss: $I^2R = (833\text{ A})^2(0.20\ \Omega) = \boxed{1.4 \times 10^2\text{ kW}}$

(*b*) 1. Now, find the current needed to transmit 200 kW of power at 4.4 kV: $I = \frac{P}{V} = \frac{200\text{ kW}}{4.4\text{ kV}} = 45.4\text{ A}$

2. Calculate the power loss: $I^2R = (45.4\text{ A})^2(0.20\ \Omega) = \boxed{0.41\text{ kW}}$

CHECK The power loss at 4.4 kV is less than one percent of the power loss at 240 V. This result is consistent with the reason for stepping up the voltage for transmission.

TAKING IT FURTHER Note that with a transmission voltage of 240 V, almost 70 percent of the power is wasted through heat loss. In addition, there is an IR (voltage) drop across the transmission line of 167 V, so the power is delivered at only 73 V. However, with transmission at 4.4 kV, only about 0.2 percent of the power is lost during transmission and there is an IR drop across the transmission line of only 9 V, so the power is delivered with only a 0.2 percent voltage drop.

* 29-4 *LC* AND *RLC* CIRCUITS WITHOUT A GENERATOR

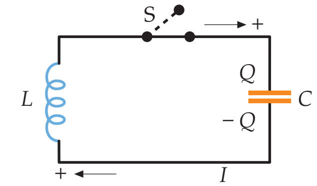

FIGURE 29-11 An *LC* circuit. When the switch is closed, the initially charged capacitor discharges through the inductor, producing a back emf.

Figure 29-11 shows a simple circuit that has inductance and capacitance but has no resistance. Such a circuit is called an ***LC* circuit.** We assume that the upper capacitor plate carries an initial positive charge Q_0 and that the switch is initially open. After the switch is closed at $t = 0$, the charge begins to flow through the inductor. Let Q be the charge on the upper plate of the capacitor and let the positive direction around the circuit be clockwise, as shown. Then,

$$I = +\frac{dQ}{dt}$$

Applying Kirchhoff's loop rule to the circuit, we have

$$L\frac{dI}{dt} + \frac{Q}{C} = 0 \qquad \text{29-33}$$

Substituting dQ/dt for I gives

$$L\frac{d^2Q}{dt^2} + \frac{1}{C}Q = 0 \qquad \text{29-34}$$

This equation is of the same form as Equation 14-2 for the acceleration of a mass on a spring:

$$m\frac{d^2x}{dt^2} + kx = 0$$

The behavior of an LC circuit is thus analogous to that of a mass on a spring—L analogous to the mass m, Q analogous to the position x, and $1/C$ analogous to the spring constant k. Also, the current I is analogous to the velocity v, because $\omega = dx/dt$ and $I = dQ/dt$. In mechanics, the mass of an object describes the inertia of the object. The greater the mass, the more opposition there is to change the velocity of the object. Similarly, the inductance L can be thought of as the inertia of an ac circuit. The greater the inductance, the more opposition there is to changes in the current I.

If we divide each term in Equation 29-34 by L and rearrange, we obtain

$$\frac{d^2Q}{dt^2} = -\frac{1}{LC}Q \qquad \text{29-35}$$

which is analogous to

$$\frac{d^2x}{dt^2} = -\frac{k}{m}x \qquad \text{29-36}$$

In Chapter 14, we found that we could write the solution of Equation 29-36 for simple harmonic motion in the form

$$x = A\cos(\omega t - \delta)$$

where $\omega = \sqrt{k/m}$ is the angular frequency, A is the displacement amplitude, and δ is the phase constant, which depends on the initial conditions. The solution to Equation 29-35 is thus

$$Q = A\cos(\omega t - \delta)$$

with

$$\omega = \frac{1}{\sqrt{LC}} \qquad \text{29-37}$$

The current I is found by differentiating:

$$I = \frac{dQ}{dt} = -\omega A \sin(\omega t - \delta)$$

If we choose our initial conditions to be $Q = Q_{\text{peak}}$ and $I = 0$ at $t = 0$, the phase constant δ is zero and $A = Q_{\text{peak}}$. Our solutions are then

$$Q = Q_{\text{peak}} \cos \omega t \qquad 29\text{-}38$$

and

$$I = -\omega Q_{\text{peak}} \sin \omega t = -I_{\text{peak}} \sin \omega t \qquad 29\text{-}39$$

where $I_{\text{peak}} = \omega Q_{\text{peak}}$.

Figure 29-12 shows graphs of Q and I versus time. The charge oscillates between the values $+Q_{\text{peak}}$ and $-Q_{\text{peak}}$ with angular frequency $\omega = 1/\sqrt{LC}$. The current oscillates between $+\omega Q_{\text{peak}}$ and $-\omega Q_{\text{peak}}$ with the same frequency. Also, the charge lags behind the current by 90° (see Problem 29-33). The current is maximum when the charge is zero and the current is zero when the charge is maximum.

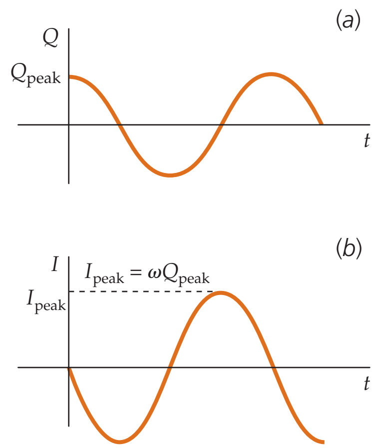

FIGURE 29-12 Graphs of (*a*) Q versus t and (*b*) I versus t for the LC circuit shown in Figure 29-11.

In our study of the oscillations of a mass on a spring, we found that the total energy is constant, and that the total energy oscillates between potential energy and kinetic energy. We also have two kinds of energy in the LC circuit—electric energy and magnetic energy. The electric energy stored in the capacitor is

$$U_e = \frac{1}{2}QV_C = \frac{1}{2}\frac{Q^2}{C}$$

Substituting $Q_{\text{peak}} \cos \omega t$ for Q, we have for the electric energy

$$U_e = \frac{1}{2}\frac{Q^2_{\text{peak}}}{C}\cos^2\omega t \qquad 29\text{-}40$$

The electric energy oscillates between its maximum value $Q^2_{\text{peak}}/(2C)$ and zero at an angular frequency of 2ω (see Problem 29-33). The magnetic energy stored in the inductor is

$$U_m = \frac{1}{2}LI^2 \qquad 29\text{-}41$$

Substituting $I = -\omega Q_{\text{peak}} \sin \omega t$ (Equation 29-39), we get

$$U_m = \frac{1}{2}L\omega^2 Q^2_{\text{peak}} \sin^2\omega t = \frac{1}{2}\frac{Q^2_{\text{peak}}}{C}\sin^2 \omega t \qquad 29\text{-}42$$

where we have used $\omega^2 = 1/LC$ (Equation 29-37). The magnetic energy also oscillates between its maximum value of $Q^2_{\text{peak}}/2C$ and zero at an angular frequency of 2ω. The sum of the electrostatic energy and the magnetic energy is the total energy, which is constant in time:

$$U_{\text{total}} = U_e + U_m = \frac{1}{2}\frac{Q^2_{\text{peak}}}{C}\cos^2 \omega t + \frac{1}{2}\frac{Q^2_{\text{peak}}}{C}\sin^2 \omega t = \frac{1}{2}\frac{Q^2_{\text{peak}}}{C}$$

This sum equals the energy initially stored on the capacitor.

Example 29-6 *LC* Oscillator

A 2.0-μF capacitor is charged to 20 V and the capacitor is then connected across a 6.0-μH inductor. (*a*) What is the frequency of oscillation? (*b*) What is the peak value of the current?

PICTURE In (*b*), the current is maximum when dQ/dt is maximum, so the current amplitude is ωQ_{peak}. Also, $Q = Q_{\text{peak}}$ when $V = V_{\text{peak}}$, where V is the voltage across the capacitor.

SOLVE

(*a*) The frequency of oscillation depends only on the values of the capacitance and the inductance:

$$f = \frac{\omega}{2\pi} = \frac{1}{2\pi\sqrt{LC}} = \frac{1}{2\pi\sqrt{(6.0 \times 10^{-6}\,\text{H})(2.0 \times 10^{-6}\,\text{F})}}$$

$$= \boxed{4.6 \times 10^{4}\,\text{Hz}}$$

(*b*) 1. The peak value of the current is related to the peak value of the charge:

$$I_{\text{peak}} = \omega Q_{\text{peak}} = \frac{Q_{\text{peak}}}{\sqrt{LC}}$$

2. The peak charge on the capacitor is related to the peak potential drop across the capacitor:

$$Q_{\text{peak}} = CV_{\text{peak}}$$

3. Substitute CV_{peak} for Q_{peak} and calculate I_{peak}:

$$I_{\text{peak}} = \frac{CV_{\text{peak}}}{\sqrt{LC}} = \frac{V_{\text{peak}}}{\sqrt{L/C}}$$

$$= \frac{(20\,\text{V})}{\sqrt{(6.0\,\mu\text{H})/(2.0\,\mu\text{F})}} = \boxed{12\,\text{A}}$$

PRACTICE PROBLEM 29-2 A 5.0-μF capacitor is charged and is then discharged through an inductor. What should the value of the inductance be so that the current oscillates with frequency 8.0 kHz?

If we include a resistor in series with the capacitor and the inductor, as in Figure 29-13, we have an ***RLC* circuit.** Kirchhoff's loop rule gives

$$L\frac{dI}{dt} + IR + \frac{Q}{C} = 0 \qquad \text{29-43}a$$

or

$$L\frac{d^2Q}{dt^2} + R\frac{dQ}{dt} + \frac{1}{C}Q = 0 \qquad \text{29-43}b$$

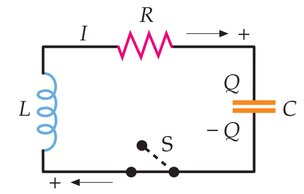

FIGURE 29-13 An *RLC* circuit.

where we have used $I = dQ/dt$ as before. Equations 29-43*a* and 29-43*b* are analogous to the equation for a damped harmonic oscillator (see Equation 14-38):

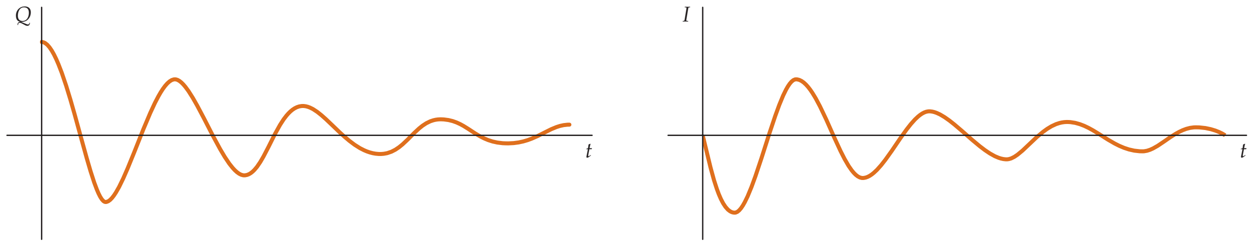
$$m\frac{d^2x}{dt^2} + b\frac{dx}{dt} + kx = 0$$

The first term, $L\,dI/dt = L\,d^2Q/dt^2$, is analogous to the mass multiplied by the acceleration, $m\,dv/dt = m\,d^2x/dt^2$; the second term, $IR = R\,dQ/dt$, is analogous to the damping term, $bv = b\,dx/dt$; and the third term, Q/C, is analogous to the restoring force kx. In the oscillation of a mass on a spring, the damping constant b leads to a dissipation of energy. In an *RLC* circuit, the resistance R is analogous to the damping constant b and leads to a dissipation of energy.

If the resistance is small, the charge and the current oscillate with (angular) frequency* that is very nearly equal to $\omega_0 = 1/\sqrt{LC}$, which is called the **natural frequency** of the circuit, but the oscillations are damped. We can understand this qualitatively from energy considerations. If we multiply each term in Equation 29-43*a* by the current I, we obtain

$$LI\frac{dI}{dt} + I^2R + I\frac{Q}{C} = 0 \qquad \text{29-44}$$

* As in Chapter 14 when we discussed mechanical oscillations, we usually omit the word *angular* when the omission will not cause confusion.



(a) (b)

FIGURE 29-14 Graphs of (*a*) Q versus t and (*b*) I versus t for the *RLC* circuit shown in Figure 29-13 when the value of R is small enough so that the oscillations are underdamped.

The magnetic energy in the inductor is given by $\frac{1}{2}LI^2$ (see Equation 28-21). Note that

$$\frac{d\left(\frac{1}{2}LI^2\right)}{dt} = LI\frac{dI}{dt}$$

where $LI\,dI/dt$ is the first term in Equation 29-44. If $LI\,dI/dt$ is positive, it equals the rate at which electrical potential energy is transformed into magnetic energy. If $LI\,dI/dt$ is negative, it equals the rate at which magnetic energy is transformed back into electrical potential energy. Note that $LI\,dI/dt$ is positive or negative depending on whether I and dI/dt have the same sign or different signs. The second term in Equation 29-44 is I^2R, the rate at which electrical potential energy is dissipated in the resistor. I^2R is never negative. Note that

$$\frac{d\left(\frac{1}{2}Q^2/C\right)}{dt} = \frac{Q}{C}\frac{dQ}{dt} = I\frac{Q}{C}$$

where IQ/C is the third term in Equation 29-44. This result is the rate of change of the electric potential energy of the capacitor, which may be positive or negative. The sum of the electric and magnetic energies is not constant for this circuit because energy is continually dissipated in the resistor. Figure 29-14 shows graphs of Q versus t and I versus t for a small resistance R in an *RLC* circuit. If we increase R, the oscillations become more heavily damped until a critical value of R is reached for which not even one oscillation exists. Figure 29-15 shows a graph of Q versus t in an *RLC* circuit when the value of R is greater than the critical damping value.

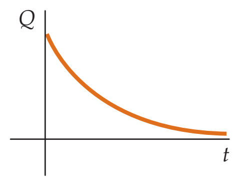


FIGURE 29-15 A graph of Q versus t for the *RLC* circuit shown in Figure 29-13 when the value of R is so large that the oscillations are overdamped.

* 29-5 PHASORS

Until this point, the circuits considered contained an ideal ac generator and only a single passive element (for example, resistor, inductor, or capacitor). In those circuits, the potential drop across the passive element equaled the emf of the generator. In circuits that contain an ideal ac generator and two or more additional elements connected in series, the sum of the potential drops across the elements at a given instant is equal to the generator emf at that instant; this is the same as with dc circuits. However, in series ac circuits the potential drops typically are not in phase, so the sum of their rms values does not equal the rms value of the generator emf.

Two-dimensional vectors, which are called **phasors,** can represent the phase relations between the current and the potential drops across resistors, capacitors, or inductors. In Figure 29-16, the potential drop across a resistor V_R is represented by a vector $\vec{V}_R$ that has magnitude $I_{\text{peak}}R$ and makes an angle θ with the x axis. This potential drop is in phase with the current. The current in a steady-state ac circuit varies with time, as

$$I = I_{\text{peak}}\cos\theta = I_{\text{peak}}\cos(\omega t - \delta) \qquad \text{29-45}$$

where ω is the angular frequency and δ is some phase constant. The potential drop across a resistor is then given by

$$V_R = IR = I_{\text{peak}}R\cos(\omega t - \delta) \qquad \text{29-46}$$

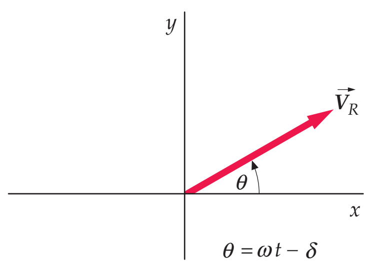

FIGURE 29-16 The potential drop across a resistor can be represented by a vector $\vec{V}_R$, which is called a phasor, that has magnitude $I_{\text{peak}}R$ and makes an angle $\theta = \omega t - \delta$ with the x axis. The phasor rotates with an angular frequency ω. The potential drop $V_R = IR$ is the x component of $\vec{V}_R$.

The potential drop across a resistor is thus equal to the x component of the phasor vector $\vec{V}_R$, which rotates counterclockwise with an angular frequency ω. The current I may be written as the x component of a phasor $\vec{I}$ having the same direction as $\vec{V}_R$.

When several components are connected together in a series combination, their potential drops add. When several components are connected in parallel, their currents add. Unfortunately, adding sines or cosines of different amplitudes and phases algebraically is awkward. It is much easier to do this by vector addition.*

Let us look at how phasors are used. Any ac current or any potential drop is written in the form $A\cos(\omega t - \delta)$, which in turn is treated as A_x, the x component of a phasor that makes an angle $(\omega t - \delta)$ with the $+x$ direction. Instead of adding two potential drops or currents algebraically, as $A\cos(\omega t - \delta_1) + B\cos(\omega t - \delta_2)$, we represent the quantities as phasors $\vec{A}$ and $\vec{B}$ and find the phasor sum $\vec{C} = \vec{A} + \vec{B}$ geometrically. The resultant potential drop or current is then the x component of the resultant phasor, $C_x = A_x + B_x$. The geometric representation conveniently shows the relative amplitudes and phases of the phasors.

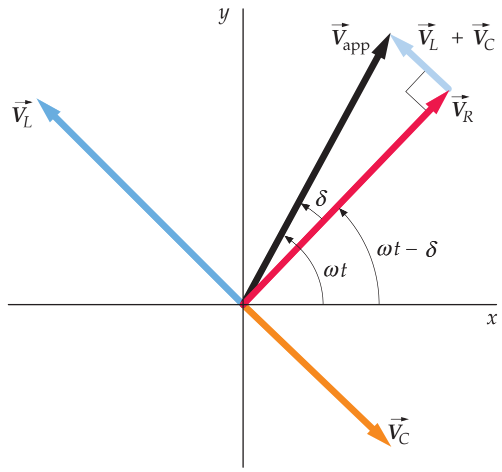

FIGURE 29-17 Phasor representations of the potential drops V_R, V_L, and V_C. Each vector rotates in the counterclockwise direction with an angular frequency ω. At any instant, the potential drop across an element equals the x component of the corresponding phasor, and the potential drop V_{app} across the *RLC*-series combination, which equals the sum of the potential drops, equals the x component of the vector sum $\vec{V}_R + \vec{V}_L + \vec{V}_C$.

Consider an ac circuit that contains an inductor L, a capacitor C, and a resistor R connected in series. They all carry the same current, which is represented as the x component of the current phasor $\vec{I}$. The potential drop across the resistor V_R is represented by a phasor $\vec{V}_R$ that has magnitude $I_{peak}R$ and is in phase with the current phasor $\vec{I}$. The potential drop across the inductor V_L is represented by a phasor $\vec{V}_L$ that has magnitude $I_{peak}X_L$ and leads the current phasor $\vec{I}$ by 90°. Similarly, the potential drop across the capacitor V_C is represented by a phasor $\vec{V}_C$ that has magnitude $I_{peak}X_C$ and lags $\vec{I}$ by 90°. Figure 29-17 shows the phasors $\vec{V}_R$, $\vec{V}_L$, $\vec{V}_C$, and $\vec{V}_{app}$, where the x component of V_{app} is the potential drop across the series combination. The phasors all rotate counterclockwise with an angular frequency ω. At any instant in time, the instantaneous value of the potential drop across any of these elements equals the x component of the corresponding phasor.

* 29-6 DRIVEN *RLC* CIRCUITS

SERIES *RLC* CIRCUIT

Figure 29-18 shows a series *RLC* circuit being sinusoidally driven by an ac generator. If the potential drop applied by the generator to the series *RLC* combination is $V_{app} = V_{app\,peak}\cos\omega t$, applying Kirchhoff's loop rule gives

$$V_{app\,peak}\cos\omega t - L\frac{dI}{dt} - IR - \frac{Q}{C} = 0$$

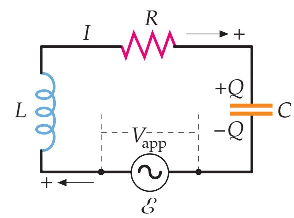

FIGURE 29-18 A series *RLC* circuit with an ac generator.

Using $I = dQ/dt$ and rearranging, we obtain

$$L\frac{d^2Q}{dt^2} + R\frac{dQ}{dt} + \frac{1}{C}Q = V_{app\,peak}\cos\omega t \qquad \text{29-47}$$

This equation is analogous to Equation 14-53 for the forced oscillation of a mass on a spring:

$$m\frac{d^2x}{dt^2} + b\frac{dx}{dt} + m\omega_0^2 x = F_0\cos\omega t$$

(In Equation 14-53, the force constant k was written in terms of the mass m and the natural angular frequency ω_0 using $k = m\omega_0^2$. The capacitance in Equation 29-47 could be similarly written in terms of L and the natural angular frequency using $1/C = L\omega_0^2$.)

* It is also easier to do using complex numbers.

We will discuss the solution of Equation 29-47 qualitatively as we did with Equation 14-53 for the forced oscillator. The current in the circuit consists of a transient current that depends on the initial conditions (for example, the initial phase of the generator and the initial charge on the capacitor) and a steady-state current that does not depend on the initial conditions. We will ignore the transient current, which decreases exponentially with time and is eventually negligible, and concentrate on the steady-state current. The steady-state current obtained by solving Equation 29-47 is

$$I = I_{\text{peak}} \cos(\omega t - \delta) \qquad \text{29-48}$$

where the phase angle δ is given by

$$\tan\delta = \frac{X_L - X_C}{R} \qquad \text{29-49}$$

PHASE CONSTANT FOR A SERIES *RLC* CIRCUIT

The peak current is

$$I_{\text{peak}} = \frac{V_{\text{app peak}}}{\sqrt{R^2 + (X_L - X_C)^2}} = \frac{V_{\text{app peak}}}{Z} \qquad \text{29-50}$$

PEAK CURRENT IN A SERIES *RLC* CIRCUIT

where

$$Z = \sqrt{R^2 + (X_L - X_C)^2} \qquad \text{29-51}$$

IMPEDANCE OF A SERIES *RLC* CIRCUIT

The quantity $X_L - X_C$ is called the **total reactance,** and Z is called the **impedance.** Combining these results, we have

$$I = \frac{V_{\text{app peak}}}{Z}\cos(\omega t - \delta) \qquad \text{29-52}$$

Equation 29-52 can also be obtained from a simple diagram using vectors called phasors. Figure 29-19 shows the phasors representing the potential drops across the resistance, the inductance, and the capacitance. The x component of each of these vectors equals the instantaneous potential drop across the corresponding element. Because the sum of the x components equals the x component of the sum, the sum of the x components equals the sum of the potential drops across these elements, which by Kirchhoff's loop rule equals the instantaneous applied potential drop.

If we represent the potential drop applied across the series combination $V_{\text{app}} = V_{\text{app peak}} \cos\omega t$ as a phasor $\vec{V}_{\text{app}}$ that has the magnitude $V_{\text{app peak}}$, we have

$$\vec{V}_{\text{app}} = \vec{V}_R + \vec{V}_L + \vec{V}_C \qquad \text{29-53}$$

In terms of the magnitudes,

$$V_{\text{app peak}} = \left|\vec{V}_R + \vec{V}_L + \vec{V}_C\right| = \sqrt{V^2_{R\,\text{peak}} + (V_{L\,\text{peak}} - V_{C\,\text{peak}})^2}$$

But $V_R = I_{\text{peak}}R$, $V_L = I_{\text{peak}}X_L$, and $V_C = I_{\text{peak}}X_C$. Thus,

$$V_{\text{app peak}} = I_{\text{peak}}\sqrt{R^2 + (X_L - X_C)^2} = I_{\text{peak}}Z$$

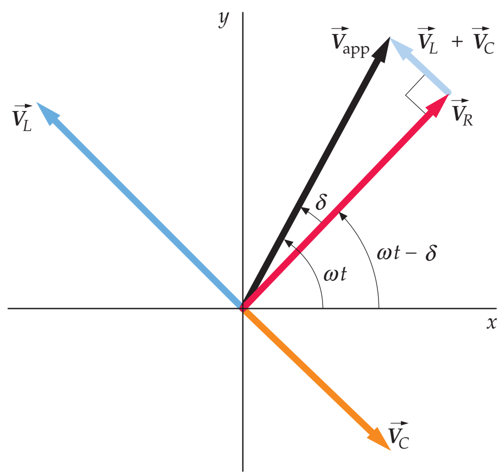

FIGURE 29-19 Phase relations among potential drops in a series *RLC* circuit. The potential drop across the resistor is in phase with the current. The potential drop across the inductor V_L leads the current by 90°. The potential drop across the capacitor lags the current by 90°. The sum of the vectors representing the potential drops gives a vector at an angle δ with the current representing the applied emf. For the case shown here, V_L is greater than V_C, and the current lags the applied potential drop by δ.

The phasor $\vec{V}_{app}$ makes an angle δ with $\vec{V}_R$, as shown in Figure 29-19. From the figure, we can see that

$$\tan\delta = \frac{|\vec{V}_L + \vec{V}_C|}{|\vec{V}_R|} = \frac{I_{peak}X_L - I_{peak}X_C}{I_{peak}R} = \frac{X_L - X_C}{R}$$

in agreement with Equation 29-49. Because $\vec{V}_{app}$ makes an angle ωt with the x axis, $\vec{V}_R$ makes an angle $\omega t - \delta$ with the x axis. This applied potential drop is in phase with the current, which is therefore given by

$$I = I_{peak}\cos(\omega t - \delta) = \frac{V_{app\,peak}}{Z}\cos(\omega t - \delta)$$

This is Equation 29-52. The relation between the impedance Z, the resistance R, and the total reactance $X_L - X_C$ is best remembered by using the right triangle shown in Figure 29-20.

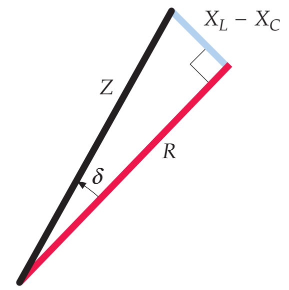

FIGURE 29-20 A right triangle relating capacitive and inductive reactance, resistance, impedance, and the phase angle in an *RLC* circuit.

RESONANCE

When X_L and X_C are equal, the total reactance is zero, and the impedance Z has its smallest value R. Then I_{peak} has its greatest value and the phase angle δ is zero, which means that the current is in phase with the applied potential drop. Let ω_{res} be the value of ω for which X_L and X_C are equal. It is obtained from

$$X_L = X_C$$

$$\omega_{res}L = \frac{1}{\omega_{res}C}$$

or

$$\omega_{res} = \frac{1}{\sqrt{LC}}$$

which equals the natural frequency ω_0. When the frequency of the applied potential drop equals the natural frequency ω_0, the impedance is smallest, I_{peak} is greatest, and the circuit is said to be at **resonance.** The natural frequency ω_0 is therefore also called the **resonance frequency.** This resonance condition in a driven *RLC* circuit is similar to that in a driven simple harmonic oscillator.

Because neither an inductor nor a capacitor dissipates energy, the average power delivered to a series *RLC* circuit is the average power supplied to the resistor. The instantaneous power supplied to the resistor is

$$P = I^2R = [I_{peak}\cos(\omega t - \delta)]^2R$$

Averaging over one or more cycles and using $(\cos^2\theta)_{av} = \frac{1}{2}$, we obtain for the average power

$$P_{av} = \frac{1}{2}I^2_{peak}R = (I_{rms})^2R \qquad 29\text{-}54$$

Using $R/Z = \cos\delta$ from Figure 29-20 and $I_{peak} = V_{app\,peak}/Z$, this can be written

$$P_{av} = \frac{1}{2}V_{app\,peak}I_{peak}\cos\delta = V_{app\,rms}I_{rms}\cos\delta \qquad 29\text{-}55$$

The quantity $\cos\delta$ is called the **power factor** of the *RLC* circuit. At resonance, δ is zero, and the power factor is 1.

The power can also be expressed as a function of the angular frequency ω. Using $I_{rms} = V_{app\,rms}/Z$, Equation 29-54 becomes

$$P_{av} = (I_{rms})^2 = (V_{app\,rms})^2\frac{R}{Z^2}$$

From the definition of impedance Z, we have

$$Z^2 = (X_L - X_C)^2 + R^2 = \left(\omega L - \frac{1}{\omega C}\right)^2 + R^2$$
$$= \frac{L^2}{\omega^2}\left(\omega^2 - \frac{1}{LC}\right)^2 + R^2$$
$$= \frac{L^2}{\omega^2}(\omega^2 - \omega_0^2)^2 + R^2$$

where we have used $\omega_0 = 1/\sqrt{LC}$. Using this expression for Z^2, we obtain the average power as a function of ω:

$$P_{\text{av}} = \frac{(V_{\text{app rms}})^2 R\omega^2}{L^2(\omega^2 - \omega_0^2)^2 + \omega^2 R^2} \qquad \text{29-56}$$

Figure 29-21 shows the average power supplied by the generator to the series combination as a function of generator frequency for two different values of the resistance R. These curves, called **resonance curves,** are the same as the power-versus-frequency curves for a driven damped oscillator (see Section 14-5). The average power is greatest when the generator frequency equals the resonance frequency. When the resistance is small, the resonance curve is narrow; when the resistance is large, the resonance curve is broad. A resonance curve can be characterized by the **resonance width** $\Delta\omega$. As shown in Figure 29-21, the resonance width is the frequency difference between the two points on the curve where the power is half its maximum value. When the width is small compared with the resonance frequency, the resonance is sharp; that is, the resonance curve is narrow.

The Q factor for a mechanical oscillator is defined as $Q_{\text{factor}} = \omega_0 m/b$ (Equations 14-42 and 14-45), where m is the mass and b is the damping constant. We then saw that for weakly-damped oscillator $Q_{\text{factor}} = 2\pi E/|\Delta E|$, where E is the total energy of the system at the beginning of a cycle and ΔE is the energy dissipated during the cycle. The ***Q* factor** for an RLC circuit can be defined in a similar way. Because L is analogous to the mass m and R is analogous to the damping constant b, the Q factor for an RLC circuit that has a small resistance is given by

$$Q_{\text{factor}} = 2\pi\left(\frac{E}{|\Delta E|}\right)_{\text{cycle}} = \frac{\omega_0 L}{R} \qquad \text{29-57}$$

When the resonance curve is reasonably narrow (that is, when Q is greater than about 2 or 3), the Q factor can be approximated by

$$Q_{\text{factor}} = \frac{\omega_0}{\Delta\omega} = \frac{f_0}{\Delta f} \qquad \text{29-58}$$

Q FACTOR FOR AN *RLC* CIRCUIT

Resonance circuits are used in radio receivers, where the resonance frequency of the circuit is varied either by varying the capacitance or the inductance. Resonance occurs when the natural frequency of the circuit equals one of the frequencies of the radio waves picked up at the antenna. At resonance, a relatively large current exists in the antenna circuit. If the Q factor of the circuit is sufficiently high, currents due to other station frequencies off resonance will be negligible compared with those currents due to the station frequency to which the circuit is tuned.

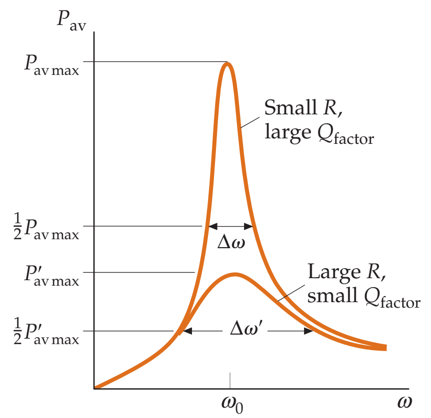

FIGURE 29-21 Plot of average power versus frequency for a series RLC circuit. The power is maximum when the frequency of the generator ω equals the natural frequency of the circuit $\omega_0 = 1/\sqrt{LC}$. If the resistance is small, the Q factor is large and the resonance is sharp. The resonance width $\Delta\omega$ of the curves is measured between points where the power is half its maximum value.

Example 29-7 Driven Series *RLC* Circuit

A series *RLC* combination that has $L = 2.0$ H, $C = 2.0\ \mu$F, and $R = 20\ \Omega$ is driven by an ideal generator that has a peak emf of 100 V and a frequency which can be varied. Find (*a*) the resonance frequency f_0, (*b*) the Q factor, (*c*) the width of the resonance Δf, and (*d*) the current amplitude at resonance.

PICTURE The resonance frequency is found from $\omega_0 = 1/\sqrt{LC}$ and the Q factor is found from $Q_{\text{factor}} = \omega_0 L/R$ (Equation 29-57).

SOLVE

(*a*) The resonance frequency is $f_0 = \omega_0/2\pi$:

$$f_0 = \frac{\omega_0}{2\pi} = \frac{1}{2\pi\sqrt{LC}} = \frac{1}{2\pi\sqrt{(2.0\text{ H})(2.0 \times 10^{-6}\text{ F})}} = \boxed{80\text{ Hz}}$$

(*b*) Use this result to calculate Q_{factor}:

$$Q_{\text{factor}} = \frac{\omega_0 L}{R} = \frac{2\pi(80\text{ Hz})(2.0\text{ H})}{20\ \Omega} = \boxed{50}$$

(*c*) Use the value of Q_{factor} to find the width of the resonance Δf, where $Q_{\text{factor}} = f_0/\Delta f$:

$$\Delta f = \frac{f_0}{Q_{\text{factor}}} = \frac{80\text{ Hz}}{50} = \boxed{1.6\text{ Hz}}$$

(*d*) At resonance, the impedance is equal to R and I_{peak} is $V_{\text{app peak}}/R$:

$$I_{\text{peak}} = \frac{V_{\text{app peak}}}{R} = \frac{\mathcal{E}_{\text{peak}}}{R} = \frac{100\text{ V}}{20\ \Omega} = \boxed{5.0\text{ A}}$$

CHECK At resonance the inductive and capacitances each equal $X_L = \omega_0 L = 2\pi(80\text{ Hz})(2.0\text{ H}) = 1.0\text{ k}\Omega$. The resistance is given as $R = 20\ \Omega$. Because the resistance is much smaller than the inductive reactance at resonance, we expect the Q factor to be high and the resonance to be sharp. The Part (*b*) and (*c*) results meet this expectation.

TAKING IT FURTHER The width of 1.6 Hz is about 2.0 percent of the resonance frequency of 80 Hz, so the resonance peak is quite sharp.

Example 29-8 Driven Series *RLC* Circuit Current, Phase, and Power

Try It Yourself

If the generator in Example 29-7 has a frequency of 60 Hz, find (*a*) the peak current, (*b*) the phase constant δ, (*c*) the power factor, and (*d*) the average power delivered.

PICTURE The peak current is the peak applied potential drop divided by the total impedance of the series combination. The phase angle δ is found from $\tan\delta = (X_L - X_C)/R$. You can use either Equation 29-54 or Equation 29-55 to find the average power delivered.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
(*a*) 1. Write the peak current in terms of $V_{\text{app peak}}$ and the impedance.	$I_{\text{peak}} = \dfrac{V_{\text{app peak}}}{Z} = \dfrac{\mathcal{E}_{\text{peak}}}{Z}$
2. Calculate the capacitive and inductive reactances and the total reactance.	$X_C = 1326\ \Omega$, $X_L = 754\ \Omega$ so $X_L - X_C = -572\ \Omega$
3. Calculate the total impedance Z.	$Z = 573\ \Omega$
4. Use the results of steps 2 and 3 to calculate I_{peak}.	$I_{\text{peak}} = \boxed{0.17\text{ A}}$
(*b*) Use the results of Part (*a*) steps 2 and 3 to calculate δ.	$\delta = \tan^{-1}\dfrac{X_L - X_C}{R} = \boxed{-88.0^\circ}$

(*c*) Use your value of δ to compute the power factor. $\cos\delta = \boxed{0.035}$

(*d*) Calculate the average power delivered from Equation 29-54. $P_{\text{av}} = \frac{1}{2}I_{\text{peak}}^2 R = \boxed{0.29\text{ W}}$

CHECK To check our result for the average power using the power factor found in Part (*c*), we have $P_{\text{av}} = \frac{1}{2}V_{\text{app peak}}I_{\text{peak}}\cos\delta = \frac{1}{2}\mathcal{E}_{\text{peak}}I_{\text{peak}}\cos\delta = 0.29\text{ W}$. This result is in agreement with our result for Part (*d*).

TAKING IT FURTHER The frequency of 60 Hz is well below the resonance frequency of 80 Hz. (Recall that the width of the resonance peak, calculated in Example 29-7, is only 1.6 Hz.) As a result, the total reactance is much greater in magnitude than the resistance. This result is always the case far from resonance. Similarly, a peak current of 0.17 A is much less than the peak current at resonance, which was found to be 5.0 A in Example 29-7. Finally, we see from Figure 29-19 that a negative phase angle δ means that the current leads the applied potential drop.

CONCEPT CHECK 29-1

A circuit consists of an ideal constant-frequency generator, a resistor, a capacitor and an inductor with a moveable soft-iron core—all connected in series. You notice that if you nudge the soft-iron core a bit deeper into the induction coil, the rms current increases slightly. Prior to the nudge, the resonance frequency of the circuit was (*a*) below the generator frequency, (*b*) equal to the generator frequency, (*c*) above the generator frequency.

Example 29-9 Driven Series *RLC* Circuit at Resonance — *Try It Yourself*

Find the peak potential drop across the resistor, the inductor, and the capacitor at resonance for the circuit in Example 29-7.

PICTURE The peak potential drop across the resistor is I_{peak} multiplied by R. Similarly, the peak potential drop across the inductor or capacitor is I_{peak} multiplied by the appropriate reactance. We found that at resonance $I_{\text{peak}} = 5.0$ A and $f_0 = 80$ Hz in Example 29-7.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. Calculate $V_{R\,\text{peak}} = I_{\text{peak}}R$.	$V_{R\,\text{peak}} = I_{\text{peak}}R = \boxed{100\text{ V}}$
2. Express $V_{L\,\text{peak}}$ in terms of I_{peak} and X_L.	$V_{L\,\text{peak}} = I_{\text{peak}}X_L = I_{\text{peak}}\omega_0 L = \boxed{5.0\text{ kV}}$
3. Express $V_{C\,\text{peak}}$ in terms of I_{peak} and X_C.	$V_{C\,\text{peak}} = I_{\text{peak}}X_C = \dfrac{I_{\text{peak}}}{\omega_0 C} = \boxed{5.0\text{ kV}}$

CHECK The inductive and capacitive reactances are equal, as we would expect at resonance. (We solved for the resonance frequency by setting them equal.)

TAKING IT FURTHER The phasor diagram for the potential drops across the resistor, capacitor, and inductor is shown in Figure 29-22. The peak potential drop across the resistor is a relatively safe 100 V, equal to the peak emf of the generator. However, the peak potential drops across the inductor and the capacitor are a dangerously high 5.0 kV. These potential drops are 180° out of phase. At resonance, the potential drop across the inductor at any instant is the negative of the potential drop across the capacitor, so they always sum to zero, leaving the potential drop across the resistor equal to the emf in the circuit.

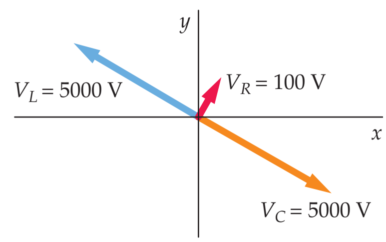

FIGURE 29-22

Example 29-10 *RC* Low-Pass Filter

A resistor R and capacitor C are in series with an ideal generator, as shown in Figure 29-23. The generator applies a potential difference across the RC combination given by $V_{\text{app}} = \sqrt{2}\,V_{\text{app rms}}\cos\omega t$. Find the rms potential difference across the capacitor $V_{\text{out rms}}$ as a function of frequency ω.

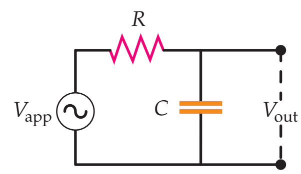

FIGURE 29-23 The peak output voltage decreases as frequency increases.

PICTURE The rms potential difference across the capacitor is the product of the rms current and the capacitive reactance. The rms current is found from the potential difference applied by the generator and the impedance of the series RC combination.

SOLVE

1. The potential drop across the capacitor is I_{rms} multiplied by X_C: $V_{\text{out rms}} = I_{\text{rms}} X_C$

2. The rms current depends on the applied rms potential difference and the impedance: $I_{\text{rms}} = \dfrac{V_{\text{app rms}}}{Z}$

3. In this circuit, only R and X_C contribute to the total impedance: $Z = \sqrt{R^2 + X_C^2}$

4. Substitute those expressions and $X_C = 1/(\omega C)$ to find the output rms potential difference:

$$V_{\text{out rms}} = I_{\text{rms}} X_C = \frac{V_{\text{app rms}} X_C}{\sqrt{R^2 + X_C^2}} = \frac{V_{\text{app rms}}}{\sqrt{1 + \dfrac{R^2}{X_C^2}}} = \boxed{\frac{V_{\text{app rms}}}{\sqrt{1 + (\omega RC)^2}}}$$

CHECK The dimensions of our step 4 result are correct. The dimension of ω is 1/T and the dimension of RC is T, so the product ωRC is dimensionless.

TAKING IT FURTHER This circuit is called an *RC low-pass filter*, because it transmits low frequencies with greater amplitude than high frequencies. In fact, the output potential difference equals the potential difference applied by the generator in the limit that $\omega \to 0$, but also approaches zero for $\omega \to \infty$, as shown in the graph of the ratio of output potential difference to applied potential difference in Figure 29-24.

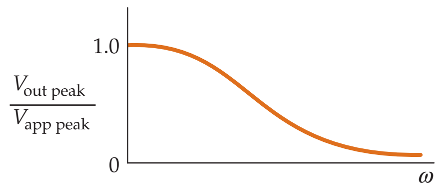

FIGURE 29-24

PRACTICE PROBLEM 29-3 Find the output potential difference for this circuit if the capacitor is replaced by an inductor L.

Example 29-11 An FM Tuner *Context-Rich*

You have been tinkering with building a radio tuner using your new knowledge of physics. You know that the FM dial gives its frequencies in megahertz, and you would like to determine what percentage of change in an inductor would allow you to tune for the whole FM range. You decide to start at midrange and determine a percent increase and decrease needed for inductance. A variable inductor is usually an iron-core solenoid, and the inductance is increased by further inserting the core. The FM dial goes from 88 MHz to 108 MHz.

PICTURE We can relate inductance to the resonant frequency with $\omega = 2\pi f$ and $\omega = 1\sqrt{LC}$. Then, if we find the percent change in frequency, we can determine the percent change in inductance. The capacitance C does not vary.

SOLVE

1. The resonant angular frequency ω is related to the inductance L: $\omega = 1/\sqrt{LC}$

and

$\omega = 2\pi f$

so

$$f = \frac{1}{2\pi\sqrt{LC}}$$

2. Solving for L gives: $L = a/f^2$

where

$a = (4\pi^2 C)^{-1}$

3. Express the fractional change in L in terms of the frequencies. When L is maximum, f is minimum and vice versa. The middle frequency f_{mid} is halfway between the maximum and minimum frequency and L_{mid} is the inductance when $f = f_{\text{mid}}$:

$$\frac{\Delta L}{L} = \frac{L_{\text{max}} - L_{\text{min}}}{L_{\text{mid}}} = \frac{a/f_{\text{max}}^2 - a/f_{\text{min}}^2}{a/f_{\text{mid}}^2}$$

$$= f_{\text{mid}}^2\left(\frac{1}{f_{\text{max}}^2} - \frac{1}{f_{\text{min}}^2}\right) = 98^2\left(\frac{1}{108^2} - \frac{1}{88^2}\right)$$

$$= -0.417$$

4. The minus sign is not relevant, except as an indication that when the inductance increases the resonant frequency decreases. Express the step 3 result as a percentage:

The inductance varies by about $\boxed{\text{42 percent}}$

A shipboard radio, circa 1920. Exposed at the operator's left are the inductance coils and capacitor plates of the tuning circuit. *(© George H. Clark Radioana Collection-Archive Center, National Museum of American History.)*

PARALLEL RLC CIRCUIT

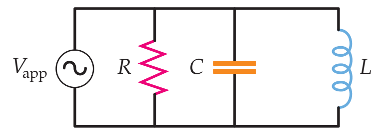

FIGURE 29-25 A parallel *RLC* circuit.

Figure 29-25 shows a resistor R, a capacitor C, and an inductor L connected in parallel across an ac generator. The total current I from the generator divides into three currents: the current I_R in the resistor, the current I_C in the capacitor, and the current I_L in the inductor. The instantaneous potential drop V_{app} is the same across each element. The current in the resistor is in phase with the potential drop and the phasor $\vec{I}_R$ has magnitude V_{peak}/R. Because the potential drop across an inductor *leads* the current in the inductor by 90°, I_L *lags* the potential drop by 90°, and the phasor $\vec{I}_L$ has magnitude V_{peak}/X_L. Similarly, I_C leads the potential drop by 90° and the phasor $\vec{I}_C$ has magnitude V_{peak}/X_C. These currents are represented by phasors in Figure 29-26. The total current I is the x component of the vector sum of the individual current phasors as shown in the figure. The magnitude of the total current phasor is

$$I = \sqrt{I_R^2 + (I_L - I_C)^2} = \sqrt{\left(\frac{V_{\text{peak}}}{R}\right)^2 + \left(\frac{V_{\text{peak}}}{X_L} - \frac{V_{\text{peak}}}{X_C}\right)^2} = \frac{V_{\text{peak}}}{Z} \qquad \text{29-59}$$

where the total impedance Z is related to the resistance and the capacitive and inductive reactances by

$$\frac{1}{Z^2} = \frac{1}{R^2} + \left(\frac{1}{X_L} - \frac{1}{X_C}\right)^2 \qquad \text{29-60}$$

At resonance, the currents in the inductor and capacitor are 180° out of phase, so the total current is a minimum and is just the current in the resistor. We see from Equation 29-59 that this occurs if Z is maximum, so $1/Z$ is minimum. Then, we see from Equation 29-60 that if $X_L = X_C$, $1/Z$ has its minimum value $1/R$. Equating X_L with X_C and solving for ω obtains the resonant frequency, which equals the natural frequency $\omega_0 = 1/\sqrt{LC}$.

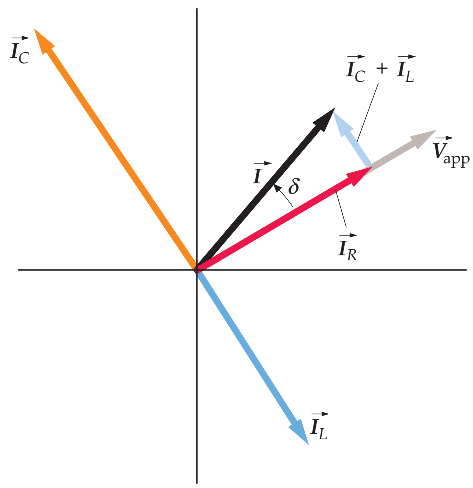

FIGURE 29-26 A phasor diagram for the currents in the parallel *RLC* circuit shown in Figure 29-25. The potential drop is the same across each element. The current in the resistor is in phase with the potential drop. The current in the capacitor leads the potential drop by 90° and the current in the inductor lags the potential drop by 90°. The phase difference δ between the total current and the potential drop depends on the relative magnitudes of the currents, which depend on the values of the resistance and of the capacitive and inductive reactances.

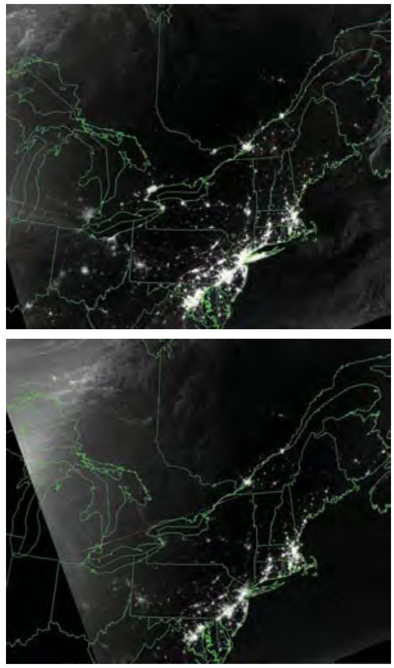
The Electric Grid: Power to the People



The pair of satellite images shows how a power failure affected many American and Canadian cities during the evening of Thursday, August 14, 2003. The top image was taken 20 hours before the blackout while the bottom image was taken 7 hours after the blackout. *(Courtesy of Chris Elridge/U.S. Airforce.)*

All around the world, people depend on electrical distribution systems, or grids, for reliable electric power. Generators, substations that have transformers, and high-voltage transmission lines are all necessary to efficiently move electrical energy from one place to another.[*] As of 2002, over 150 000 miles of high-voltage ac transmission lines and more than 10 000 transmission substations were part of the grid in the United States alone.[†] Grids are growing in complexity[‡] all over the world.[#, °] Unfortunately, as grids grow, so do the number of possible points of failure.

Most electrical grid failures are small scale, caused by local weather, by equipment failure,[§] or even by animals.[¶] But these failures give clues to the causes of large-scale power outages. Power surges within transformers and lines are the primary cause of local outages. Damage is prevented from propagating, or cascading, by relay switches that close off the line and act as surge suppressors for the system as a whole. Rarely, local outages are caused when there is much more demand than local generators can supply.

Sometimes the same mechanisms meant to prevent damage from a local outage can cause the outage to cascade. On November 9, 1965, a relay switch tripped at a hydroelectric plant in southern Ontario. The current from that line was shunted to five other transmission lines, which caused the relay switches for those lines to trip. Because of this dramatic reduction in load, the generators sped up, which meant that the power they provided was out of phase with power from other providers.[**] Over the course of a few minutes, relay after relay tripped, and many generators were shut down as they were isolated from their loads. Within four seconds, relays had tripped throughout the northeastern United States. Within a few minutes, generators were taken off-line, and over 30 million people were left without electricity for several hours.

That blackout prompted the formation of the National Electric Reliability Council.[††] Measures put in place for coordination of electric loads[‡‡, ##] have prevented many large blackouts, but blackouts have still happened. In July 1977, a lightning strike to transmission lines in New York tripped relays, and because of the slow response of the system operator,[°°] New York City was left without power for three days.[§§] On August 14, 2003, an unfortunate combination of high demand, a transmission line shorting against an untrimmed tree, and inadequate communications led to a blackout in the northeast United States and Canada that left 50 million people without power, some for days.[¶¶]

To prevent future outages, technical improvements to the grid are being actively sought. One improvement is software able to monitor and control portions of the grid with speed and flexibility.[***] Other improvements may include higher capacity transmission lines, improved transformers, and more responsive maintenance programs.[†††, ‡‡‡]

Summary

1. Reactance is a frequency-dependent property of capacitors and inductors that is analogous to the resistance of a resistor.
2. Impedance is a frequency-dependent property of an ac circuit or circuit loop that is analogous to the resistance in a dc circuit.
3. Phasors are two-dimensional vectors that allow us to picture the phase relations in a circuit.
4. Resonance occurs when the frequency of the generator equals the natural frequency of the oscillating circuit.

TOPIC	RELEVANT EQUATIONS AND REMARKS	
1. Alternating-Current Generators	An ac generator is a device that transforms mechanical energy into electrical energy. This transformation can be accomplished by using the mechanical energy to either rotate a conducting coil in a magnetic field or to rotate a magnet in a conducting coil.	
Emf generated	$\mathcal{E} = \mathcal{E}_{\text{peak}} \cos(\omega t + \delta)$	29-1
2. Current		
Rms current	$I_{\text{rms}} = \sqrt{(I^2)_{\text{av}}}$	29-8
Rms current and peak current	$I_{\text{rms}} = \frac{I}{\sqrt{2}} I_{\text{peak}}$	29-9
For a resistor	$I_{\text{rms}} = \frac{V_{R\,\text{rms}}}{R}$ potential drop and current in phase	29-12
For an inductor	$I_{\text{rms}} = \frac{V_{L\,\text{rms}}}{\omega L} = \frac{V_{L\,\text{rms}}}{X_L}$ potential drop leads current by 90°	29-22
For a capacitor	$I_{\text{rms}} = \frac{V_{C\,\text{rms}}}{1/\omega C} = \frac{V_{C\,\text{rms}}}{X_C}$ potential drop lags current by 90°	29-26
3. Reactance		
Inductive reactance	$X_L = \omega L$	29-21
Capacitive reactance	$X_C = \frac{1}{\omega C}$	29-27
4. Average Power		
To a resistor	$P_{\text{av}} = V_{R\,\text{rms}} I_{\text{rms}} = (I_{\text{rms}})^2 R$	29-10, 29-12
To an inductor or to a capacitor	$P_{\text{av}} = 0$	
5. *Transformers	A transformer is a device used to increase or decrease the voltage in a circuit without an appreciable loss in power. For a transformer with N_1 turns in the primary and N_2 turns in the secondary, the potential difference across the secondary coil is related to the potential drop across the primary coil by $V_2 = \frac{N_2}{N_1} V_1$	29-30

TOPIC	RELEVANT EQUATIONS AND REMARKS	
	If there are no power losses, $$V_{1\,\text{rms}}I_{1\,\text{rms}} = V_{2\,\text{rms}}I_{2\,\text{rms}}$$	29-32
6. *LC and RLC Series Circuits	If a capacitor is discharged through an inductor, the charge and the voltage on the capacitor oscillate with angular frequency $$\omega = \frac{1}{\sqrt{LC}}$$ The current in the inductor oscillates with the same frequency, but it is out of phase with the charge by 90°. The energy oscillates between electric energy in the capacitor and magnetic energy in the inductor. If the circuit also has resistance, the oscillations are damped because energy is dissipated in the resistor.	29-37
7. *Phasors	Phasors are two-dimensional vectors that represent the current $\vec{I}$, the potential drop across a resistor $\vec{V}_R$, the potential drop across a capacitor $\vec{V}_C$, and the potential drop across an inductor $\vec{V}_L$ in an ac circuit. These phasors rotate in the counterclockwise direction with an angular velocity that is equal to the angular frequency ω of the current. $\vec{V}_R$ is in phase with the current, $\vec{V}_L$ leads the current by 90°, and $\vec{V}_C$ lags the current by 90°. The x component of each phasor equals the magnitude of the current or the corresponding potential drop at any instant.	
8. *Driven Series RLC Circuit		
Applied potential drop	$$V_{\text{app}} = V_{\text{app peak}} \cos \omega t$$	
Current	$$I = \frac{V_{\text{app peak}}}{Z}\cos(\omega t - \delta)$$	29-52
Impedance Z	$$Z = \sqrt{R^2 + (X_L - X_C)^2}$$	29-51
Phase angle δ	$$\tan\delta = \frac{X_L - X_C}{R}$$	29-49
Average power	$$P_{\text{av}} = (I_{\text{rms}})^2 R = V_{\text{app rms}} I_{\text{rms}} \cos\delta = \frac{(V_{\text{app rms}})^2 R\omega^2}{L^2(\omega^2 - \omega_0^2)^2 + \omega^2 R^2}$$	29-54, 29-55, 29-56
Power factor	The quantity $\cos\delta$ in Equation 29-55 is called the power factor of the RLC circuit. At resonance, δ is zero, the power factor is 1, and $$P_{\text{av}} = V_{\text{app rms}} I_{\text{rms}}$$	
Resonance	When the rms current is maximum, the circuit is said to be at resonance. The conditions for resonance are $$Z = \sqrt{R^2 + (X_L - X_C)^2} = R$$ $X_L = X_C$, so $$\omega = \omega_0 = \frac{1}{\sqrt{LC}} \quad \text{and} \quad \delta = 0$$	
9. *Q Factor	The sharpness of the resonance curve is described by the Q factor: $$Q_{\text{factor}} = \frac{\omega_0 L}{R}$$ (29-57) When the resonance curve is reasonably narrow, the Q factor can be approximated by $$Q_{\text{factor}} = \frac{\omega_0}{\Delta\omega} = \frac{f_0}{\Delta f}$$	29-57, 29-58

Answers to Concept Check

Answers to Practice Problems

29-1 (*a*) 2.8 A, (*b*) 96 W, (*c*) 1.9×10^2 W

29-2 79 μH

29-3 $V_{\text{out rms}} = V_{\text{in rms}}/\sqrt{1 + (R/L)^2/\omega^2}$. This circuit is a *high-pass filter*.

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • A coil in an ac generator rotates at 60 Hz. How much time elapses between successive peak emf values of the coil?

2 • If the rms voltage in an ac circuit is doubled, the peak voltage is (*a*) doubled, (*b*) halved, (*c*) increased by a factor of $\sqrt{2}$, (*d*) not changed.

3 • If the frequency in the circuit shown in Figure 29-27 is doubled, the inductance of the inductor will (*a*) double, (*b*) not change, (*c*) halve, (*d*) quadruple. SSM

4 • If the frequency in the circuit shown in Figure 29-27 is doubled, the inductive reactance of the inductor will (*a*) double, (*b*) not change, (*c*) halve, (*d*) quadruple.

FIGURE 29-27 Problems 3 and 4

5 • If the frequency in the circuit in Figure 29-28 is doubled, the capacitive reactance of the circuit will (*a*) double, (*b*) not change, (*c*) halve, (*d*) quadruple.

FIGURE 29-28 Problem 5

6 • (*a*) In a circuit consisting solely of an ac generator and an ideal inductor, are there any time intervals when the inductor receives energy from the generator? If so, when? Explain your answer. (*b*) Are there any time intervals when the inductor supplies energy back to the generator? If so when? Explain your answer.

7 • (*a*) In a circuit consisting of a generator and a capacitor, are there any time intervals when the capacitor receives energy from the generator? If so, when? Explain your answer. (*b*) Are there any time intervals when the capacitor supplies power to the generator? If so, when? Explain your answer. SSM

8 • (*a*) Show that the SI unit of inductance multiplied by the SI unit of capacitance is equivalent to seconds squared. (*b*) Show that the SI unit of inductance divided by the SI unit of resistance is equivalent to seconds.

9 • Suppose you increase the rotation rate of the coil in the generator shown in the simple ac circuit in Figure 29-29. Then the rms current (*a*) increases, (*b*) does not change, (*c*) may increase or decrease depending on the magnitude of the original frequency, (*d*) may increase or decrease depending on the magnitude of the resistance, (*e*) decreases. SSM

FIGURE 29-29 Problem 9

10 • If the inductance value is tripled in a circuit consisting solely of a variable inductor and a variable capacitor, how would you have to change the capacitance so that the natural frequency of the circuit is unchanged? (*a*) Triple the capacitance. (*b*) Decrease the capacitance to one-third of its original value. (*c*) You should not change the capacitance. (*d*) You cannot determine how to change the capacitance from the data given.

11 • Consider a circuit consisting solely of an ideal inductor and an ideal capacitor. How does the maximum energy stored in the capacitor compare to the maximum value stored in the inductor? (*a*) They are the same and each is equal to the total energy stored in the circuit. (*b*) They are the same and each is equal to half of the total energy stored in the circuit. (*c*) The maximum energy stored in the capacitor is larger than the maximum energy stored in the inductor. (*d*) The maximum energy stored in the inductor is larger than the maximum energy stored in the capacitor. (*e*) You cannot compare the maximum energies based on the data given because the ratio of the maximum energies depends on the actual capacitance and inductance values. SSM

12 • True or false:

(*a*) A driven series *RLC* circuit that has a high *Q* factor has a narrow resonance curve.

(*b*) A circuit consists solely of a resistor, an inductor, and a capacitor, all connected in series. If the resistance of the resistor is doubled, the natural frequency of the circuit remains the same.

(*c*) At resonance, the impedance of a driven series *RLC* combination equals the resistance *R*.

(*d*) At resonance, the current in a driven series *RLC* circuit is in phase with the voltage applied to the combination.

13 • True or false:

(*a*) Near resonance, the power factor of a driven series *RLC* circuit is close to zero.

(*b*) The power factor of a driven series *RLC* circuit does not depend on the value of the resistance.
(*c*) The resonance frequency of a driven series *RLC* circuit does not depend on the value of the resistance.
(*d*) At resonance, the peak current of a driven series *RLC* circuit does not depend on the capacitance or the inductance.
(*e*) For frequencies below the resonant frequency, the capacitive reactance of a driven series *RLC* circuit is larger than the inductive reactance.
(*f*) For frequencies below the resonant frequency of a driven series *RLC* circuit, the phase of the current leads (is ahead of) the phase of the applied voltage.

14 • You may have noticed that sometimes two radio stations can be heard when your receiver is tuned to a specific frequency. This situation often occurs when you are driving and are between two cities. Explain how this situation can occur.

15 • True or false:
(*a*) At frequencies much higher than or much lower than the resonant frequency of a driven series *RLC* circuit, the power factor is close to zero.
(*b*) The larger the resonance width of a driven series *RLC* circuit is, the larger the *Q* factor for the circuit is.
(*c*) The larger the resistance of a driven series *RLC* circuit is, the larger the resonance width for the circuit is.

16 • An ideal transformer has N_1 turns on its primary and N_2 turns on its secondary. The average power delivered to a load resistance R connected across the secondary is P_2 when the primary rms voltage is V_1. The rms current in the primary windings can then be expressed as (*a*) P_2/V_1, (*b*) $(N_1/N_2)(P_2/V_1)$, (*c*) $(N_2/N_1)(P_2/V_1)$, (*d*) $(N_2/N_1)2(P_2/V_1)$.

17 • True or false:
(*a*) A transformer is used to change frequency.
(*b*) A transformer is used to change voltage.
(*c*) If a transformer steps up the current, it must step down the voltage.
(*d*) A step-up transformer steps down the current.
(*e*) The standard household wall-outlet voltage in Europe is 220 V, about twice that used in the United States. If a European traveler wants her hair dryer to work properly in the United States, she should use a transformer that has more windings in its secondary coil than in its primary coil.
(*f*) The standard household wall-outlet voltage in Europe is 220 V, about twice that used in the United States. If an American traveler wants his electric razor to work properly in Europe, he should use a transformer that steps up the current. SSM

ESTIMATION AND APPROXIMATION

18 •• **Engineering Application** The impedances of motors, transformers, and electromagnets include both resistance and inductive reactance. Suppose that the phase of the current to a large industrial plant lags the phase of the applied voltage by 25° when the plant is under full operation and using 2.3 MW of power. The power is supplied to the plant from a substation 4.5 km from the plant; the 60 Hz rms line voltage at the plant is 40 kV. The resistance of the transmission line from the substation to the plant is 5.2 Ω. The cost per kilowatt-hour to the company that owns the plant is \$0.14, and the plant pays only for the actual energy used. (*a*) Estimate the resistance and inductive reactance of the plant's total load. (*b*) Estimate the rms current in the power lines and the rms voltage at the substation. (*c*) How much power is lost in transmission? (*d*) Suppose that the phase at which the current lags the phase of the applied voltage is reduced to 18° by adding a bank of capacitors in series with the load. How much money would be saved by the electric utility during one month of operation, assuming the plant operates at full capacity for 16 h each day? (*e*) What must be the capacitance of this bank of capacitors to achieve this change in phase angle?

ALTERNATING CURRENT IN RESISTORS, INDUCTORS, AND CAPACITORS

19 • A 100-W lightbulb is screwed into a standard 120-V-rms. socket. Find (*a*) the rms current, (*b*) the peak current, and (*c*) the peak power. SSM

20 • A circuit breaker is rated for a current of 15 A rms at a voltage of 120 V rms. (*a*) What is the largest value of peak current that the breaker can carry? (*b*) What is the maximum average power that can be supplied by this circuit?

21 • What is the reactance of a 1.00-μH inductor at (*a*) 60 Hz, (*b*) 600 Hz, and (*c*) 6.00 kHz? SSM

22 • An inductor has a reactance of 100 Ω at 80 Hz. (*a*) What is its inductance? (*b*) What is its reactance at 160 Hz?

23 • At what frequency would the reactance of a 10-μF capacitor equal the reactance of a 1.0-mH inductor?

24 • What is the reactance of a 1.00-nF capacitor at (*a*) 60.0 Hz, (*b*) 6.00 kHz, and (*c*) 6.00 MHz?

25 • A 20-Hz ac generator that produces a peak emf of 10 V is connected to a 20-μF capacitor. Find (*a*) the peak current and (*b*) the rms current. SSM

26 • At what frequency is the reactance of a 10-μF capacitor (*a*) 1.00 Ω, (*b*) 100 Ω, and (*c*) 10.0 mΩ?

27 •• A circuit consists of two ideal ac generators and a 25-Ω resistor, all connected in series. The potential difference across the terminals of one of the generators is given by $V_1 = (5.0\text{ V})\cos(\omega t - \alpha)$, and the potential difference across the terminals of the other generator is given by $V_2 = (5.0\text{ V})\cos(\omega t + \alpha)$, where $\alpha = \pi/6$. (*a*) Use Kirchhoff's loop rule and a trigonometric identity to find the peak current in the circuit. (*b*) Use a phasor diagram to find the peak current in the circuit. (*c*) Find the current in the resistor if $\alpha = \pi/4$ and the amplitude of V_2 is increased from 5.0 V to 7.0 V.

*UNDRIVEN CIRCUITS CONTAINING CAPACITORS, RESISTORS, AND INDUCTORS

28 • (*a*) Show that $1/\sqrt{LC}$ has units of inverse seconds by substituting SI units for inductance and capacitance into the expression. (*b*) Show that $\omega_0 L/R$ (the expression for the *Q* factor) is dimensionless by substituting SI units for angular frequency, inductance, and resistance into the expression.

29 • (*a*) What is the period of oscillation of an *LC* circuit consisting of a 2.0-mH coil and a 20-μF capacitor? (*b*) A circuit that oscillates consists solely of an 80-μF capacitor and a variable ideal inductor. What inductance is needed in order to tune this circuit to oscillate at 60 Hz? SSM

30 • An *LC* circuit has capacitance C_0 and inductance L. A second *LC* circuit has capacitance $\frac{1}{2}C_0$ and inductance $2L$, and a third *LC* circuit has capacitance $2C_0$ and inductance $\frac{1}{2}L$. (*a*) Show that each circuit oscillates with the same frequency. (*b*) In which circuit would the peak current be greatest if the peak voltage across the capacitor in each circuit were the same?

31 •• A 5.0-μF capacitor is charged to 30 V and is then connected across an ideal 10-mH inductor. (*a*) How much energy is stored in the system? (*b*) What is the frequency of oscillation of the circuit? (*c*) What is the peak current in the circuit?

32 •• A coil with internal resistance can be modeled as a resistor and an ideal inductor in series. Assume that the coil has an internal resistance of 1.00 Ω and an inductance of 400 mH. A 2.00-μF capacitor is charged to 24.0 V and is then connected across coil. (*a*) What is the initial voltage across the coil? (*b*) How much energy is dissipated in the circuit before the oscillations die out? (*c*) What is the frequency of oscillation of the circuit? (Assume the internal resistance is sufficiently small that it has no impact on the frequency of the circuit.) (*d*) What is the quality factor of the circuit?

33 •• An inductor and a capacitor are connected, as shown in Figure 29-30. Initially, the switch is open, and the left plate of the capacitor has charge Q_0. The switch is then closed. (*a*) Plot both Q versus t and I versus t on the same graph, and explain how it can be seen from these two plots that the current leads the charge by 90°. (*b*) The expressions for the charge and for the current are given by Equations 29-38 and 29-39, respectively. Use trigonometry and algebra to show that the current leads the charge by 90°. SSM

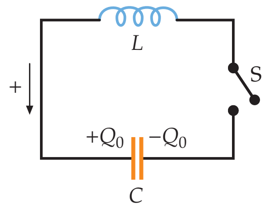

FIGURE 29-30 Problem 33

DRIVEN *RL* CIRCUITS

34 •• A circuit consists of a resistor, an ideal 1.4-H inductor, and an ideal 60-Hz generator, all connected in series. The rms voltage across the resistor is 30 V and the rms voltage across the inductor is 40 V. (*a*) What is the resistance of the resistor? (*b*) What is the peak emf of the generator?

35 •• A coil that has a resistance of 80.0 Ω has an impedance of 200 Ω when driven at a frequency of 1.00 kHz. What is the inductance of the coil? SSM

36 •• **Engineering Application** A two-conductor transmission line simultaneously carries a superposition of two voltage signals, so the potential difference between the two conductors is given by $V = V_1 + V_2$, where $V_1 = (10.0\text{ V})\cos(\omega_1 t)$ and $V_2 = (10.0\text{ V})\cos(\omega_2 t)$, where $\omega_1 = 100$ rad/s and $\omega_2 = 10\,000$ rad/s. A 1.00-H inductor and a 1.00-kΩ shunt resistor are inserted into the transmission line as shown in Figure 29-31. (Assume that the output is connected to a load that draws only an insignificant amount of current.) (*a*) What is the voltage (V_{out}) at the output of the transmission line? (*b*) What is the ratio of the low-frequency amplitude to the high-frequency amplitude at the output?

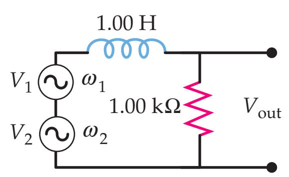

FIGURE 29-31 Problem 36

37 •• A coil is connected to a 120-V-rms, 60-Hz line. The average power supplied to the coil is 60 W, and the rms current is 1.5 A. Find (*a*) the power factor, (*b*) the resistance of the coil, and (*c*) the inductance of the coil. (*d*) Does the current lag or lead the voltage? Explain your answer. (*e*) Support your answer to Part (*d*) by determining the phase angle.

38 •• A 36-mH inductor that has a resistance of 40 Ω is connected to an ideal ac voltage source whose output is given by $\mathcal{E} = (345\text{ V})\cos(150\pi t)$, where t is in seconds. Determine (*a*) the peak current in the circuit, (*b*) the peak and rms voltages across the inductor, (*c*) the average power dissipation, and (*d*) the peak and average magnetic energy stored in the inductor.

39 •• A coil that has a resistance R and an inductance L has a power factor equal to 0.866 when driven at a frequency of 60 Hz. What is the coil's power factor if it is driven at 240 Hz? SSM

40 •• A resistor and an inductor are connected in parallel across an ideal ac voltage source whose output is given by $\mathcal{E} = \mathcal{E}_{max}\cos\omega t$ as shown in Figure 29-32. Show that (*a*) the current in the resistor is given by $I_R = (\mathcal{E}_{peak}/R)\cos\omega t$, (*b*) the current in the inductor is given by $I_L = (\mathcal{E}_{peak}/X_L)\cos(\omega t - 90°)$, and (*c*) the current in the voltage source is given by $I = I_R + I_L = I_{peak}\cos(\omega t - \delta)$, where $I_{peak} = \mathcal{E}_{peak}/Z$.

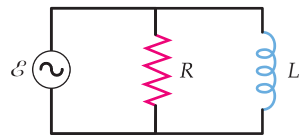

FIGURE 29-32 Problem 40

41 •• Figure 29-33 shows a load resistor that has a resistance of $R_L = 20.0\ \Omega$ connected to a high-pass filter consisting of an inductor that has an inductance $L = 3.20$-mH inductor and a resistor that has resistance $R = 4.00\ \Omega$. The output of the ideal ac generator is given by $\mathcal{E} = (100\text{ V})\cos(2\pi f t)$. Find the rms currents in all three branches of the circuit if the driving frequency is (*a*) 500 Hz and (*b*) 2000 Hz. Find the fraction of the total average power supplied by the ac generator that is delivered to the load resistor if the frequency is (*c*) 500 Hz and (*d*) 2000 Hz. SSM

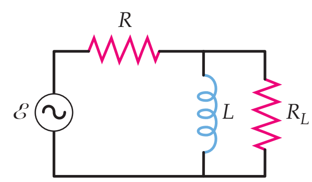

FIGURE 29-33 Problem 41

42 •• An ideal ac voltage source whose emf $\mathcal{E}_1$ is given by $(20\text{ V})\cos(2\pi f t)$ and an ideal battery whose emf $\mathcal{E}_2$ is 16 V are connected to a combination of two resistors and an inductor (Figure 29-34), where $R_1 = 10\ \Omega$, $R_2 = 8.0\ \Omega$, and $L = 6.0$ mH. Find the average power delivered to each resistor if the driving frequency is (*a*) 100 Hz, (*b*) 200 Hz, and (*c*) 800 Hz.

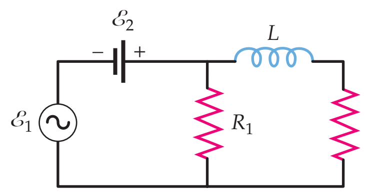

FIGURE 29-34 Problem 42

43 •• An ac circuit contains a resistor and an ideal inductor connected in series. The rms voltage drop across the series combination is 100 V and the rms voltage drop across the inductor alone is 80 V. What is the rms voltage drop across the resistor?

FILTERS AND RECTIFIERS

44 •• **Engineering Application** The circuit shown in Figure 29-35 is called an *RC high-pass filter* because it transmits input voltage signals that have high frequencies with greater amplitude than it transmits input voltage signals that have low frequencies. If the input voltage is given by $V_{in} = V_{in\ peak}\cos\omega t$, show that the output voltage is $V_{out} = V_H\cos(\omega t - \delta)$ where $V_H = V_{in\ peak}/\sqrt{1 + (\omega RC)^{-2}}$.

(Assume that the output is connected to a load that draws only an insignificant amount of current.) Show that this result justifies calling this circuit a high-pass filter.

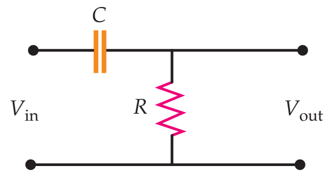

FIGURE 29-35 Problem 44

45 •• (*a*) Find an expression for the phase constant δ in Problem 44 in terms of ω, R, and C. (*b*) What is the value of δ in the limit that $\omega \to 0$? (*c*) What is the value of δ in the limit that $\omega \to \infty$? (*d*) Explain your answers to Parts (*b*) and (*c*).

46 •• **SPREADSHEET** Assume that in Problem 44, $R = 20\ \text{k}\Omega$ and $C = 15\ \text{nF}$. (*a*) At what frequency is $V_H = \frac{1}{\sqrt{2}} V_{\text{in peak}}$? That particular frequency is known as the 3-dB frequency, or $f_{3\text{dB}}$, for the circuit. (*b*) Using a spreadsheet program, make a graph of $\log_{10}(V_H)$ versus $\log_{10}(f)$, where f is the frequency. Make sure that the scale extends from at least 10% of the 3-dB frequency to ten times the 3-dB frequency. (*c*) Make a graph of δ versus $\log_{10}(f)$ for the same range of frequencies as in Part (*b*). What is the value of the phase constant when the frequency is equal to the 3-dB frequency?

47 •• A slowly varying voltage signal $V(t)$ is applied to the input of the high-pass filter of Problem 44. Slowly varying means that during one time constant (equal to RC) there is no significant change in the voltage signal. Show that under those conditions the output voltage is proportional to the time derivative of $V(t)$. This situation is known as a *differentiation circuit*. SSM

48 •• We can describe the output from the high-pass filter from Problem 44 using a decibel scale: $\beta = (20\ \text{dB})\log_{10}(V_H/V_{\text{in peak}})$, where β is the output in decibels. Show that for $V_H = \frac{1}{\sqrt{2}} V_{\text{in peak}}$, $\beta = 3.0\ \text{dB}$. The frequency at which $V_H = \frac{1}{\sqrt{2}} V_{\text{in peak}}$ is known as $f_{3\text{dB}}$ (the 3-dB frequency). Show that for $f \ll f_{3\text{dB}}$, the output β drops by 6 dB if the frequency f is halved.

49 •• Show that the average power dissipated in the resistor of the high-pass filter of Problem 44 is given by

$$P_{av} = \frac{V^2_{\text{in peak}}}{2R[1 + (\omega RC)^{-2}]}.$$ SSM

50 •• One application of the high-pass filter of Problem 44 is as a noise filter for electronic circuits (a filter that blocks out low-frequency noise). Using a resistance value of 20 kΩ, find a value for the capacitance for the high-pass filter that attenuates a 60-Hz input voltage signal by a factor of 10, that is, so $V_H = \frac{1}{10} V_{\text{in peak}}$.

51 •• **ENGINEERING APPLICATION** The circuit shown in Figure 29-36 is an example of a low-pass filter. (Assume that the output is connected to a load that draws only an insignificant amount of current.) (*a*) If the input voltage is given by $V_{in} = V_{\text{in peak}} \cos \omega t$, show that the output voltage is $V_{out} = V_L \cos(\omega t - \delta)$ where $V_L = V_{\text{in peak}}/\sqrt{1 + (\omega RC)^2}$. (*b*) Discuss the trend of the output voltage in the limiting cases $\omega \to 0$ and $\omega \to \infty$. SSM

52 •• (*a*) Find an expression for the phase angle δ for the low-pass filter of Problem 51 in terms of ω, R, and C. (*b*) Find the value of δ in the limit that $\omega \to 0$ and in the limit that $\omega \to \infty$. Explain your answer.

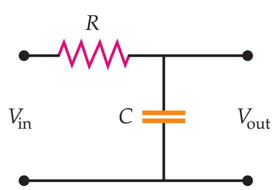

FIGURE 29-36 Problems 51 and 52

53 •• **SPREADSHEET** Using a spreadsheet program, make a graph of V_L versus input frequency f and a graph of phase angle δ versus input frequency for the low-pass filter of Problems 51 and 52. Use a resistance value of 10 kΩ and a capacitance value of 5.0 nF.

54 ••• A rapidly varying voltage signal $V(t)$ is applied to the input of the low-pass filter of Problem 51. Rapidly varying means that during one time constant (equal to RC) there are significant changes in the voltage signal. Show that under those conditions the output voltage is proportional to the integral of $V(t)$ with respect to time. This situation is known as an *integration circuit*.

55 ••• **ENGINEERING APPLICATION** The circuit shown in Figure 29-37 is a *trap filter*. (Assume that the output is connected to a load that draws only an insignificant amount of current.) (*a*) Show that the *trap filter* acts to reject signals in a band of frequencies centered at $\omega = 1/\sqrt{LC}$. (*b*) How does the width of the frequency band rejected depend on the resistance R? SSM

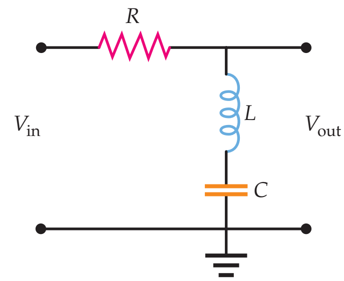

FIGURE 29-37 Problem 55

56 ••• **ENGINEERING APPLICATION** A half-wave rectifier for transforming an ac voltage into a dc voltage is shown in Figure 29-38. The diode in the figure can be thought of as a one-way valve for current. It allows current to pass in the forward direction (the direction of the arrowhead) only when V_{in} is at a higher electric potential than V_{out} by 0.60 V (i.e., whenever $V_{in} - V_{out} \geq +0.60$ V). The resistance of the diode is effectively infinite when $V_{in} - V_{out}$ is less than +0.60 V. Plot two cycles of both input and output voltages as a function of time, on the same graph, assuming the input voltage is given by $V_{in} = V_{\text{in peak}} \cos \omega t$.

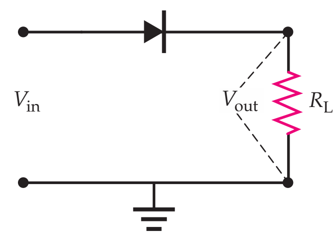

FIGURE 29-38 Problem 56

57 ••• **ENGINEERING APPLICATION** The output of the rectifier of Problem 56 can be further filtered by putting its output through a low-pass filter as shown in Figure 29-39*a*. The resulting output is a dc voltage with a small ac component (ripple) shown in Figure 29-39*b*. If the input frequency is 60 Hz and the load resistance is 1.00 kΩ, find the value for the capacitance so that the output voltage varies by less than 50 percent of the mean value over one cycle.

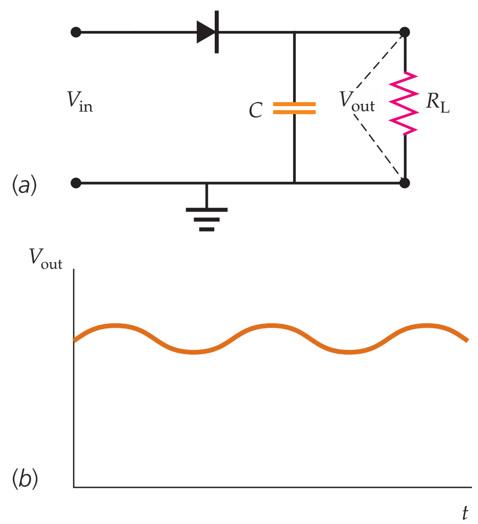

FIGURE 29-39 Problem 57

DRIVEN *LC* CIRCUITS

58 •• The generator voltage in Figure 29-40 is given by $\mathcal{E} = (100\ \text{V})\cos(2\pi ft)$. (*a*) For each branch, what is the peak current and what is the phase of the current relative to the phase of the generator voltage? (*b*) At the resonance frequency there is no current in the generator. What is the angular frequency at resonance? (*c*) At the resonance frequency, find the current in the inductor and the current in the capacitor. Express your results as functions of time. (*d*) Draw a phasor diagram showing the phasors for the applied voltage, the generator current, the capacitor current, and the inductor current for the case where the frequency is higher than the resonance frequency.

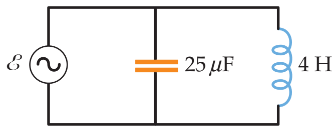

FIGURE 29-40 Problem 58

59 •• A circuit consists of an ideal ac generator, a capacitor, and an ideal inductor, all connected in series. The charge on the capacitor is given by $Q = (15\ \mu\text{C})\cos(\omega t + \frac{\pi}{4})$, where $\omega = 1250$ rad/s. (*a*) Find the current in the circuit as a function of time. (*b*) Find the capacitance if the inductance is 28 mH. (*c*) Write expressions for the electrical energy U_e, the magnetic energy U_m, and the total energy U as functions of time.

60 ••• **Engineering Application** One method for determining the compressibility of a dielectric material uses a driven *LC* circuit that has a parallel-plate capacitor. The dielectric is inserted between the plates and the change in resonance frequency is determined as the capacitor plates are subjected to a compressive stress. In one such arrangement, the resonance frequency is 120 MHz when a dielectric of thickness 0.100 cm and dielectric constant $\kappa = 6.80$ is placed between the plates. Under a compressive stress of 800 atm, the resonance frequency decreases to 116 MHz. Find the Young's modulus of the dielectric material. (Assume that the dielectric constant does not change with pressure.)

61 ••• Figure 29-41 shows an inductor in series with a parallel-plate capacitor. The capacitor has a width w of 20 cm and a gap of 2.0 mm. A dielectric that has a dielectric constant of 4.8 can be slid in and out of the gap. The inductor has an inductance of 2.0 mH. When half the dielectric is between the capacitor plates (when $x = \frac{1}{2}w$), the resonant frequency of this combination is 90 MHz. (*a*) What is the capacitance of the capacitor without the dielectric? (*b*) Find the resonance frequency as a function of x for $0 \le x \le w$.

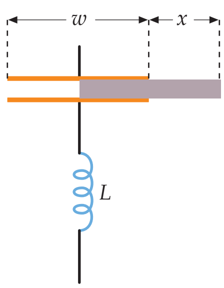

FIGURE 29-41 Problem 61

DRIVEN *RLC* CIRCUITS

62 • A circuit consists of an ideal ac generator, a 20-μF capacitor, and an 80-Ω resistor, all connected in series. The output of the generator has a peak emf of 20 V, and the armature of the generator rotates at 400 rad/s. Find (*a*) the power factor, (*b*) the rms current, and (*c*) the average power supplied by the generator.

63 •• Show that the expression $P_{av} = R\mathcal{E}_{rms}^2/Z^2$ gives the correct result for a circuit containing only an ideal ac generator and (*a*) a resistor, (*b*) a capacitor, and (*c*) an inductor. In the expression $P_{av} = R\mathcal{E}_{rms}^2/Z^2$, P_{av} is the average power supplied by the generator, $\mathcal{E}_{rms}$ is the root-mean-square value of the emf of the generator, R is the resistance, C is the capacitance, and L is the inductance. [In Part (*a*), $C = L = 0$; in Part (*b*), $R = L = 0$; and in Part (*c*), $R = C = 0$.] SSM

64 •• A series *RLC* circuit that has an inductance of 10 mH, a capacitance of 2.0 μF, and a resistance of 5.0 Ω is driven by an ideal ac voltage source that has a peak emf of 100 V. Find (*a*) the resonant frequency and (*b*) the root-mean-square current at resonance. When the frequency is 8000 rad/s, find (*c*) the capacitive and inductive reactances, (*d*) the impedance, (*e*) the root-mean-square current, and (*f*) the phase angle.

65 •• Find (*a*) the Q factor and (*b*) the resonance width (in hertz) for the circuit in Problem 64. (*c*) What is the power factor when $\omega = 8000$ rad/s? SSM

66 •• **Engineering Application** FM radio stations typically operate at frequencies separated by 0.20 MHz. Thus, when your radio is tuned to a station operating at a frequency of 100.1 MHz, the resonance width of the receiver circuit should be much smaller than 0.20 MHz, so that you do not receive signal from stations operating at adjacent frequencies. Assume your receiving circuit has a resonance width of 0.050 MHz. When tuned in to that particular station, what is the Q factor of your circuit?

67 •• A coil is connected to a 60-Hz ac generator with a peak emf equal to 100 V. At this frequency, the coil has an impedance of 10 Ω and a reactance of 8.0 Ω. (*a*) What is the peak current in the coil? (*b*) What is the phase angle between the current and the applied voltage? (*c*) A capacitor is put in series with the coil and the generator. What capacitance is required so that the current is in phase with the generator emf? (*d*) What is the peak voltage measured across the capacitor?

68 •• An ideal 0.25-H inductor and a capacitor are connected in series with an ideal 60-Hz generator. A digital voltmeter is used to measure the rms voltages across the inductor and capacitor independently. The voltmeter reading across the capacitor is 75 V and that across the inductor is 50 V. (*a*) Find the capacitance and the rms current in the circuit. (*b*) What is the rms voltage across the series combination of the capacitor and the inductor?

69 •• In the circuit shown in Figure 29-42 the ideal generator produces an rms voltage of 115 V when operated at 60 Hz. What is the rms voltage between points (*a*) A and B, (*b*) B and C, (*c*) C and D, (*d*) A and C, and (*e*) B and D? SSM

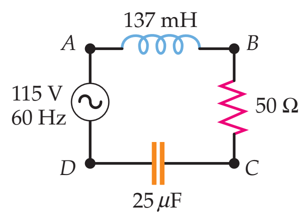

FIGURE 29-42 Problem 69

70 •• When an *RLC* series circuit is connected to a 120-V-rms, 60-Hz line, the rms current in the circuit is 11 A and the current leads the line voltage by 45°. (*a*) Find the average power supplied to the circuit. (*b*) What is the resistance in the circuit? (*c*) If the inductance in the circuit is 50 mH, find the capacitance in the circuit. (*d*) Without changing the inductance, by how much should you change the capacitance to make the power factor equal to 1? (*e*) Without changing the capacitance, by how much should you change the inductance to make the power factor equal to 1?

71 •• **Spreadsheet** Plot the circuit impedance versus the angular frequency for each of the following circuits: (*a*) a driven series *LR* circuit, (*b*) a driven series *RC* circuit, and (*c*) a driven series *RLC* circuit.

72 •• In a driven series *RLC* circuit, the ideal generator has a peak emf equal to 200 V, the resistance is 60.0 Ω, and the capacitance is 8.00 μF. The inductance can be varied from 8.00 mH to 40.0 mH by the insertion of an iron core in the solenoid. The angular frequency of the generator is 2500 rad/s. If the capacitor voltage is not to exceed 150 V, find (*a*) the peak current and (*b*) the range of inductances that is safe to use.

73 •• A certain electrical device draws an rms current of 10 A at an average power of 720 W when connected to a 120-V-rms, 60-Hz power line. (*a*) What is the impedance of the device? (*b*) What series combination of resistance and reactance would have the same impedance as this device? (*c*) If the current leads the emf, is the reactance inductive or capacitive?

74 •• A method for measuring inductance is to connect the inductor in series with a known capacitance, a known resistance, an ac ammeter, and a variable-frequency signal generator. The frequency of the signal generator is varied and the emf is kept constant until the current is maximum. (*a*) If the capacitance is 10 μF, the peak emf is 10 V, the resistance is 100 Ω, and the rms current in the circuit is maximum when the driving frequency is 5000 rad/s, what is the value of the inductance? (*b*) What is the maximum rms current?

75 •• A resistor and a capacitor are connected in parallel across an ac generator (Figure 29-43) that has an emf given by $\mathcal{E} = \mathcal{E}_{peak} \cos \omega t$. (*a*) Show that the current in the resistor is given by $I_R = (\mathcal{E}_{peak}/R) \cos \omega t$. (*b*) Show that the current in the capacitor branch is given by $I_C = (\mathcal{E}_{peak}/X_C) \cos(\omega t + 90°)$. (*c*) Show that the current in the generator is given by $I = I_{peak} \cos(\omega t + \delta)$, where $\tan \delta = R/X_C$ and $I_{peak} = \mathcal{E}_{peak}/Z$.

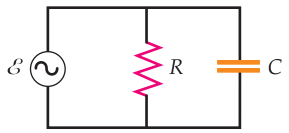

FIGURE 29-43 Problem 75

76 ••• Figure 29-44 shows a plot of average power P_{av} versus generator frequency ω for a series *RLC* circuit driven by an ac generator. The average power P_{av} is given by Equation 29-56. The full width at half-maximum, $\Delta\omega$, is the width of the resonance curve between the two points, where P_{av} is one-half its maximum value. Show that for a sharply peaked resonance, $\Delta\omega \approx R/L$ and that $Q_{factor} \approx \omega_0/\Delta\omega$ (Equation 29-58). *Hint: The half-power points occur when the denominator of Equation 29-56 is equal to twice the value it has at resonance; that is, when* $L^2(\omega^2 - \omega_0^2)^2 + \omega^2R^2 \approx +\omega_0^2R^2$. *Let* ω_1 *and* ω_2 *be the solutions of this equation. Then, show that* $\Delta\omega = \omega_2 - \omega_1 \approx R/L$.

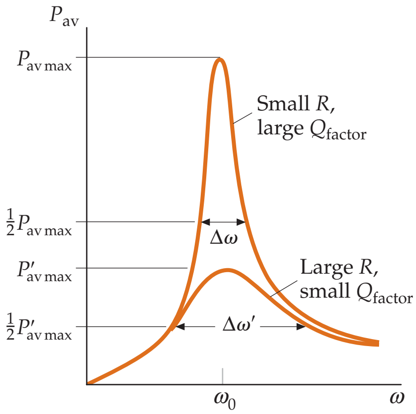

FIGURE 29-44 Problem 76

77 ••• Show by direct substitution that $L\frac{d^2Q}{dt^2} + R\frac{dQ}{dt} + \frac{1}{C}Q = 0$ (Equation 29-43*b*) is satisfied by $Q = Q_0 e^{-t/\tau} \cos \omega' t$, where $\tau = 2L/R$, $\omega' = \sqrt{1/(LC) - 1/\tau^2}$, and Q_0 is the charge on the capacitor at $t = 0$.

78 ••• **Engineering Application** One method for measuring the magnetic susceptibility of a sample uses an *LC* circuit consisting of an air-core solenoid and a capacitor. The resonant frequency of the circuit without the sample is determined and then measured again with the sample inserted in the solenoid. Suppose you have a solenoid that is 4.00 cm long, is 3.00 mm in diameter, and has 400 turns of fine wire. You have a sample that is inserted in the solenoid and completely fills the air space. Neglect end effects. (*a*) Calculate the inductance of the empty solenoid. (*b*) What value for the capacitance of the capacitor should you choose so that the resonance frequency of the circuit without a sample is exactly 6.0000 MHz? (*c*) When a sample is inserted in the solenoid, you determine that the resonance frequency drops to 5.9989 MHz. Use your data to determine the sample's susceptibility.

*THE TRANSFORMER

79 • A rms voltage of 24 V is required for a device whose impedance is 12 Ω. (*a*) What should the turns ratio of a transformer be, so that the device can be operated from a 120-V-rms line? (*b*) Suppose the transformer is accidentally connected in reverse with the secondary winding across the 120-V-rms line and the 12-Ω load across the primary. How much rms current will then be in the primary winding? SSM

80 • A transformer has 400 turns in the primary and 8 turns in the secondary. (*a*) Is this a step-up or a step-down transformer? (*b*) If the primary is connected to a 120-V-rms voltage source, what is the open-circuit rms voltage across the secondary? (*c*) If the primary rms current is 0.100 A, what is the secondary rms current, assuming negligible magnetization current and no power loss?

81 • The primary of a step-down transformer has 250 turns and is connected to a 120-V-rms line. The secondary is to supply 20 A rms at 9.0 V rms. Find (*a*) the rms current in the primary and (*b*) the number of turns in the secondary, assuming 100 percent efficiency.

82 •• An audio oscillator (ac source) that has an internal resistance of 2000 Ω and an open-circuit rms output voltage of 12.0 V is to be used to drive a loudspeaker coil that has a resistance of 8.00 Ω. (*a*) What should be the ratio of primary to secondary turns of a transformer so that maximum average power is transferred to the speaker? (*b*) Suppose a second identical speaker is connected in parallel with the first speaker. How much average power is then supplied to the two speakers combined?

83 • The distribution circuit of a residential power line is operated at 2000 V rms. This voltage must be reduced to 240 V rms for use within residences. If the secondary side of the transformer has 400 turns, how many turns are in the primary?

GENERAL PROBLEMS

84 •• A resistor that has a resistance R carries a current given by $(5.0\text{ A}) \sin 2\pi f t + (7.0\text{ A}) \sin 4\pi f t$, where $f = 60$ Hz. (*a*) What is the rms current in the resistor? (*b*) If $R = 12\ \Omega$, what is the average power delivered to the resistor? (*c*) What is the rms voltage across the resistor?

85 •• Figure 29-45 shows the voltage versus time for a *square-wave* voltage source. If $V_0 = 12$ V, (*a*) what is the rms voltage of this source? (*b*) If this alternating waveform is rectified by eliminating the negative voltages, so that only the positive voltages remain, what is the new rms voltage? SSM

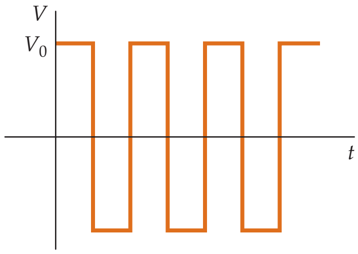

FIGURE 29-45 Problem 85

86 •• What are the average values and rms values of current for the two current waveforms shown in Figure 29-46?

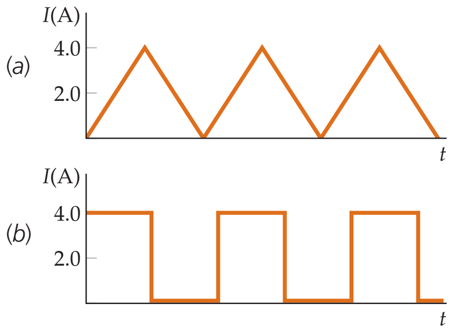

FIGURE 29-46 Problem 86

87 •• In the circuit shown in Figure 29-47, $\mathcal{E}_1 = (20\text{ V})\cos 2\pi f t$, where $f = 180$ Hz; $\mathcal{E}_2 = 18$ V; and $R = 36\ \Omega$. Find the maximum, minimum, average, and rms values of the current in the resistor.

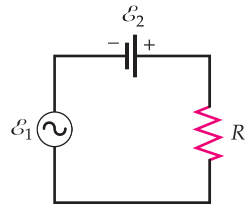

FIGURE 29-47 Problems 87, 88, and 89

88 •• Repeat Problem 87 if the resistor is replaced by a 2.0-μF capacitor.

89 ••• A circuit consists of an ac generator, a capacitor and an ideal inductor—all connected in series. The emf of the generator is given by $\mathcal{E}_{\text{peak}} \cos \omega t$. (a) Show that the charge on the capacitor obeys the equation $L\dfrac{d^2Q}{dt^2} + \dfrac{Q}{C} = \mathcal{E}_{\text{peak}} \cos \omega t$. (*b*) Show by direct substitution that this equation is satisfied by $Q = Q_{\text{peak}} \cos \omega t$ where $Q_{\text{peak}} = -\dfrac{\mathcal{E}_{\text{peak}}}{L(\omega^2 - \omega_0^2)}$. (*c*) Show that the current can be written as $I = I_{\text{peak}} \cos(\omega t - \delta)$, where $I_{\text{peak}} = \dfrac{\omega \mathcal{E}_{\text{peak}}}{L|\omega^2 - \omega_0^2|} = \dfrac{\mathcal{E}_{\text{peak}}}{|X_L - X_C|}$, $\delta = -90°$ for $\omega < \omega_0$, and $\delta = 90°$ for $\omega > \omega_0$, where ω_0 is the resonance frequency. SSM

CHAPTER 30

SET ACROSS THE DESERT NEAR SOCORRO, NEW MEXICO, THE NATIONAL RADIO ASTRONOMY OBSERVATORY'S VERY LARGE ARRAY IS A SYSTEM OF 27 RADIO ANTENNAS SET IN A Y-SHAPED CONFIGURATION. BECAUSE THE INFORMATION GATHERED FROM THE ARRAY IS COMBINED ELECTRONICALLY, THE INSTRUMENT HAS A RESOLUTION THAT IS 22 MILES WIDE. *(NRAO/AUI.)*

Maxwell's Equations and Electromagnetic Waves

? Did you ever wonder whether a radio antenna generates a wave equally in all directions?

(See Example 30-5.)

Maxwell's equations, first proposed by the great Scottish physicist James Clerk Maxwell, relate the electric and magnetic field vectors $\vec{E}$ and $\vec{B}$ and their sources, which are electric charges and currents. These equations summarize the experimental laws of electricity and magnetism—the laws of Coulomb, Gauss, Biot–Savart, Ampère, and Faraday. These experimental laws hold in general except for Ampère´s law, which applies only to steady continuous currents.

In this chapter, we will see how Maxwell was able to generalize Ampère's law with the invention of the displacement current (Section 30-1). Maxwell was then able to show that the generalized laws of electricity and magnetism imply the existence of electromagnetic waves.

30-1 MAXWELL'S DISPLACEMENT CURRENT

Maxwell's equations play a role in classical electromagnetism analogous to the role of Newton's laws in classical mechanics. In principle, all problems in classical electricity and magnetism can be solved using Maxwell's equations, just as all problems in classical mechanics can be solved by using Newton's laws. Maxwell's equations are considerably more complicated than Newton's laws, however, and their application to most problems involves mathematics beyond the scope of this book. Nevertheless, Maxwell's equations are of great theoretical importance. For example, Maxwell showed that these equations can be combined to yield a wave equation for the electric and magnetic field vectors $\vec{E}$ and $\vec{B}$. Such **electromagnetic waves** are generated by accelerating charges (for example, the charges in an alternating current in an antenna). Electromagnetic waves were first produced in the laboratory by Heinrich Hertz in 1887. Maxwell showed that his equations predicted the speed of electromagnetic waves in free space to be

$$c = \frac{1}{\sqrt{\mu_0 \epsilon_0}} \qquad 30\text{-}1$$

THE SPEED OF ELECTROMAGNETIC WAVES

where ϵ_0, the electric constant, is the constant appearing in Coulomb's and Gauss's laws and μ_0, the magnetic constant, is the constant appearing in the Biot–Savart law and Ampère's law. Maxwell noticed with great excitement the coincidence that the measure for the speed of light equaled $1/\sqrt{\mu_0\epsilon_0}$, and Maxwell correctly surmised that light itself is an electromagnetic wave. Today, the value of c is defined as $2.997\,924\,58 \times 10^8$ m/s, the value of μ_0 is defined as $4\pi \times 10^{-7}$ N/A^2, and the value of ϵ_0 is defined by Equation 30-1.

Ampère's law (Equation 27-16) relates the line integral of the magnetic field around some closed curve C to the current that passes through any surface bounded by that curve:

$$\oint_C \vec{B} \cdot d\vec{\ell} = \mu_0 I_S \qquad \text{for any closed curve } C \qquad 30\text{-}2$$

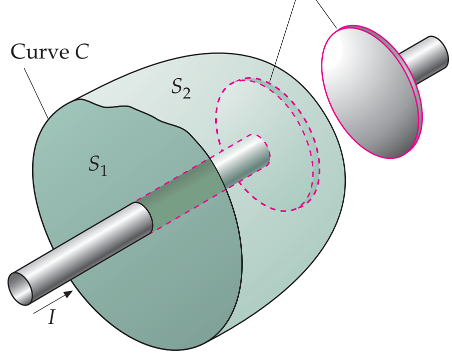

FIGURE 30-1 Two surfaces S_1 and S_2 bounded by the same curve C. The current I passes through surface S_1 but not through surface S_2. Ampère's law, which relates the line integral of the magnetic field around the curve C to the total current passing through any surface bounded by C, is not valid when the current is not continuous, as when it stops at the capacitor plate here.

Maxwell recognized a flaw in Ampère's law. Figure 30-1 shows two different surfaces, S_1 and S_2, bounded by the same curve C, which encircles a current carrying wire that is connected to a capacitor plate. The current through surface S_1 is I, but no current exists through surface S_2 because the charge stops on the capacitor plate. Thus, ambiguity exists in the phrase "the current through any surface bounded by the curve." Such a problem arises when the current is not continuous.

Maxwell showed that the law can be generalized to include all situations if the current I in the equation is replaced by the sum of the current I and another term I_d, called **Maxwell's displacement current,** defined as

$$I_d = \epsilon_0 \frac{d\phi_e}{dt} \qquad 30\text{-}3$$

DEFINITION—DISPLACEMENT CURRENT

where ϕ_e is the flux of the electric field through the same surface bounded by the curve C. The generalized form of Ampère's law is then

$$\oint_C \vec{B} \cdot d\vec{\ell} = \mu_0(I + I_d) = \mu_0 I + \mu_0\epsilon_0 \frac{d\phi_e}{dt} \qquad 30\text{-}4$$

GENERALIZED FORM OF AMPÈRE'S LAW

We can understand this generalization by considering Figure 30-1 again. Let us call the sum $I + I_d$* the generalized current. According to the argument just stated, the same generalized current must cross any surface bounded by the curve C. The surfaces S_1 and S_2 together form a single closed surface. Thus, the sum of the generalized currents into the region enclosed by the two surfaces S_1 and S_2, is equal to the sum of the generalized currents out of the region. If a net current I into the enclosed region exists, an equal net displacement current I_d out of the enclosed region must exist. In the enclosed region in the figure, a net current I into the region exists that increases the charge Q_{inside} within the region:

$$I = \frac{dQ_{\text{inside}}}{dt}$$

The net flux of the electric field out of the enclosed region is related to the charge enclosed by Gauss's law:

$$\phi_{\text{e net}} = \oint_S E_n \, dA = \frac{1}{\epsilon_0} Q_{\text{inside}}$$

Solving for the charge gives

$$Q_{\text{inside}} = \epsilon_0 \phi_{\text{e net}}$$

and taking the derivative of each side gives

$$\frac{dQ_{\text{inside}}}{dt} = \epsilon_0 \frac{d\phi_{\text{e net}}}{dt}$$

The rate of increase of the enclosed charge is thus proportional to the rate of increase of the net flux of the electric field out of the region:

$$\frac{dQ_{\text{inside}}}{dt} = \epsilon_0 \frac{d\phi_{\text{e net}}}{dt} = I_d$$

Thus, the net current into the volume equals the net displacement current out of the volume. The generalized current is thus continuous, and this is *always* the case.

It is interesting to compare Equation 30-4 to Equation 28-6:

$$\mathcal{E} = \oint_C \vec{E} \cdot d\vec{\ell} = -\frac{d\phi_m}{dt} = -\int_S \frac{\partial B_n}{\partial t} \, dA \qquad 30\text{-}5$$

FARADAY'S LAW

which in this chapter will be referred to as Faraday's law. (Equation 30-5 is a restricted form of Faraday's law, a form that does include emfs associated with time-varying magnetic fields, but does not include emfs associated with moving conductors.) According to Faraday's law, a changing magnetic flux produces an electric field whose line integral around a closed curve is proportional to the rate of change of magnetic flux through any surface bounded by the curve. Maxwell's modification of Ampère's law shows that a changing electric flux produces a magnetic field whose line integral around a curve is proportional to the rate of change of the electric flux. We thus have the interesting reciprocal result that a changing magnetic field produces an electric field (Faraday's law) and a changing electric field produces a magnetic field (generalized form of Ampère's law). Note, no magnetic analog of a current I exists. This is consistent with the observation that the magnetic monopole, the magnetic analog of an electric charge, does not exist.†

* In more advanced treatments, the generalized current is taken as the sum of a conduction current and a displacement current, where the conduction current is attributed to the motion of free (delocalized) charge carriers, and the displacement current is what is referred to in this book as the displacement current and a term associated with the motion of bound (localized) charge carriers.

† The question of the existence of magnetic monopoles has theoretical importance. Numerous attempts to observe magnetic monopoles have been made but to date no one has been unambiguously successful.

Example 30-1 Calculating Displacement Current

A parallel-plate capacitor has closely spaced circular plates of radius R. The current I in the wires connected to the plates is 2.5 A, as shown in Figure 30-2. Compute the displacement current I_d through surface S passing between the plates by directly computing the rate of change of the flux of $\vec{E}$ through surface S.

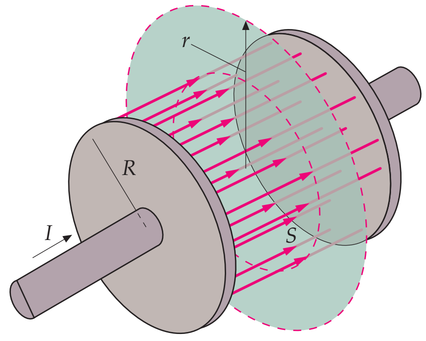

FIGURE 30-2 The surface S between the capacitor plates is penetrated by electric field lines. The charge Q on the positively charged plate is increasing at 2.5 C/s = 2.5 A. The distance between the plates is not drawn to scale. The plates are much closer together than the plates shown in the figure.

PICTURE The displacement current is $I_d = \epsilon_0\, d\phi_e/dt$, where ϕ_e is the electric flux through the surface between the plates. Because the parallel plates are closely spaced, the electric field in the region between the plates is uniform and perpendicular to the plates. Outside the region between the plates the electric field is negligible. Thus, the electric flux is simply $\phi_e = EA$, where E is the electric field between the plates and A is the plate area.

SOLVE

1. The displacement current is found by taking the time derivative of the electric flux: $$I_d = \epsilon_0 \frac{d\phi_e}{dt}$$
2. The flux equals the electric field magnitude multiplied by the plate area: $$\phi_e = EA$$
3. The electric field is proportional to the charge density on the plates, which we treat as uniformly distributed: $$E = \frac{\sigma}{\epsilon_0} = \frac{Q/A}{\epsilon_0}$$
4. Substitute these results to calculate I_d: $$I_d = \epsilon_0 \frac{d(EA)}{dt} = \epsilon_0 A \frac{dE}{dt} = \epsilon_0 A \frac{d}{dt}\left(\frac{Q}{A\epsilon_0}\right) = \frac{dQ}{dt} = \boxed{2.5\text{ A}}$$

CHECK The step-4 result is equal to the current in the wires, as expected.

Example 30-2 Calculating $\vec{B}$ from Displacement Current

The circular plates in Example 30-1 have a radius of $R = 3.0$ cm. Find the magnetic field strength B at a point between the plates a distance $r = 2.0$ cm from the axis through the centers of the plates when the current into the positive plate is 2.5 A.

PICTURE We find B from the generalized form of Ampère's law (Equation 30-4). We chose a circular path C of radius $r = 2.0$ cm about the centerline joining the plates, as shown in Figure 30-3. We then calculate the displacement current through the surface S bounded by C. By symmetry, $\vec{B}$ is tangent to C and has the same magnitude everywhere on C.

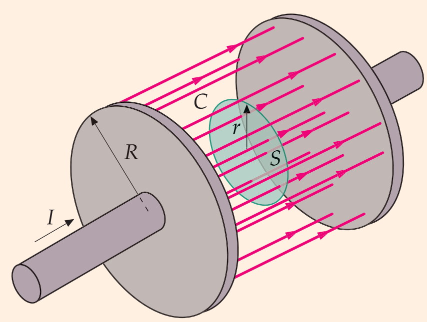

FIGURE 30-3 The distance between the plates is not drawn to scale. The plates are much closer together than they appear.

SOLVE

1. We find B from the generalized form of Ampère's law: $$\oint_C \vec{B}\cdot d\vec{\ell} = \mu_0(I + I_d)$$ where $$I_d = \epsilon_0 \frac{d\phi_e}{dt}$$
2. The line integral is B multiplied by the circumference of the circle: $$\oint_C \vec{B}\cdot d\vec{\ell} = B\cdot 2\pi r$$

3. Because no charges are moving through the surface S, $I = 0$. Thus, the generalized current through S is just the displacement current:

$$\oint_C \vec{B}\cdot d\vec{\ell} = \mu_0 I + \mu_0\epsilon_0\frac{d\phi_e}{dt}$$

$$B\cdot 2\pi r = 0 + \mu_0\epsilon_0\frac{d\phi_e}{dt}$$

4. The electric flux through S equals the product of the uniform field strength E and the area A of the flat surface S bounded by the curve C, and E is equal to σ/ϵ_0:

$$\phi_e = AE = \pi r^2 E = \pi r^2\frac{\sigma}{\epsilon_0}$$

$$= \pi r^2\frac{Q}{\epsilon_0\pi R^2} = \frac{Qr^2}{\epsilon_0 R^2}$$

5. Substitute these results into step 3 and solve for B:

$$B\cdot 2\pi r = \mu_0\epsilon_0\frac{d}{dt}\left(\frac{Qr^2}{\epsilon_0 R^2}\right) = \mu_0\frac{r^2}{R^2}\frac{dQ}{dt}$$

$$B = \frac{\mu_0}{2\pi}\frac{r}{R^2}\frac{dQ}{dt} = \frac{\mu_0}{2\pi}\frac{r}{R^2}I$$

$$= (2\times 10^{-7}\,\mathrm{T\cdot m/A})\frac{0.02\text{ m}}{(0.03\text{ m})^2}(2.5\text{ A})$$

$$= \boxed{1.11\times 10^{-5}\,\mathrm{T}}$$

30-2 MAXWELL'S EQUATIONS

Maxwell's equations are

$$\oint_S E_n\,dA = \frac{1}{\epsilon_0}Q_{\text{inside}} \qquad \text{30-6}a$$

GAUSS'S LAW

$$\oint_S B_n\,dA = 0 \qquad \text{30-6}b$$

GAUSS'S LAW FOR MAGNETISM

$$\oint_C \vec{E}\cdot d\vec{\ell} = -\frac{d}{dt}\int_S B_n\,dA = -\int_S\frac{\partial B_n}{\partial t}\,dA \qquad \text{30-6}c$$

FARADAY'S LAW

$$\oint_C \vec{B}\cdot d\vec{\ell} = \mu_0(I + I_d),\text{ where } I_d = \epsilon_0\int_S\frac{\partial E_n}{\partial t}\,dA \qquad \text{30-6}d$$

AMPÈRE'S LAW

MAXWELL'S EQUATIONS*

Gauss's law (Equation 30-6*a*) states that the flux of the electric field through any closed surface equals $1/\epsilon_0$ multiplied by the net charge inside the surface. As discussed in Chapter 22, Gauss's law implies that the electric field $\vec{E}$ due to a point charge varies inversely as the square of the distance from the charge. This law describes how electric field lines diverge from a positive charge and converge on a negative charge. Its experimental basis is Coulomb's law.

* In all four of Maxwell's equations, the integration paths C and the integration surfaces S are at rest and the integrations take place at an instant in time.

Gauss's law for magnetism (Equation 30-6*b*) states that the flux of the magnetic field $\vec{B}$ through *any* closed surface is zero. This equation describes the experimental observation that magnetic field lines do not diverge from any point in space or converge to any point in space; that is, it implies that isolated magnetic poles do not exist.

Faraday's law (Equation 30-6*c*) states that the line integral of the electric field $\vec{E}$ around any closed curve C equals the negative of the rate of change of the flux of the magnetic field $\vec{B}$ through any surface S bounded by curve C. (S is not a closed surface, so the magnetic flux through S is not necessarily zero.) Faraday's law describes how electric field lines encircle any area through which the magnetic flux is changing, and it relates the electric field vector $\vec{E}$ to the rate of change of the magnetic field vector $\vec{B}$.

Ampère's law modified to include Maxwell's displacement current (Equation 30-6*d*) states that the line integral of the magnetic field $\vec{B}$ around any closed curve C equals μ_0 multiplied by the sum of the current I through any surface S bounded by the curve and the displacement current I_d through the same surface. This law describes how the magnetic field lines encircle an area through which a current or a displacement current is passing.

In Section 30-3, we show how wave equations for both the electric field $\vec{E}$ and the magnetic field $\vec{B}$ can be derived from Maxwell's equations.

30-3 THE WAVE EQUATION FOR ELECTROMAGNETIC WAVES

In Section 15-1, we saw that waves on a string obey a partial differential equation called the **wave equation:**

$$\frac{\partial^2 y(x, t)}{\partial x^2} = \frac{1}{v^2}\frac{\partial^2 y(x, t)}{\partial t^2} \qquad \text{30-7}$$

where $y(x, t)$ is the wave function, which for string waves is the displacement of the string. The velocity of the wave is given by $v = \sqrt{F_T/\mu}$, where F_T is the tension and μ is the linear mass density. The general solution to this equation is

$$y(x, t) = y_1(x - vt) + y_2(x + vt)$$

where y_1 and y_2 are functions of $x - vt$ and $x + vt$, respectively. The general solution functions can be expressed as a superposition of harmonic wave functions of the form

$$y(x, t) = y_0 \sin(kx - \omega t) \qquad \text{and} \qquad y(x, t) = y_0 \sin(kx + \omega t)$$

where $k = 2\pi/\lambda$ is the wave number and $\omega = 2\pi f$ is the angular frequency.

Maxwell's equations imply that $\vec{E}$ and $\vec{B}$ obey wave equations similar to Equation 30-7. We consider only empty space (space in which no charges or currents exist) and we assume that the electric and magnetic fields $\vec{E}$ and $\vec{B}$ are functions of time and one space coordinate only, which we will take to be the x coordinate. Such a wave is called a **plane wave,** because $\vec{E}$ and $\vec{B}$ are uniform throughout any plane perpendicular to the x axis. For a plane electromagnetic wave traveling parallel to the x axis, the x components of the fields are zero, so the vectors $\vec{E}$ and $\vec{B}$ are perpendicular to the x axis and each obeys the wave equation:

$$\frac{\partial^2 \vec{E}}{\partial x^2} = \frac{1}{c^2}\frac{\partial^2 \vec{E}}{\partial t^2} \qquad \text{30-8}a$$

WAVE EQUATION FOR $\vec{E}$

$$\frac{\partial^2 \vec{B}}{\partial x^2} = \frac{1}{c^2}\frac{\partial^2 \vec{B}}{\partial t^2} \qquad \text{30-8}b$$

WAVE EQUATION FOR $\vec{B}$

where $c = 1/\sqrt{\mu_0 \epsilon_0}$ is the speed of the waves. (*Note:* Dimensional analysis helps in remembering these equations. For each equation, the numerators on both sides are the same and the denominators on both sides have the dimension of length squared.)

DERIVATION OF THE WAVE EQUATION

We can relate the space derivative of one of the field vectors to the time derivative of the other field vector by applying Faraday's law (Equation 30-6*c*) and the modified version of Ampère's law (Equation 30-6*d*) to appropriately chosen curves in space. We first relate the space derivative of E_y to the time derivative of B_z by applying Equation 30-6*c* (Faraday's law) to the rectangular curve of sides Δx and Δy lying in the xy plane (Figure 30-4). The circulation of $\vec{E}$ around C, for small Δx and Δy, is given by

$$\oint_C \vec{E} \cdot d\vec{\ell} = E_y(x_2)\,\Delta y - E_y(x_1)\,\Delta y = [E_y(x_2) - E_y(x_1)]\,\Delta y$$

where $E_y(x_1)$ is the value of E_y at $x = x_1$ and $E_y(x_2)$ is the value of E_y at $x = x_2$. The contributions of the type $E_x \Delta x$ from the top and bottom of this curve are zero because $E_x = 0$. Because Δx is very small (compared to the wavelength), we can approximate the difference in E_y on the left and right sides of this curve (at x_1 and at x_2) by

$$E_y(x_2) - E_y(x_1) = \Delta E_y \approx \frac{\partial E_y}{\partial x}\Delta x$$

Then

$$\oint_C \vec{E} \cdot d\vec{\ell} \approx \frac{\partial E_y}{\partial x}\Delta x\,\Delta y$$

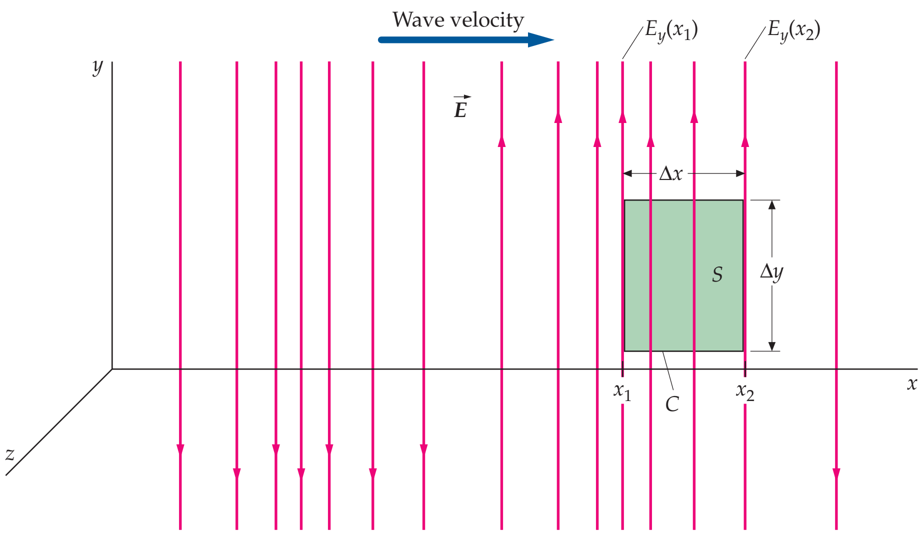

FIGURE 30-4 A rectangular curve in the xy plane for the derivation of Equation 30-9.

Faraday's law is

$$\oint_C \vec{E} \cdot d\vec{\ell} = -\int_S \frac{\partial B_n}{\partial t} dA$$

The flux of $\partial B_n/\partial t$ through the rectangular surface bounded by this curve is given by

$$\int_S B_n \, dA \approx \frac{\partial B_z}{\partial t} \Delta x \, \Delta y$$

Faraday's law then gives

$$\frac{\partial E_y}{\partial x} \Delta x \, \Delta y = -\frac{\partial B_z}{\partial t} \Delta x \, \Delta y$$

or

$$\frac{\partial E_y}{\partial x} = -\frac{\partial B_z}{\partial t} \qquad \text{30-9}$$

Equation 30-9 implies that if there is a component of the electric field E_y that depends on x, there must be a component of the magnetic field B_z that depends on time or, conversely, if there is a component of the magnetic field B_z that depends on time, there must be a component of the electric field E_y that depends on x. We can get a similar equation relating the space derivative of the magnetic field B_z to the time derivative of the electric field E_y by applying Ampère's law (Equation 30-6*d*) to the curve of sides Δx and Δz in the xz plane shown in Figure 30-5.

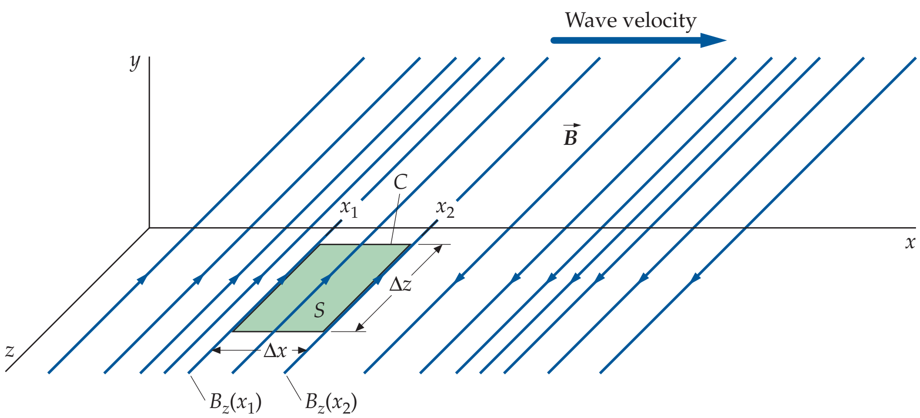

FIGURE 30-5 A rectangular curve in the $y = 0$ plane for the derivation of Equation 30-10.

For the case of no currents ($I = 0$), Equation 30-6*d* is

$$\oint_C \vec{B} \cdot d\vec{\ell} = \mu_0 \epsilon_0 \int_S \frac{\partial E_n}{\partial t} dA$$

The details of this calculation are similar to those for Equation 30-9. The result is

$$\frac{\partial B_z}{\partial x} = -\mu_0 \epsilon_0 \frac{\partial E_y}{\partial t} \qquad \text{30-10}$$

We can eliminate either B_z or E_y from Equations 30-9 and 30-10 by differentiating both sides of either equation with respect to either x or t. If we differentiate both sides of Equation 30-9 with respect to x, we obtain

$$\frac{\partial}{\partial x}\left(\frac{\partial E_y}{\partial x}\right) = -\frac{\partial}{\partial x}\left(\frac{\partial B_z}{\partial t}\right)$$

Interchanging the order of the time and space derivatives on the term to the right of the equal sign gives

$$\frac{\partial^2 E_y}{\partial x^2} = -\frac{\partial}{\partial t}\left(\frac{\partial B_z}{\partial x}\right)$$

Using Equation 30-10, we substitute for $\partial B_z/\partial x$ to obtain

$$\frac{\partial^2 E_y}{\partial x^2} = -\frac{\partial}{\partial t}\left(-\mu_0\epsilon_0\frac{\partial E_y}{\partial t}\right)$$

which yields the wave equation

$$\frac{\partial^2 E_y}{\partial x^2} = \mu_0\epsilon_0\frac{\partial^2 E_y}{\partial t^2} \qquad \text{30-11}$$

Comparing Equation 30-11 with Equation 30-7, we see that E_y obeys a wave equation for waves with speed $v = 1/\sqrt{\mu_0\epsilon_0}$, which is Equation 30-1.

If we had instead chosen to eliminate E_y from Equations 30-9 and 30-10 (by differentiating Equation 30-9 with respect to t, for example), we would have obtained an equation identical to Equation 30-11 except with B_z replacing E_y. We can thus see that both the electric field E_y and the magnetic field B_z obey a wave equation for waves traveling with the velocity $1/\sqrt{\mu_0\epsilon_0}$. By substituting the measured values for μ_0 and ϵ_0, Maxwell showed that the value of $1/\sqrt{\mu_0\epsilon_0}$ is equal to the measured value for speed of light.

By following the same line of reasoning as used above, and applying Equation 30-6*c* (Faraday's law) to the curve in the *xz* plane (Figure 30-5), we would obtain

$$\frac{\partial E_z}{\partial x} = \frac{\partial B_y}{\partial t} \qquad \text{30-12}$$

Similarly, the application of Equation 30-6*d* to the curve in the *xy* plane (Figure 30-4) gives

$$\frac{\partial B_y}{\partial x} = \mu_0\epsilon_0\frac{\partial E_z}{\partial t} \qquad \text{30-13}$$

We can use these results to show that, for a wave propagating in the x direction, the components E_z and B_y also obey the wave equation.

To show that the magnetic field B_z is in phase with the electric field E_y, consider the harmonic wave function of the form

$$E_y = E_0 \sin(kx - \omega t) \qquad \text{30-14}$$

If we substitute this solution into Equation 30-9, we have

$$\frac{\partial B_z}{\partial t} = -\frac{\partial E_y}{\partial x} = -kE_0\cos(kx - \omega t)$$

To solve for B_z, we take the integral of $\partial B_z/\partial t$ with respect to time. Doing so yields

$$B_z = \int\frac{\partial B_z}{\partial t}\,dt = \frac{k}{\omega}E_0\sin(kx - \omega t) + f(x) \qquad \text{30-15}$$

where $f(x)$ is an arbitrary function of x.

PRACTICE PROBLEM 30-1

Verify Equation 30-15 by showing that $\frac{\partial}{\partial t}\left[\frac{k}{\omega}E_0\sin(kx - \omega t) + f(x)\right]$ is equal to $-kE_0\cos(kx - \omega t)$.

We next substitute the solution (Equation 30-14) into Equation 30-10 and obtain

$$\frac{\partial B_z}{\partial x} = -\mu_0\epsilon_0 \frac{\partial E_y}{\partial t} = \omega\mu_0\epsilon_0 E_0 \cos(kx - \omega t)$$

Solving for B_z gives

$$B_z = \int \frac{\partial B_z}{\partial x}\,dx = \frac{\omega\mu_0\epsilon_0}{k} E_0 \sin(kx - \omega t) + g(t) \qquad 30\text{-}16$$

where $g(t)$ is an arbitrary function of time. Equating the right sides of Equations 30-15 and 30-16 gives

$$\frac{k}{\omega} E_0 \sin(kx - \omega t) + f(x) = \frac{\omega\mu_0\epsilon_0}{k} E_0 \sin(kx - \omega t) + g(t)$$

Substituting c for ω/k and $1/c^2$ for $\mu_0\epsilon_0$ gives

$$\frac{1}{c} E_0 \sin(kx - \omega t) + f(x) = \frac{1}{c} E_0 \sin(kx - \omega t) + g(t)$$

which implies $f(x) = g(t)$ for all values of x and t. These remain equal only if $f(x) = g(t) =$ constant (independent of both x and t). Thus, Equation 30-15 becomes

$$B_z = \frac{k}{\omega} E_0 \sin(kx - \omega t) + \text{constant} = B_0 \sin(kx - \omega t) \qquad 30\text{-}17$$

where $B_0 = (k/\omega)E_0 = (1/c)E_0$. The integration constant was dropped because it plays no part in the wave. It merely allows for the presence of a static uniform magnetic field. Because the electric and magnetic fields oscillate in phase and have the same frequency, we have the general result that the magnitude of the electric field is c multiplied by the magnitude of the magnetic field for an electromagnetic wave:

$$E = cB \qquad 30\text{-}18$$

The direction of propagation of an electromagnetic wave is always the direction of the vector product $\vec{E} \times \vec{B}$. For the wave described in the preceding discussion, the electric and magnetic fields are given by $\vec{E} = E_0 \sin(kx - \omega t)\hat{j}$ and $\vec{B} = B_0 \sin(kx - \omega t)\hat{k}$. Thus,

$$\vec{E} \times \vec{B} = [E_0 \sin(kx - \omega t)\hat{j}] \times [B_0 \sin(kx - \omega t)\hat{k}] = E_0 B_0 \sin^2(kx - \omega t)\hat{i}$$

The term on the right is a vector in the $+x$ direction, so we have verified that $\vec{E} \times \vec{B}$ is in the direction of propagation for this electromagnetic wave.

We see that Maxwell's equations imply wave equations 30-8*a* and 30-8*b* for the electric and magnetic fields; and that if E_y varies harmonically, as in Equation 30-14, the magnetic field B_z is in phase with E_y and has an amplitude related to the amplitude of E_y by $B_z = E_y/c$. The electric and magnetic fields are perpendicular to each other and to the direction of the wave propagation.

! The direction of propagation of an electromagnetic wave is always the direction of the vector product $\vec{E} \times \vec{B}$.

Example 30-3 $\vec{B}(x, t)$ for a Linearly Polarized Plane Wave

The expression for the electric field of a certain electromagnetic wave is given by $\vec{E}(x, t) = E_0 \sin(ky + \omega t)\hat{k}$. (*a*) What is the direction of propagation of the wave? (*b*) What is the corresponding expression for the magnetic field on the wave?

PICTURE The argument of the sine function gives the direction of propagation. $\vec{B}$ is perpendicular to both $\vec{E}$ and to the direction of propagation. $\vec{B}$ and $\vec{E}$ are in phase and $\vec{E} \times \vec{B}$ is in the direction of propagation.

SOLVE

(*a*) The argument of the sine function $(ky + \omega t)$ tells us the direction of propagation:

The direction of propagation is the $-y$ direction, which is the direction of $-\hat{j}$.

(*b*) 1. $\vec{B}$ is in phase with $\vec{E}$ and is perpendicular to both $\vec{E}$ and the direction of propagation $\hat{k}$. (That is, $\vec{B}$ is perpendicular to both $\hat{j}$ and $\hat{k}$.) This result means:

Either $\vec{B}(y, t) = +B_0 \sin(ky + \omega t)\hat{i}$ or

$\vec{B}(y, t) = -B_0 \sin(ky + \omega t)\hat{i}$

2. $\vec{E} \times \vec{B}$ is in the direction of propagation, $-\hat{j}$. Assume $\vec{B}(x, t) = +B_0 \sin(ky + \omega t)\hat{i}$ and calculate the product $\vec{E} \times \vec{B}$:

$$\begin{aligned}\vec{E} \times \vec{B} &= E_0 \sin(ky + \omega t)\hat{k} \times B_0 \sin(ky + \omega t)\hat{i}\\ &= E_0B_0 \sin^2(ky + \omega t)(\hat{k} \times \hat{i})\\ &= E_0B_0 \sin^2(ky + \omega t)\hat{j}\end{aligned}$$

3. The step-2 result contradicts the reality that the direction of propagation is the $-y$ direction. Take the cross product $\vec{E} \times \vec{B}$ with the other choice for the expression for the magnetic field:

$$\begin{aligned}\vec{E} \times \vec{B} &= E_0 \sin(ky + \omega t)\hat{k} \times (-B_0) \sin(ky + \omega t)\hat{i}\\ &= E_0(-B_0) \sin^2(ky + \omega t)(\hat{k} \times \hat{i})\\ &= -E_0B_0 \sin^2(ky + \omega t)\hat{j}\end{aligned}$$

4. The step-3 result is in the direction of propagation. The correct expression for the magnetic field is:

$$\boxed{\vec{B}(x, t) = -B_0 \sin(ky + \omega t)\hat{i}}$$

where $B_0 = E_0/c$ (Equation 30-18).

CHECK The step-4 result is perpendicular to both $\vec{E}$ and to the direction of propagation, as expected.

Example 30-4 $\vec{B}$ (*x*, *t*) for a Circular Polarized Plane Wave

The expression for the electric field of a certain electromagnetic wave is given by $\vec{E}(x, t) = E_0 \sin(kx - \omega t)\hat{j} + E_0\cos(kx - \omega t)\hat{k}$. (*a*) Find the corresponding magnetic field of the same wave. (*b*) Compute $\vec{E} \cdot \vec{B}$ and $\vec{E} \times \vec{B}$.

PICTURE We can solve this example by using the principle of superposition. The given electric field is the superposition of two fields, the one given in Equation 30-14 and the other given by $E_0 \cos(kx - \omega t)\hat{k}$.

SOLVE

(*a*) 1. From the arguments of the trigonometric functions we can see that the direction of propagation is the $+x$ direction:

The wave is traveling in the $+x$ direction.

2. The given electric field can be considered as the superposition of $\vec{E}_1 = E_0 \sin(kx - \omega t)\hat{j}$ and $\vec{E}_2 = E_0 \cos(kx - \omega t)\hat{k}$. Find the magnetic fields $\vec{B}_1$ and $\vec{B}_2$ associated with these electric fields, respectively. Use the procedure followed in Example 30-3:

For $\vec{E}_1 = E_0 \sin(kx - \omega t)\hat{j}$, $\vec{B}_1 = B_0 \sin(kx - \omega t)\hat{k}$

where $B_0 = E_0/c$ (Equation 30-18),

and

For $\vec{E}_2 = E_0 \cos(kx - \omega t)\hat{k}$, $\vec{B}_2 = -B_0 \cos(kx - \omega t)\hat{j}$

where $B_0 = E_0/c$.

3. The superposition of magnetic fields gives the resultant magnetic field:

$$\boxed{\begin{aligned}\vec{B}(x, t) &= \vec{B}_1 + \vec{B}_2\\ &= B_0 \sin(kx - \omega t)\hat{k} - B_0 \cos(kx - \omega t)\hat{j}\\ &\text{where}\\ &B_0 = E_0/c\end{aligned}}$$

(*b*) 1. Let $\theta = kx - \omega t$ to simplify the notation and calculate $\vec{E} \cdot \vec{B}$:

$$\begin{aligned}\vec{E} \cdot \vec{B} &= (E_0 \sin\theta\, \hat{j} + E_0 \cos\theta\, \hat{k}) \cdot (B_0 \sin\theta\, \hat{k} - B_0 \cos\theta\, \hat{j})\\ &= E_0B_0 \sin^2\theta\, \hat{j} \cdot \hat{k} - E_0B_0 \sin\theta \cos\theta\, \hat{j} \cdot \hat{j}\\ &\quad + E_0B_0 \cos\theta \sin\theta\, \hat{k} \cdot \hat{k} - E_0B_0 \cos^2\theta\, \hat{k} \cdot \hat{j}\\ &= 0 - E_0B_0 \sin\theta \cos\theta + E_0B_0 \cos\theta \sin\theta - 0 = \boxed{0}\end{aligned}$$

2. Calculate $\vec{E} \times \vec{B}$:

$$\begin{aligned}\vec{E} \times \vec{B} &= (E_0 \sin\theta\, \hat{j} + E_0 \cos\theta\, \hat{k}) \times (-B_0 \cos\theta\, \hat{j} + B_0 \sin\theta\, \hat{k}) \\ &= -E_0B_0 \sin\theta \cos\theta\, (\hat{j} \times \hat{j}) + E_0B_0 \sin^2\theta\, (\hat{j} \times \hat{k}) \\ &\quad - E_0B_0 \cos^2\theta\, (\hat{k} \times \hat{j}) + E_0B_0 \cos\theta \sin\theta\, (\hat{k} \times \hat{k}) \\ &= 0 + E_0B_0 \sin^2\theta\, \hat{i} + E_0B_0 \cos^2\theta\, \hat{i} + 0 = \boxed{E_0B_0\hat{i}}\end{aligned}$$

CHECK The Part (*b*), step 1 result verifies that $\vec{E}$ and $\vec{B}$ are perpendicular to one another and the the Part (*b*), step 2 result verifies that the $+x$ direction is the direction of propagation.

TAKING IT FURTHER This type of electromagnetic wave is said to be *circularly polarized*. At a fixed value of x, both $\vec{E}$ and $\vec{B}$ rotate in a circle with angular frequency ω.

PRACTICE PROBLEM 30-2 Calculate $\vec{E} \cdot \vec{E}$ and $\vec{B} \cdot \vec{B}$. Note that the fields $\vec{E}$ and $\vec{B}$ are constant in magnitude.

30-4 ELECTROMAGNETIC RADIATION

Figure 30-6 shows the electric and magnetic field vectors of an electromagnetic wave. The electric and magnetic fields are perpendicular to each other and perpendicular to the direction of propagation of the wave. Electromagnetic waves are thus transverse waves. The electric and magnetic fields are in phase and, at each point in space and at each instant in time, their magnitudes are related by

$$E = cB \qquad 30\text{-}18$$

where $c = 1/\sqrt{\mu_0\epsilon_0}$ is the speed of the wave. The direction of propagation of an electromagnetic wave is the direction of the cross product $\vec{E} \times \vec{B}$.

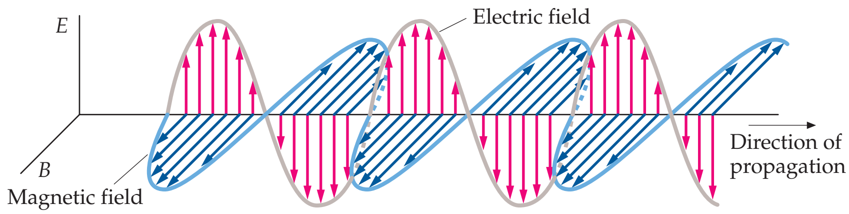

FIGURE 30-6 The electric and magnetic field vectors in an electromagnetic wave. The fields are in phase, perpendicular to each other, and perpendicular to the direction of propagation of the wave.

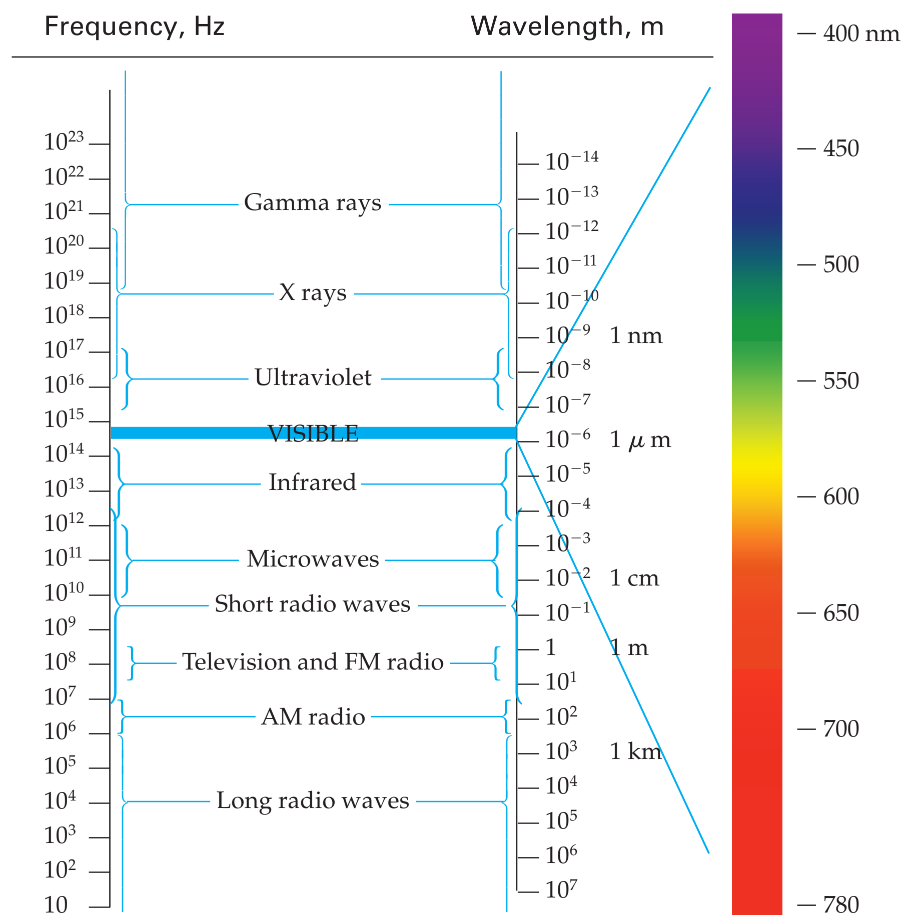
THE ELECTROMAGNETIC SPECTRUM

The various types of electromagnetic waves (for example, radio waves and gamma rays) differ only in wavelength and frequency, which are related according to the equation $f\lambda = c$. Table 30-1 lists the **electromagnetic spectrum** and the names usually associated with the various frequency and wavelength ranges. These ranges are often not well defined and sometimes overlap. For example, electromagnetic waves that have wavelengths of approximately 0.1 nm are usually called X rays, but if the electromagnetic waves originate from nuclear radioactivity, they are called gamma rays.

The human eye is sensitive to electromagnetic radiation that has wavelengths between 400 and 780 nm,* which is the range called **visible light.** The shortest wavelengths of visible light are those of violet light and the longest wavelengths are those of red light. Electromagnetic waves that have wavelengths shorter than 400 nm but longer than 10 nm (the longest wavelength in the X-rays region) are called **ultraviolet rays. Infrared waves** have wavelengths longer than 780 nm but

* Light whose wavelength is between 700 and 780 nm can only be seen under special circumstances that include the light intensity being very high.

Table 30-1 The Electromagnetic Spectrum



shorter than 100 μm. Heat radiation emitted by objects at temperatures in the range of room temperature is in the infrared region of the electromagnetic spectrum. There are no limits on the wavelengths of electromagnetic radiation; that is, all wavelengths (or frequencies) are theoretically possible.

The differences in wavelengths of the various kinds of electromagnetic waves have important physical consequences. As you know, the behavior of waves depends strongly on the relative sizes of the wavelengths and the objects or apertures (openings) the waves encounter. Because the wavelengths of visible light are in the rather narrow range between 400 and 780 nm, they are much smaller than most obstacles. Thus, the ray approximation (introduced in Section 15-4) is often valid. The wavelength and frequency are also important in determining the kinds of interactions between electromagnetic waves and matter. X rays, for example, have very short wavelengths and high frequencies. They easily penetrate many materials that are opaque to lower-frequency light waves, which are absorbed by the materials. Microwaves have wavelengths between 1 mm and 30 cm. Wavelengths in that range are used to heat food in microwave ovens. The main mechanism of this heating is that molecules which have large dipole moments align themselves in the electric field of the radiation. This electric field flips its direction at twice the frequency of the radiation, so the polar molecules must rotate rapidly to keep up with the alternating electric field. These rapidly rotating molecules bump into surrounding molecules—causing them to heat up. Bluetooth and other wireless local-area-network protocols use wavelengths in the microwave region.

PRODUCTION OF ELECTROMAGNETIC WAVES

Electromagnetic waves are produced when free charges accelerate or when electrons bound to atoms and molecules make transitions to lower energy states. Radio waves, which have frequencies between 550 and 1600 kHz for AM and between 88 and 108 MHz for FM, are produced by electric currents oscillating in radio transmission antennas. The frequency of the emitted waves equals the frequency of oscillation of the charges.

A continuous spectrum of X rays is produced by the deceleration of electrons when they crash into a metal target. The radiation produced is called **bremsstrahlung** (which means "braking radiation" in the German language). Accompanying the broad, continuous bremsstrahlung spectrum is a discrete spectrum of X-ray lines produced by transitions of core electrons in the atoms of the target material.

Synchrotron radiation arises from the circular orbital motion of charged particles (usually electrons or positrons) in nuclear accelerators called synchrotrons. Originally considered a nuisance by accelerator scientists, X rays produced by synchrotrons are now used as a medical diagnostic tool because of the ease of manipulating the beams with reflection and diffraction optics. Synchrotron radiation is also emitted by charged particles trapped in magnetic fields associated with stars and galaxies. It is believed that most low-frequency radio waves reaching Earth from outer space originate as synchrotron radiation.

Heat is radiated by thermally excited molecular motion. The spectrum of heat radiation is the blackbody radiation spectrum discussed in Section 20-4.

Light waves, which have frequencies of the order of 10^{14} Hz, are generally produced by transitions of bound atomic charges. We discuss sources of light waves in Chapter 31.

ELECTRIC DIPOLE RADIATION

Figure 30-7 is a schematic drawing of an electric-dipole radio antenna that consists of two conducting rods connected to an alternating-current generator. At time $t = 0$ (Figure 30-7*a*), the ends of the rods are charged, and an electric field parallel to the rod exists near the rod. A magnetic field also exists, which is not shown, encircling the rods due to the current in the rods. The fluctuations in these fields move out away from the rods with the speed of light. After one-fourth period, at $t = T/4$ (Figure 30-7*b*), the rods are uncharged, and the electric field near the rod is zero. At $t = T/2$ (Figure 30-7*c*), the rods are again charged, but the charges are opposite those at $t = 0$. The electric and magnetic fields at a great distance from the antenna are quite different from the fields near the antenna. Far from the antenna, the electric and magnetic fields oscillate in phase with simple harmonic motion, perpendicular to each other and to the direction of propagation of the wave. Figure 30-8 shows the electric and magnetic fields far from an electric dipole antenna.

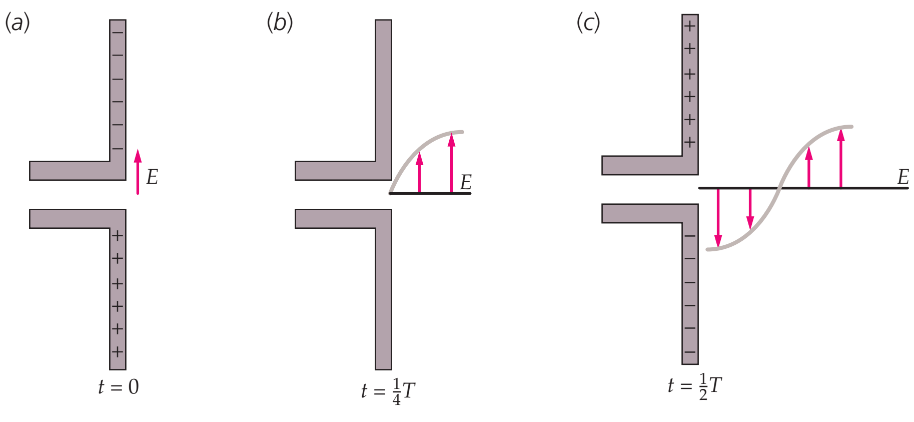


FIGURE 30-7 An electric dipole radio antenna for radiating electromagnetic waves. Alternating current is supplied to the antenna by a generator (not shown). The fluctuations in the electric field due to the fluctuations in the charges in the antenna propagate outward at the speed of light. There is also a fluctuating magnetic field (not shown) perpendicular to the paper due to the current in the antenna.

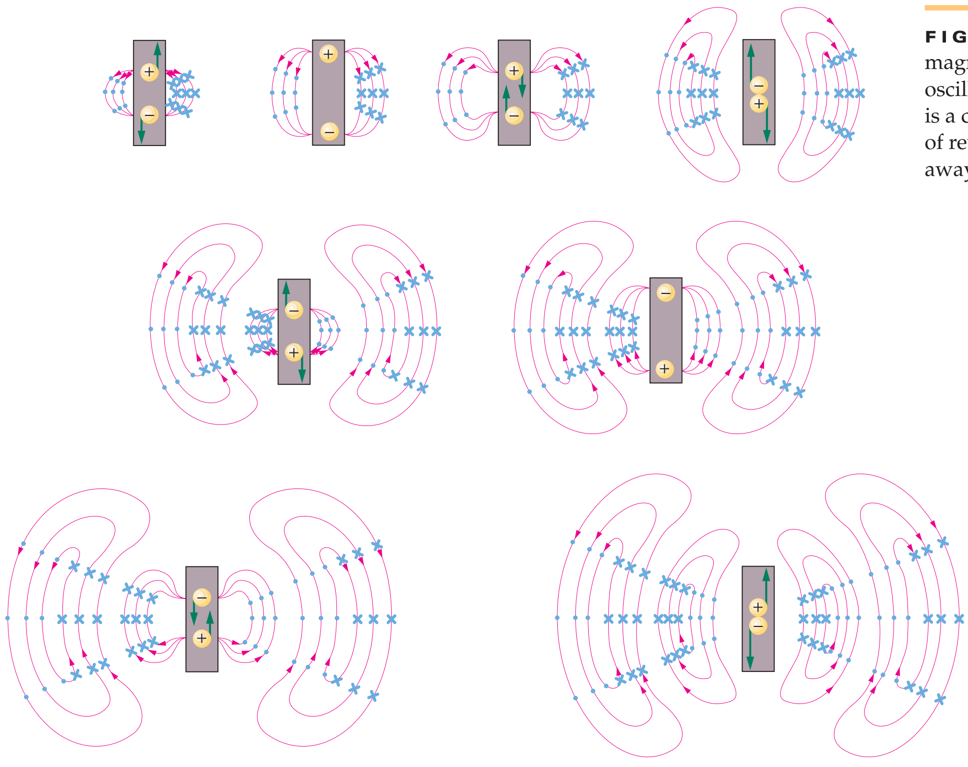

FIGURE 30-8 Electric field lines (in red) and magnetic field lines (in blue) produced by an oscillating electric dipole. Each magnetic field line is a circle with the long axis of the dipole as its axis of revolution. The cross product $\vec{E} \times \vec{B}$ is directed away from the dipole at all points.

Electromagnetic waves of radio or television frequencies can be detected by an electric dipole antenna placed parallel to the electric field of the incoming wave, so that it induces an alternating current in the antenna (Figure 30-9). These electromagnetic waves can also be detected by a loop antenna placed perpendicular to the magnetic field, so that the changing magnetic flux through the loop induces a current in the loop (Figure 30-10). Electromagnetic waves of frequencies in the visible light range are detected by the eye or by photographic film, both of which are mainly sensitive to the electric field.

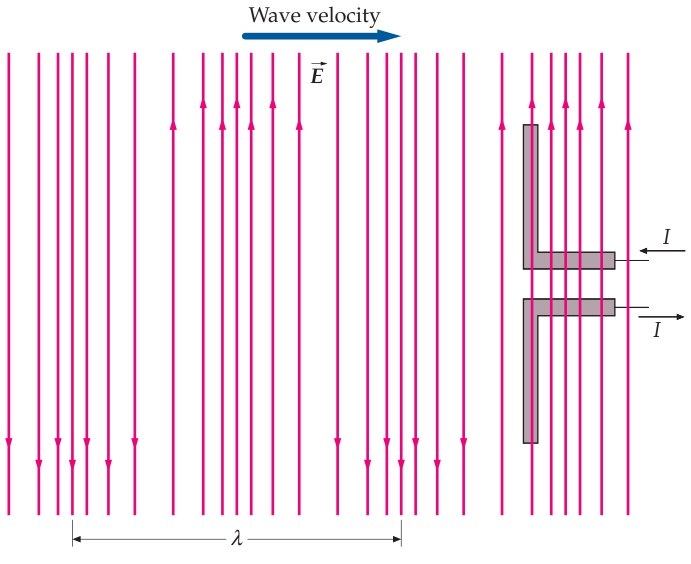

FIGURE 30-9 An electric dipole antenna for detecting electromagnetic waves. The alternating electric field of the incoming wave produces an alternating current in the antenna. The magnetic field lines (not shown) are perpendicular to the plane of the page.

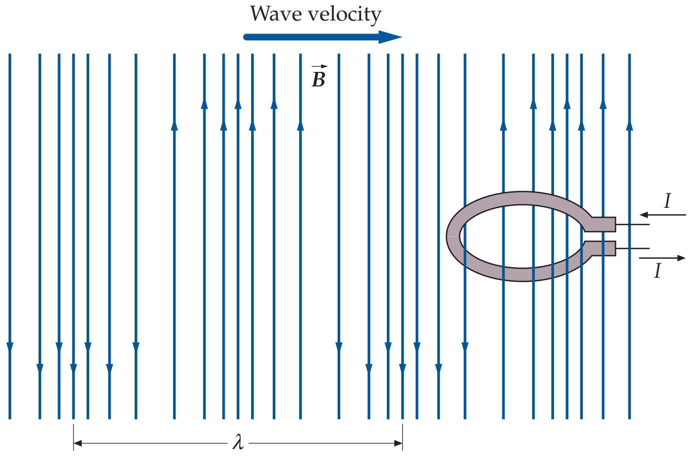

FIGURE 30-10 Loop antenna for detecting electromagnetic radiation. The alternating magnetic flux through the loop due to the magnetic field of the radiation induces an alternating current in the loop. The electric field lines (not shown) are perpendicular to the plane of the page.

The radiation from a dipole antenna, such as that shown in Figure 30-7, is called electric dipole radiation. Many electromagnetic waves exhibit the characteristics of electric dipole radiation. An important feature of this type of radiation is that the intensity of the electromagnetic waves radiated by a dipole antenna is zero along the axis of the antenna and maximum in the radial direction (away from the axis). If the dipole is in the y direction with its center at the origin, as in Figure 30-11, the intensity is zero along the y axis and maximum in the xz plane. In the direction of a line making an angle θ with the y axis, the intensity is proportional to $\sin^2\theta$.

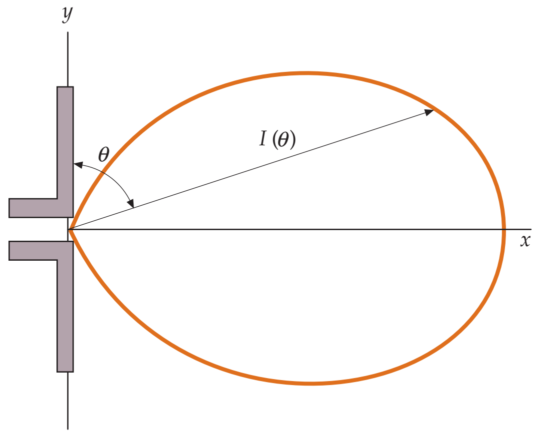

FIGURE 30-11 Polar plot of the intensity of electromagnetic radiation from an electric dipole antenna versus angle. The intensity $I(\theta)$ is proportional to the length of the arrow. The intensity is maximum perpendicular to the antenna (at $\theta = 90°$) and minimum along the antenna at $\theta = 0$ or $\theta = 180°$.

Example 30-5 EMF Induced in a Loop Antenna

A loop antenna consisting of a single 10.0-cm radius loop of wire is used to detect electromagnetic waves for which $E_{\mathrm{rms}} = 0.150$ V/m. If the plane of the loop is perpendicular to the magnetic field, find the rms emf induced in the loop when the frequency of the plane wave is (*a*) 600 kHz and (*b*) 60.0 MHz.

PICTURE The induced emf in the wire is related to the rate of change of the magnetic flux through the loop by Faraday's law (Equation 30-5). Using Equation 30-18, we can obtain the rms value of the magnetic field from the given rms value of the electric field.

SOLVE

(*a*) 1. Faraday's law relates the emf to the rate of change of the magnetic flux through the flat stationary surface bounded by the loop:

$$\mathcal{E} = -\frac{d\phi_{\mathrm{m}}}{dt}$$

2. The wavelength of a 600-kHz wave traveling at speed c is $\lambda = c/f = 500$ m. Over the flat surface bounded by the 10-cm radius loop $\vec{B}$ is quite uniform.

$$\phi_{\mathrm{m}} = BA = \pi r^2 B \quad \text{so} \quad \mathcal{E} = -\frac{d\phi_{\mathrm{m}}}{dt} = -\pi r^2 \frac{\partial B}{\partial t}$$

and

$$\mathcal{E}_{\mathrm{rms}} = \pi r^2 \left(\frac{\partial B}{\partial t}\right)_{\mathrm{rms}}$$

3. Compute $\partial B_{\mathrm{rms}}/\partial t$ from a sinusoidal B:

$$B = B_0 \sin(kx - \omega t)$$

$$\frac{\partial B}{\partial t} = -\omega B_0 \cos(kx - \omega t)$$

4. Calculate the rms value of $\partial B/\partial t$. The rms value of any sinusoidal function of time equals $1/\sqrt{2}$, and the peak value divided by $\sqrt{2}$ equals the rms value:

$$\left(\frac{\partial B}{\partial t}\right)_{\mathrm{rms}} = \omega B_0[-\cos(kx - \omega t)]_{\mathrm{rms}} = \omega B_0 \frac{1}{\sqrt{2}} = \omega B_{\mathrm{rms}}$$

5. Using $E = cB$ (Equation 30-18), relate the rms value of $\partial B/\partial t$ to E_{rms}:

$$E = cB$$

so

$$B_{\mathrm{rms}} = \frac{E_{\mathrm{rms}}}{c}$$

6. Substituting into the step-3 result gives:

$$\left(\frac{\partial B}{\partial t}\right)_{\mathrm{rms}} = \omega B_{\mathrm{rms}} = \omega \frac{E_{\mathrm{rms}}}{c} = \frac{2\pi f}{c} E_{\mathrm{rms}}$$

7. Substituting the step-6 result into the step-2 result, calculate $\mathcal{E}_{\mathrm{rms}}$ at $f = 600$ kHz:

$$\mathcal{E}_{\mathrm{rms}} = \pi r^2 \left(\frac{\partial B}{\partial t}\right)_{\mathrm{rms}} = \pi r^2 \frac{2\pi f}{c} E_{\mathrm{rms}}$$

$$= \pi (0.100\ \mathrm{m})^2 \frac{2\pi(6.00 \times 10^5\ \mathrm{Hz})}{3.00 \times 10^8\ \mathrm{m/s}} (0.150\ \mathrm{V/m})$$

$$= \boxed{5.92 \times 10^{-5}\ \mathrm{V} = 59.2\ \mu\mathrm{V}}$$

(*b*) The induced emf is proportional to the frequency [Part (*a*), step 4], so at 60 MHz it will be 100 times greater than at 600 kHz:

$$\mathcal{E}_{\text{rms}} = (100)(5.92 \times 10^{-5}\text{ V}) = 0.00592\text{ V}$$

$$= \boxed{5.92\text{ mV}}$$

CHECK Step 7 of Part (*a*) shows that $\mathcal{E}_{\text{rms}}$ increases with increases in frequency, E_{rms}, and area. These results are all expected.

TAKING IT FURTHER For Part (*b*) the frequency is 60.0 MHz, so $\lambda = c/f = 5.00$ m. $\vec{B}$ is not as uniform over the surface bounded by the 10-cm radius loop when $\lambda = 5.00$ m as it is when $\lambda = 500$ m, as in Part (*a*). However, $\vec{B}$ on the surface when $\lambda = 5.00$ m is sufficiently uniform that the Part (*b*) result is sufficiently accurate for most purposes.

ENERGY AND MOMENTUM IN AN ELECTROMAGNETIC WAVE

Like other waves, electromagnetic waves carry energy and momentum. The energy carried is described by the intensity, which is the average power per unit area incident on a surface perpendicular to the direction of propagation. The momentum per unit time per unit area carried by an electromagnetic wave is called the **radiation pressure.**

Intensity Consider an electromagnetic wave traveling toward the right and a cylindrical region that has a length L, a cross-sectional area A, and its central axis from left to right. The average amount of electromagnetic energy U_{av} within this region equals $u_{\text{av}}\mathcal{V}$ where u_{av} is the average energy density and $\mathcal{V} = LA$ is the volume of the cylindrical region. In the time it takes the electromagnetic wave to travel the distance L, all of the electromagnetic energy equal to $u_{\text{av}}LA$ passes through the right end of the region. The time Δt for the wave to travel the distance L is L/c, so the power P_{av} (the energy per unit time) passing out the right end of the region is

$$P_{\text{av}} = U_{\text{av}}/\Delta t = u_{\text{av}}LA/(L/c) = u_{\text{av}}Ac$$

and the intensity I (the average power per unit area) is

$$I = P_{\text{av}}/A = u_{\text{av}}c$$

The total energy density in the wave u is the sum of the electric and magnetic energy densities. The electric energy density u_{e} (Equation 24-9) and magnetic energy density u_{m} (Equation 28-22) are given by

$$u_{\text{e}} = \frac{1}{2}\epsilon_0 E^2 \qquad \text{and} \qquad u_{\text{m}} = \frac{B^2}{2\mu_0}$$

At each point in a region where there is an electromagnetic wave in free space, E equals cB, so we can express the magnetic energy density in terms of the electric field:

$$u_{\text{m}} = \frac{B^2}{2\mu_0} = \frac{(E/c)^2}{2\mu_0} = \frac{E^2}{2\mu_0 c^2} = \frac{1}{2}\epsilon_0 E^2$$

where we have used $\mu_0\epsilon_0 = 1/c^2$. Thus, the electric and magnetic energy densities are equal. Using $E = cB$, we may express the total energy density in several useful ways:

$$u = u_{\text{e}} + u_{\text{m}} = \epsilon_0 E^2 = \frac{B^2}{\mu_0} = \frac{EB}{\mu_0 c} \qquad 30\text{-}19$$

ENERGY DENSITY IN AN ELECTROMAGNETIC WAVE

To compute the average energy density, we replace the instantaneous fields E and B by their rms values $E_{rms} = \frac{1}{\sqrt{2}}E_0$ and $B_{rms} = \frac{1}{\sqrt{2}}B_0$, where E_0 and B_0 are the maximum values of the fields. The intensity is then

$$I = u_{av}c = \frac{E_{rms}B_{rms}}{\mu_0} = \frac{1}{2}\frac{E_0B_0}{\mu_0} = |\vec{S}|_{av} \qquad 30\text{-}20$$

INTENSITY OF AN ELECTROMAGNETIC WAVE

where the vector

$$\vec{S} = \frac{\vec{E} \times \vec{B}}{\mu_0} \qquad 30\text{-}21$$

DEFINITION—POYNTING VECTOR

is called the **Poynting vector** after its discoverer, John Poynting. The average magnitude of $\vec{S}$ is the intensity of the wave, and the direction of $\vec{S}$ is the direction of propagation of the wave.

Radiation pressure We now show by a simple example that an electromagnetic wave carries momentum. Consider a plane wave traveling in the $+x$ direction that is incident on a stationary charge, as shown in Figure 30-12. Let $\vec{E}$ be in the $+y$ direction and $\vec{B}$ in the $+z$ direction, and neglect the time dependence of the fields. The particle experiences a force $q\vec{E}$ in the $+y$ direction and is thus accelerated by the electric field. At any time t, the velocity in the $+y$ direction is

$$v_y = a_y t = \frac{qE}{m}t$$

After a short time t_1, the charge has acquired kinetic energy equal to

$$K = \frac{1}{2}mv_y^2 = \frac{1}{2}\frac{mq^2E^2t_1^2}{m^2} = \frac{1}{2}\frac{q^2E^2}{m}t_1^2 \qquad 30\text{-}22$$

When the charge is moving in the y direction, it experiences a magnetic force

$$\vec{F}_m = q\vec{v} \times \vec{B} = qv_y\,\hat{j} \times B\,\hat{k} = qv_yB\,\hat{i} = \frac{q^2EB}{m}t\,\hat{i}$$

Note that this force is in the direction of propagation of the wave. Using $dp_x = F_x\,dt$, we find for the momentum p_x transferred by the wave to the particle in time t_1:

$$p_x = \int_0^{t_1} F_x\,dt = \int_0^{t_1}\frac{q^2EB}{m}t\,dt = \frac{1}{2}\frac{q^2EB}{m}t_1^2$$

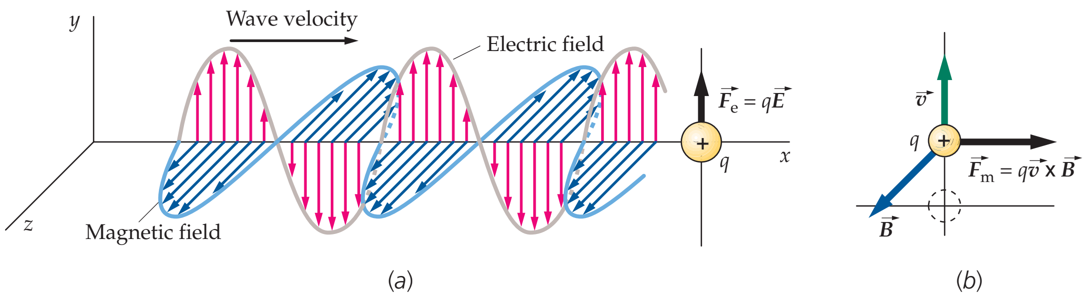

FIGURE 30-12 An electromagnetic wave incident on a point charge that is initially at rest on the x axis. (a) The electric force $q\vec{E}$ accelerates the charge in the $+y$ direction. (b) When the velocity $\vec{v}$ of the charge is in the $+y$ direction, the magnetic force $q\vec{v} \times \vec{B}$ accelerates the charge in the direction of propagation (the $+x$ direction) of the wave.

If we use $B = E/c$, this becomes

$$p_x = \frac{1}{c}\left(\frac{1}{2}\frac{q^2E^2}{m}t_1^2\right) \qquad 30\text{-}23$$

Comparing Equations 30-22 and 30-23, we see that the momentum acquired by the charge in the direction of the wave is $1/c$ multiplied by the energy. Although our simple calculation was not rigorous, the results are correct. The magnitude of the momentum carried by an electromagnetic wave is $1/c$ multiplied by the energy carried by the wave:

$$p = \frac{U}{c} \qquad 30\text{-}24$$

MOMENTUM AND ENERGY IN AN ELECTROMAGNETIC WAVE

Because the intensity is the energy per unit area per unit time, the intensity divided by c is the momentum carried by the wave per unit area per unit time. The momentum carried per unit time is a force. The intensity divided by c is thus a force per unit area, which is a pressure. This pressure is the radiation pressure P_r:

$$P_r = \frac{I}{c} \qquad 30\text{-}25$$

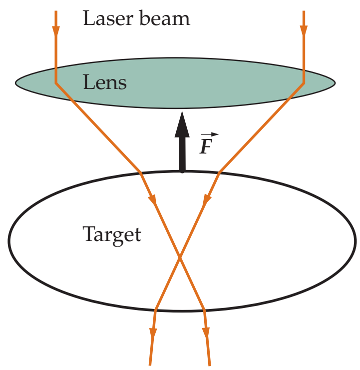
RADIATION PRESSURE AND INTENSITY

We can relate the radiation pressure to the electric or magnetic fields by using Equation 30-20 to relate I to E and B, and Equation 30-18 to eliminate either E or B:

$$P_r = \frac{I}{c} = \frac{E_0B_0}{2\mu_0 c} = \frac{E_{rms}B_{rms}}{\mu_0 c} = \frac{E_0^2}{2\mu_0 c^2} = \frac{B_0^2}{2\mu_0} \qquad 30\text{-}26$$

RADIATION PRESSURE IN TERMS OF E AND B

Consider an electromagnetic wave incident normally on some surface. If the surface absorbs energy U from the electromagnetic wave, it also absorbs momentum p given by Equation 30-24, and the pressure exerted on the surface equals the radiation pressure. If the wave is reflected, the momentum transferred is $2p$ because the wave now carries momentum in the opposite direction. The pressure exerted on the surface by the wave is then twice that given by Equation 30-26.



"Laser tweezers" make use of the momentum carried by electromagnetic waves to manipulate targets on a molecular scale. The two rays shown are refracted as they pass through a transparent target, such as a biological cell or, on an even smaller scale, a tiny transparent bead attached to a large molecule within a cell. At each refraction, the rays are bent downward, which increases the downward component of momentum of the rays. The target thus exerts a downward force on the laser beams, and the laser beams exert an upward force on the target, which pulls the target toward the laser source. The force is typically of the order of piconewtons. Laser tweezers have been used to accomplish such astonishing feats as stretching out coiled molecules of DNA.

Example 30-6 Radiation Pressure 3.0 m from a Lightbulb

A lightbulb emits spherical electromagnetic waves uniformly in all directions. Find (*a*) the intensity, (*b*) the radiation pressure, and (*c*) the electric and magnetic field magnitudes at a distance of 3.0 m from the lightbulb, assuming that 50 W of electromagnetic radiation is emitted.

PICTURE At a distance r from the lightbulb, the energy is spread uniformly over the surface of a sphere of radius r—an area equal to $4\pi r^2$. The intensity is the power divided by the area. The radiation pressure can then be found from $P_r = I/c$.

SOLVE

(*a*) 1. Divide the power output by the area to find the intensity: $I = \frac{50\text{ W}}{4\pi r^2}$

2. Substitute $r = 3.0$ m: $I = \frac{50\text{ W}}{4\pi(3.0\text{ m})^2} = \boxed{0.44\text{ W/m}^2}$

(*b*) The radiation pressure is the intensity divided by the speed of light:

$$P_r = \frac{I}{c} = \frac{0.44\ \text{W/m}^2}{3.00 \times 10^8\ \text{m/s}} = \boxed{1.5 \times 10^{-9}\ \text{Pa}}$$

(*c*) 1. B_0 is related to P_r by Equation 30-26:

$$B_0 = \sqrt{2\mu_0 P_r}$$
$$= [2(4\pi \times 10^{-7}\ \text{T}\cdot\text{m/A})(1.5 \times 10^{-9}\ \text{Pa})]^{1/2}$$
$$= 6.1 \times 10^{-8}\ \text{T}$$

2. The maximum value of the electric field E_0 is c multiplied by B_0:

$$E_0 = cB_0 = (3.00 \times 10^8\ \text{m/s})(6.1 \times 10^{-8}\ \text{T})$$
$$= 18\ \text{V/m}$$

3. The electric and magnetic field magnitudes at that point are of the form:

$$\boxed{\begin{array}{l} E = E_0 \sin \omega t \quad \text{and} \quad B = B_0 \sin \omega t \\ \text{with } E_0 = 18\ \text{V/m} \\ \text{and } B_0 = 6.1 \times 10^{-8}\ \text{T} \end{array}}$$

CHECK Our Part (*b*) result is a very small pressure. (It is fourteen orders of magnitude less than atmospheric pressure.) We do not perceive any pressure on us by the light from a lightbulb, so a very small pressure is as expected.

TAKING IT FURTHER Only about 2 percent of the power consumed by incandescent bulbs is transformed into visible light.

Example 30-7 A Laser Rocket

Context-Rich

You are stranded in space a distance of 20 m from your spaceship. You carry a 1.0-kW laser. If your total mass, including your space suit and laser, is 95 kg, how long will it take you to reach the spaceship if you point the laser beam directly away from the ship?

PICTURE The laser emits light, which carries with it momentum. By momentum conservation, you are given an equal and opposite momentum toward the spaceship. The momentum carried by light is $p = U/c$, where U is the energy of the light. If the power of the laser is $P = dU/dt$, then the rate of change of momentum produced by the laser is $dp/dt = (dU/dt)/c = P/c$. This force is the force exerted on you, which is constant.

SOLVE

1. The time taken is related to the distance and the acceleration. We assume that you are initially at rest relative to the spaceship:

$$x = \frac{1}{2}at^2 \quad t = \sqrt{\frac{2x}{a}}$$

2. Your acceleration is the force divided by your mass, and the force is the power divided by c:

$$a = \frac{F}{m} = \frac{P/c}{m} = \frac{P}{mc}$$

3. Use $x = \frac{1}{2}at^2$ to calculate the time t:

$$t = \sqrt{\frac{2x}{a}} = \sqrt{\frac{2xmc}{P}}$$
$$= \sqrt{\frac{2(20\ \text{m})(95\ \text{kg})(3.00 \times 10^8\ \text{m/s})}{1000\ \text{W}}}$$
$$= 3.38 \times 10^4\ \text{s} = \boxed{9.4\ \text{h}}$$

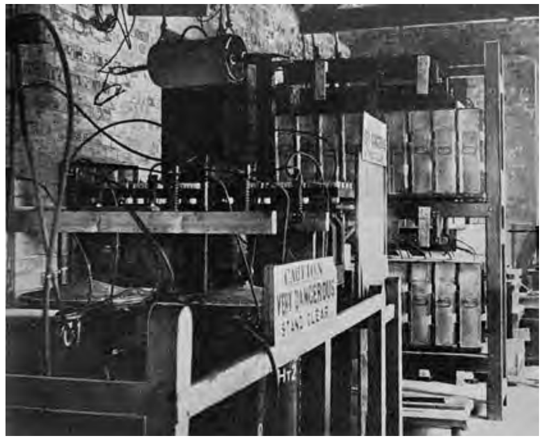
CHECK You expect the time to be long because you know from experience that the pressure from a lightbulb is very small. The step-3 result is as expected.

TAKING IT FURTHER Note that the acceleration is extremely small—only about 10^{-9} g. Your speed when you reach the spaceship would be $v = at = 1.2$ mm/s, which is practically imperceptible.

PRACTICE PROBLEM 30-3 How long would it take you to reach the spaceship if you took off one of your shoelaces and threw it as fast as you could in the direction opposite the ship? (To answer this, you must first estimate the mass of the shoelace and the maximum speed that you can throw the shoelace.) Compare this time with the step-3 result.

Physics Spotlight

Wireless: Sharing the Spectrum



Marconi's transmitter. This transmitter was used in 1901 during the first transatlantic radio broadcast. *(Cornwall, UK, to Newfoundland, USA.)*

One day in March 1998,[*] the remote heart monitors at Baylor University Medical Center and Dallas Methodist Hospital stopped working. WFFA, a Dallas television station, was testing its new digital broadcast system on its licensed frequency. The heart monitors, longtime unlicensed low-power users of the same frequency, were overwhelmed by the test. No patients were harmed, and the station stopped further testing until the hospitals could replace their monitors with ones that used different frequencies.[†] In 2000, the Wireless Medical Telemetry Service established a set of licensed frequencies for medical monitoring devices.[‡]

When Guglielmo Marconi transmitted signals on his wireless telegraph in 1896, he used a spark-gap transmitter.[#] The sparks produced electromagnetic radiation at frequencies over a range of 5 or more orders of magnitude (from a few kilohertz up to 2 GHz). When more than one wireless telegraph was transmitting in the same area, they had to take turns and follow rules. One reckless operator could wreck communications for an entire area.[°]

In 1903, the International Telegraph Union began to study the problems of radiotelegraphy. In 1906, the first Radio Telegraph Convention, signed in Berlin, assigned the frequency of 500 kHz to maritime distress signals.[§] Ships were directed to use less than 1 kW of power, unless they were over 300 km from the nearest shore station.[¶] (These communications were still broadband, but the transmitted power spectrum peaked at 500 kHz.) The first practical alternative to spark-gap transmitters was a continuous wave circuit invented by Edwin Armstrong in 1912.[**] Also in 1912, the International Radiotelegraph Convention issued the first table of frequency allocations,[††] but spark-gap transmitters were still plentiful and could overwhelm local and regional communications.[‡‡]

Radio transmissions became concentrated around narrowing frequency bands. In 1927, national bodies were established to coordinate use of the electromagnetic spectrum.[##] By 1934, the international body was renamed the International Telecommunication Union.[°°] The Federal Communications Commission regulates the radio frequency portions of the spectrum in the United States.[§§] Since then, the ITU and the FCC have cooperated in international frequency allocation with other regulatory bodies around the world.

As new services have been added, changes and accommodations have been made to allocations of the frequency spectrum. These changes are not always made globally. For instance, in the United States, cell phone service frequencies are at 850 and 1900 MHz. In many other countries, cell phone bands are at 900 and 1800 MHz.[¶¶]

No matter what the power, devices that have the potential of emitting electromagnetic interference have to be certified that they do not disturb the spectrum beyond their frequency allocation outside of a small radius.[***] Many applications share frequency bands that do not have exclusive licenses granted to any one application. For instance, microwave ovens, wireless computer devices, and some cordless telephones all operate at frequencies close to 2.4 GHz.[†††] Low-power applications that are not the licensed users of a frequency sometimes need frequencies of their own, as demonstrated by the new medical telemetry bands. Occasionally, wireless receivers in an area pick up broadband interference caused by the intermittent sparking of a short circuit. In essence, the malfunctioning electrical equipment has become an unlicensed spark-gap transmitter.

Summary

1. Maxwell's equations summarize the fundamental laws of physics that govern electricity and magnetism.
2. Electromagnetic waves include light, radio waves, television waves, X rays, gamma rays, microwaves, and others.

TOPIC	RELEVANT EQUATIONS AND REMARKS	
1. Maxwell's Displacement Current	Ampère's law can be generalized to apply to currents that are not steady (and not continuous) if the current I is replaced by $I + I_d$, where I_d is Maxwell's displacement current: $$I_d = \epsilon_0 \frac{d\phi_e}{dt}$$	30-3
Generalized form of Ampère's law	$$\oint_C \vec{B} \cdot d\vec{\ell} = \mu_0(I + I_d) = \mu_0 I + \mu_0\epsilon_0 \frac{d\phi_e}{dt}$$	30-4
2. Maxwell's Equations	The laws of electricity and magnetism are summarized by Maxwell's equations.	
Gauss's law	$$\oint_S E_n\, dA = \frac{1}{\epsilon_0} Q_{\text{inside}}$$	30-6*a*
Gauss's law for magnetism (isolated magnetic poles do not exist)	$$\oint_S B_n\, dA = 0$$	30-6*b*
Faraday's law (form that does not include motional emf)	$$\oint_C \vec{E} \cdot d\vec{\ell} = -\frac{d}{dt}\int_S B_n\, dA = -\int_S \frac{\partial B_n}{\partial t}\, dA$$	30-6*c*
Ampère's law modified	$$\oint_C \vec{B} \cdot d\vec{\ell} = \mu_0(I + I_d) = \mu_0 I + \mu_0\epsilon_0 \int_S \frac{\partial E_n}{\partial t}\, dA$$	30-6*d*
3. The Wave Equation for Electromagnetic Waves	Maxwell's equations imply that the electric and magnetic field vectors in free space obey a wave equation. $$\frac{\partial^2 \vec{E}}{\partial x^2} = \frac{1}{c^2}\frac{\partial^2 \vec{E}}{\partial t^2}$$ (30-8*a*) $$\frac{\partial^2 \vec{B}}{\partial x^2} = \frac{1}{c^2}\frac{\partial^2 \vec{B}}{\partial t^2}$$	30-8*a*, 30-8*b*
4. Electromagnetic Waves	In an electromagnetic wave, the electric and magnetic field vectors are perpendicular to each other and to the direction of propagation. Their magnitudes are related by $$E = cB$$ The vector product $\vec{E} \times \vec{B}$ is in the direction of propagation.	30-18
Wave speed	$$c = \frac{1}{\sqrt{\mu_0\epsilon_0}} = 3.00 \times 10^8\ \text{m/s}$$	30-1
Electromagnetic spectrum	The various types of electromagnetic waves—light, radio waves, X rays, gamma rays, microwaves, and others—differ only in wavelength and frequency. The human eye is sensitive to the range from about 400 nm to 780 nm.	
Electric dipole radiation	Electromagnetic waves are produced when free electric charges accelerate. Oscillating charges in an electric dipole antenna radiate electromagnetic waves with an intensity that is greatest in directions perpendicular to the antenna. There is no radiated intensity along the long axis of the antenna. Perpendicular to the antenna and far away from it, the electric field of the electromagnetic wave is parallel to the antenna.	
Energy density in an electromagnetic wave	$$u = u_e + u_m = \epsilon_0 E^2 = \frac{B^2}{\mu_0} = \frac{EB}{\mu_0 c}$$	30-19

TOPIC	RELEVANT EQUATIONS AND REMARKS	
Intensity of an electromagnetic wave	$I = u_{av}c = \frac{E_{rms}B_{rms}}{\mu_0} = \frac{1}{2}\frac{E_0B_0}{\mu_0} = \lvert\vec{S}\rvert_{av}$	30-20
Poynting vector	$\vec{S} = \frac{\vec{E}\times\vec{B}}{\mu_0}$	30-21
Momentum and energy in an electromagnetic wave	$p = \frac{U}{c}$	30-24
Radiation pressure and intensity	$P_r = \frac{I}{c}$	30-25

Answers to Practice Problems

30-2 $\vec{E}\cdot\vec{E} = E_0^2$ and $\vec{B}\cdot\vec{B} = B_0^2$

30-3 About 5 h for a 10-g shoelace thrown at 10 m/s. Light beam propulsion takes almost twice as long as shoelace propulsion.

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • True or false:

(*a*) The displacement current has different units than the conduction current.

(*b*) Displacement current only exists if the electric field in the region is changing with time.

(*c*) In an oscillating *LC* circuit, no displacement current exists between the capacitor plates when the capacitor is momentarily fully charged.

(*d*) In an oscillating *LC* circuit, no displacement current exists between the capacitor plates when the capacitor is momentarily uncharged. SSM

2 • Using SI units, show that $\epsilon_0\, d\phi_e/dt$ has units of current.

3 • True or false:

(*a*) Maxwell's equations apply only to electric and magnetic fields that are constant over time.

(*b*) The electromagnetic wave equation can be derived from Maxwell's equations.

(*c*) Electromagnetic waves are transverse waves.

(*d*) The electric and magnetic fields of an electromagnetic wave in free space are in phase. SSM

4 • Theorists have speculated about the existence of *magnetic monopoles*, and several experimental searches for such monopoles have occurred. Suppose magnetic monopoles were found and that the magnetic field at a distance r from a monopole of strength q_m is given by $B = (\mu_0/4\pi)q_m/r^2$. Modify the Gauss's law for magnetism equation to be consistent with such a discovery.

5 • (*a*) For each of the following pairs of electromagnetic waves, which has the higher frequency: (1) visible light or X rays, (2) green light or red light, (3) infrared waves or red light. (*b*) For each of the following pairs of electromagnetic waves, which has the longer wavelength: (1) visible light or microwaves, (2) green light or ultraviolet light, (3) gamma rays or ultraviolet light.

6 • The detection of radio waves can be accomplished with either an electric dipole antenna or a loop antenna. True or false:

(*a*) The electric dipole antenna works according to the Faraday's law.

(*b*) If a linearly polarized radio wave is approaching you head on such that its electric field oscillates vertically, to best detect this wave the normal to a loop antenna's plane should be oriented so that it points either right or left.

(*c*) If a linearly polarized radio wave is approaching you such that its electric field oscillates in a horizontal plane, to best detect this wave using a dipole antenna the antenna should be oriented vertically.

7 • A transmitter emits electromagnetic waves using an electric dipole antenna oriented vertically. (*a*) A receiver to detect the waves also uses an electric dipole antenna that is one mile from the transmitting antenna and at the same altitude. How should the receiver's electric dipole antenna be oriented for optimum signal reception? (*b*) A receiver to detect these waves uses a loop antenna that is one mile from the transmitting antenna and at the same altitude. How should the loop antenna be oriented for optimum signal reception?

8 • Show that the expression $(\vec{E}\times\vec{B})/\mu_0$ for the Poynting vector $\vec{S}$ (Equation 30-21) has units of watts per square meter (the SI units for electromagnetic wave intensity).

9 • If a red light beam, a green light beam, and a violet light beam, all traveling in empty space, have the same intensity, which light beam carries more momentum? (*a*) the red light beam, (*b*) the green light beam, (*c*) the violet light beam, (*d*) They all have the same momentum. (*e*) You cannot determine which beam carries the most momentum from the data given. SSM

10 • If a red light plane wave, a green light plane wave, and a violet light plane wave, all traveling in empty space, have the same intensity, which wave has the largest peak electric field? (*a*) the red light wave, (*b*) the green light wave, (*c*) the violet light wave, (*d*) They all have the same peak electric field. (*e*) You cannot determine the largest peak electric field from the data given.

11 • Two sinusoidal plane electromagnetic waves are identical except that wave A has a peak electric field that is three times the peak electric field of wave B. How do their intensities compare? (*a*) $I_A = \frac{1}{3}I_B$, (*b*) $I_A = \frac{1}{9}I_B$, (*c*) $I_A = 3I_B$, (*d*) $I_A = 9I_B$, (*e*) You cannot determine how their intensities compare from the data given.

ESTIMATION AND APPROXIMATION

12 •• **Engineering Application** In *laser cooling and trapping*, the forces associated with radiation pressure are used to slow down atoms from thermal speeds of hundreds of meters per second at room temperature to speeds of a few meters per second or slower. An isolated atom will absorb only radiation of specific frequencies. If the frequency of the laser-beam radiation is tuned so that the target atoms will absorb the radiation, then the radiation is absorbed during a process called *resonant absorption*. The cross-sectional area of the atom for resonant absorption is approximately equal to λ^2, where λ is the wavelength of the laser light. (*a*) Estimate the acceleration of a rubidium atom (molar mass 85 g/mol) in a laser beam whose wavelength is 780 nm and intensity is 10 W/m^2. (*b*) About how long would it take such a light beam to slow a rubidium atom in a gas at room temperature (300 K) to near-zero speed?

13 •• **Engineering Application** One of the first successful satellites launched by the United States in the 1950s was essentially a large spherical (aluminized) Mylar balloon from which radio signals were reflected. After several orbits around Earth, scientists noticed that the orbit itself was changing with time. They eventually determined that radiation pressure from sunlight was causing the orbit of this object to change—a phenomenon not taken into account in planning the mission. Estimate the ratio of the radiation-pressure force by the sunlight on the satellite to the gravitational force by Earth's gravity on the satellite. SSM

14 •• Some science fiction writers have described solar sails that could propel interstellar spaceships. Imagine a giant sail on a spacecraft subjected to radiation pressure from our Sun. (*a*) Explain why this arrangement works better if the sail is highly reflective rather than highly absorptive. (*b*) If the sail is assumed highly reflective, show that the force exerted by the sunlight on the spacecraft's sail is given by $P_S A/(4\pi r^2 c)$ where P_S is the power output of the Sun (3.8×10^{26} W), A is the surface area of the sail, r is the distance from the Sun, and c is the speed of light. (Assume the area of the sail is much larger than the area of the spacecraft so that all the force is due to radiation pressure on the sail only.) (*c*) Using a reasonable value for A, compare the force on the spacecraft due to the radiation pressure and the force on the spacecraft due to the gravitational force of the Sun on the spacecraft. Does the result imply that such a system will work? Explain your answer.

MAXWELL'S DISPLACEMENT CURRENT

15 • A parallel-plate capacitor has circular plates and no dielectric between the plates. Each plate has a radius equal to 2.3 cm and the plates are separated by 1.1 mm. Charge is flowing onto the upper plate (and off of the lower plate) at a rate of 5.0 A. (*a*) Find the rate of change of the electric field strength in the region between the plates. (*b*) Compute the displacement current in the region between the plates and show that it equals 5.0 A. SSM

16 • In a region of space, the electric field varies with time as $(0.050\ \mathrm{N/C})\sin\omega t$, where $\omega = 2000$ rad/s. Find the peak displacement current through a surface that is perpendicular to the electric field and has an area equal to 1.00 m^2.

17 •• For Problem 15, show that the magnetic field strength between the plates a distance r from the axis through the centers of both plates is given by $B = (1.9 \times 10^{-3}\ \mathrm{T/m})r$.

18 •• The capacitors referred to in this problem have only empty space between the plates. (*a*) Show that a parallel-plate capacitor has a displacement current in the region between its plates that is given by $I_d = C\,dV/dt$, where C is the capacitance and V is the potential difference between the plates. (*b*) A 5.00–nF parallel-plate capacitor is connected to an ideal ac generator so the potential difference between the plates is given by $V = V_0 \cos\omega t$, where $V_0 = 3.00$ V and $\omega = 500\pi$ rad/s. Find the displacement current in the region between the plates as a function of time.

19 •• There is a current of 10 A in a resistor that is connected in series with a parallel-plate capacitor. The plates of the capacitor have an area of 0.50 m^2, and no dielectric exists between the plates. (*a*) What is the displacement current between the plates? (*b*) What is the rate of change of the electric field strength between the plates? (*c*) Find the value of the line integral $\oint_C \vec{B} \cdot d\vec{\ell}$, where the integration path C is a 10-cm-radius circle that lies in a plane that is parallel with the plates and is completely within the region between them. SSM

20 ••• Demonstrate the validity of the generalized form of Ampère's law (Equation 30-4) by showing that it gives the same result as the Biot–Savart law (Equation 27-3) in a specified situation. Figure 30-13 shows two momentarily equal but opposite point charges ($+Q$ and $-Q$) on the x axis at $x = -a$ and $x = +a$, respectively. At the same instant there is a current I in the wire connecting them, as shown. Point P is on the y axis at $y = R$. (*a*) Use the Biot–Savart law to show that the magnitude of the magnetic field at point P is given by $B = \dfrac{\mu_0 I a}{2\pi R}\dfrac{1}{\sqrt{R^2 + a^2}}$. (*b*) Now consider a circular strip of radius r and width dr in the $x = 0$ plane that has its center at the origin. Show that the flux of the electric field through this strip is given by $E_x\,dA = \dfrac{Q}{\epsilon_0(r^2 + a^2)^{3/2}}\pi r\,dr$. (*c*) Use the result from Part (*b*) to show that the total electric flux ϕ_e through a circular surface S of radius R is given by $\phi_e = \dfrac{Q}{\epsilon_0}\left(1 - \dfrac{a}{\sqrt{a^2 + R^2}}\right)$. (*d*) Find the displacement current I_d through S, and show that $I + I_d = I\dfrac{a}{\sqrt{a^2 + R^2}}$. (*e*) Finally, show that the generalized form of Ampère's law (Equation 30-4) gives the same result for the magnetic field as found in Part (*a*).

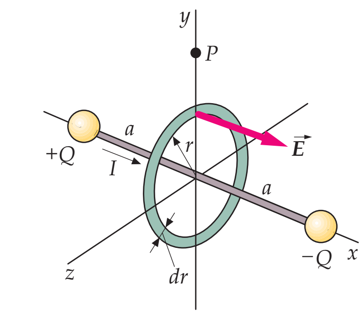

FIGURE 30-13 Problem 20

MAXWELL'S EQUATIONS AND THE ELECTROMAGNETIC SPECTRUM

21 • The color of the dominant light from the Sun is in the yellow-green region of the visible spectrum. Estimate the wavelength and frequency of the dominant light emitted by our Sun. *Hint: See Table 30-1.*

22 • (*a*) What is the frequency of microwave radiation that has a 3.00-cm-long wavelength? (*b*) Using Table 30-1, estimate the ratio of the shortest wavelength of green light to the shortest wavelength of red light.

23 • (*a*) What is the frequency of an X ray that has a 0.100-nm-long wavelength? (*b*) The human eye is sensitive to light that has a wavelength equal to 550 nm. What are the color and frequency of this light? Comment on how this answer compares to your answer for Problem 21.

ELECTRIC DIPOLE RADIATION

***Note:* All of the problems in this section are based on the following information. Refer to Figure 30-11. It can be shown that the intensity of radiation from a radiating electric dipole at a field point far from the antenna is proportional to $\sin^2\theta/r^2$, where θ is the angle between the electric dipole moment vector $\vec{p}$ and the position vector $\vec{r}$ of the field point relative to the center of the antenna. The pattern of radiation from this type of antenna is independent of the azimuthal angle, that is, you can rotate the pattern about the antenna axis and it does not change shape.**

24 •• Suppose a radiating electric dipole lies along the z axis. Let I_1 be the intensity of the radiation at a distance of 10 m and at angle of 90°. Find the intensity (in terms of I_1) at (*a*) a distance of 30 m and an angle of 90°, (*b*) a distance of 10 m and an angle of 45°, and (*c*) a distance of 20 m and an angle of 30°.

25 •• (*a*) For the situation described in Problem 24, at what angle is the intensity at a distance of 5.0 m equal to I_1? (*b*) At what distance is the intensity equal to I_1 when $\theta = 45°$?

26 •• **Engineering Application, Context-Rich** You and your engineering crew are in charge of setting up a wireless telephone network for a village in a mountainous region. The transmitting antenna of one station is an electric dipole antenna located atop a mountain 2.00 km above sea level. There is a nearby mountain that is 4.00 km from the antenna and is also 2.00 km above sea level. At that location, one member of the crew measures the intensity of the signal to be 4.00×10^{-12} W/m^2. What should be the intensity of the signal at the village that is located at sea level and 1.50 km from the transmitter?

27 ••• **Engineering Application** A radio station that uses a vertical electric dipole antenna broadcasts at a frequency of 1.20 MHz and has a total power output of 500 kW. Calculate the intensity of the signal at a horizontal distance of 120 km from the station. SSM

28 ••• **Engineering Application** Regulations require that licensed radio stations have limits on their broadcast power so as to avoid interference with signals from distant stations. You are in charge of checking compliance with the law. At a distance of 30.0 km from a radio station that broadcasts from a single vertical electric dipole antenna at a frequency of 800 kHz, the intensity of the electromagnetic wave is 2.00×10^{-13} W/m^2. What is the total power radiated by the station?

29 ••• **Engineering Application** A small private plane approaching an airport is flying at an altitude of 2.50 km above sea level. As a flight controller at the airport, you know your system uses a vertical electric dipole antenna to transmit 100 W at 24.0 MHz. What is the intensity of the signal at the plane's receiving antenna when the plane is 4.00 km from the airport? Assume the airport is at sea level.

ENERGY AND MOMENTUM IN AN ELECTROMAGNETIC WAVE

30 • An electromagnetic wave has an intensity of 100 W/m^2. Find its (*a*) rms electric field strength, and (*b*) rms magnetic field strength.

31 • The amplitude of an electromagnetic wave's electric field is 400 V/m. Find the wave's (*a*) rms electric field strength, (*b*) rms magnetic field strength, (*c*) intensity, and (*d*) radiation pressure (P_r). SSM

32 • The rms value of an electromagnetic wave's electric field strength is 400 V/m. Find the wave's (*a*) rms magnetic field strength, (*b*) average energy density, and (*c*) intensity.

33 •• (*a*) An electromagnetic wave that has an intensity equal to 200 W/m^2 is normal to a black 20 cm by 30 cm rectangular card that absorbs 100 percent of the wave. Find the force exerted on the card by the radiation. (*b*) Find the force exerted by the same wave if the card reflects 100 percent of the wave.

34 •• Find the force exerted by the electromagnetic wave on the card in Part (*b*) of Problem 33 if both the incident and the reflected waves are at angles of 30° to the normal.

35 • (*a*) For a given distance from a radiating electric dipole, at what angle (expressed as θ and measured from the dipole axis) is the intensity equal to 50 percent of the maximum intensity? (*b*) At what angle θ is the intensity equal to 1 percent of the maximum intensity? SSM

36 •• A laser pulse has an energy of 20.0 J and a beam radius of 2.00 mm. The pulse duration is 10.0 ns and the energy density is uniformly distributed within the pulse. (*a*) What is the spatial length of the pulse? (*b*) What is the energy density within the pulse? (*c*) Find the rms values of the electric and magnetic fields in the pulse.

37 •• An electromagnetic plane wave has an electric field that is parallel to the y axis, and has a Poynting vector given by $\vec{S}(x,t) = (100\ \text{W/m}^2)\cos^2(kx - \omega t)\hat{i}$, where x is in meters, $k = 10.0$ rad/m, $\omega = 3.00 \times 10^9$ rad/s, and t is in seconds. (*a*) What is the direction of propagation of the wave? (*b*) Find the wavelength and frequency of the wave. (*c*) Find the electric and magnetic fields of the wave as functions of x and t. SSM

38 •• A parallel-plate capacitor is being charged. The capacitor consists of a pair of identical circular parallel plates that each have a radius b and a separation distance d. (*a*) Show that the displacement current in the capacitor gap has the same value as the conduction current in the capacitor leads. (*b*) What is the direction of the Poynting vector in the region between the capacitor plates? (*c*) Find an expression for the Poynting vector in this region and show that its flux into the region between the plates is equal to the rate of change of the energy stored in the capacitor.

39 •• A pulsed laser fires a 1000-MW pulse that has a 200-ns duration at a small object that has a mass equal to 10.0 mg and is suspended by a fine fiber that is 4.00 cm long. If the radiation is completely absorbed by the object, what is the maximum angle of deflection of this pendulum? (Think of the system as a ballistic pendulum and assume the small object was hanging vertically before the radiation hit it.) SSM

40 •• The mirrors used in a particular type of laser are 99.99% reflecting. (*a*) If the laser has an average output power of 15 W, what is the average power of the radiation incident on one of the mirrors? (*b*) What is the force due to radiation pressure on one of the mirrors?

41 •• (*a*) Estimate the force on Earth due to the pressure of the radiation on Earth by the Sun, and compare this force to the gravitational force of the Sun on Earth. (At Earth's orbit, the intensity of sunlight is 1.37 kW/m^2.) (*b*) Repeat Part (*a*) for Mars which is at an average distance of 2.28×10^8 km from the Sun and has a radius of 3.40×10^3 km. (*c*) Which planet has the larger ratio of radiation pressure to gravitational attraction? SSM

THE WAVE EQUATION FOR ELECTROMAGNETIC WAVES

42 • Show by direct substitution that Equation 30-8*a* is satisfied by the wave function $E_y = E_0 \sin(kx - \omega t) = E_0 \sin k(x - ct)$ where $c = \omega/k$.

43 • Use the values of μ_0 and ϵ_0 in SI units to compute $1/\sqrt{\epsilon_0 \mu_0}$ and show that it is equal to 3.00×10^8 m/s.

44 •• (*a*) Use Maxwell's equations to show for a plane wave, in which $\vec{E}$ and $\vec{B}$ are independent of y and z, that $\frac{\partial E_z}{\partial x} = \frac{\partial B_y}{\partial t}$ and $\frac{\partial B_y}{\partial x} = \mu_0 \epsilon_0 \frac{\partial E_z}{\partial t}$. (*b*) Show that E_z and B_y also satisfy the wave equation.

45 •• Show that any function of the form $y(x, t) = f(x - vt)$ or $y(x, t) = g(x + vt)$ satisfies the wave equation (Equation 30-7). SSM

GENERAL PROBLEMS

46 • An electromagnetic wave has a frequency of 100 MHz and is traveling in a vacuum. The magnetic field is given by $\vec{B}(z, t) = (1.00 \times 10^{-8}\ \text{T}) \cos(kz - \omega t)\hat{\boldsymbol{i}}$. (*a*) Find the wavelength and the direction of propagation of this wave. (*b*) Find the electric field vector $\vec{E}(z, t)$. (*c*) Determine the Poynting vector, and use it to find the intensity of the wave.

47 •• **ENGINEERING APPLICATION** A circular loop of wire can be used to detect electromagnetic waves. Suppose the signal strength from a 100-MHz FM radio station 100 km distant is 4.0 μW/m^2, and suppose the signal is vertically polarized. What is the maximum rms voltage induced in your antenna, assuming your antenna is a 10.0-cm-radius loop? SSM

48 •• **ENGINEERING APPLICATION** The electric field strength from a radio station some distance from the electric dipole transmitting antenna is given by $(1.00 \times 10^{-4}\ \text{N/C}) \cos[(1.00 \times 10^6\ \text{rad/s})t]$. (*a*) What peak voltage is picked up on a 50.0-cm-long wire oriented parallel with the electric field direction? (*b*) What is the maximum voltage that can be induced by this electromagnetic wave in a conducting loop of radius 20.0 cm, and what orientation of the loop does this require?

49 ••• A parallel-plate capacitor has circular plates of radius a that are separated by a distance d. In the gap between the two plates is a thin straight wire of resistance R that connects the centers of the two plates. A time-varying voltage given by $V_0 \sin \omega t$ is applied across the plates. (*a*) What is the current drawn by the capacitor? (*b*) What is the magnetic field as a function of the radial distance r from the centerline within the capacitor plates? (*c*) What is the phase angle between the current drawn by the capacitor and the applied voltage?

50 •• A 20-kW beam of electromagnetic radiation is normal to a surface that reflects 50 percent of the radiation. What is the force exerted by the radiation on the surface?

51 •• The electric fields of two harmonic electromagnetic waves of angular frequency ω_1 and ω_2 are given by $\vec{E}_1 = E_{10} \cos(k_1 x - \omega_1 t)\hat{\boldsymbol{j}}$ and by $\vec{E}_2 = E_{20} \cos(k_2 x - \omega_2 t + \delta)\hat{\boldsymbol{j}}$. For the resultant of these two waves, find (*a*) the instantaneous Poynting vector and (*b*) the time-averaged Poynting vector. (*c*) Repeat Parts (*a*) and (*b*) if the direction of propagation of the second wave is reversed so that $\vec{E}_2 = E_{20} \cos(k_2 x + \omega_2 t + \delta)\hat{\boldsymbol{j}}$. SSM

52 •• Show that $\frac{\partial B_z}{\partial x} = -\mu_0 \epsilon_0 \frac{\partial E_y}{\partial t}$ (Equation 30-10) follows from $\oint_C \vec{B} \cdot d\vec{\ell} = \mu_0 \epsilon_0 \int_S \frac{\partial E_n}{\partial t} dA$ (Equation 30-6*d* and where $I = 0$) by integrating along a suitable curve C and over a suitable surface S in a manner that parallels the derivation of Equation 30-9.

53 •• For your backpacking excursions, you have purchased a radio capable of detecting a signal as weak as 1.00×10^{-14} W/m^2. This radio has a 2000-turn coil antenna that has a radius of 1.00 cm wound on an iron core that increases the magnetic field by a factor of 200. The broadcast frequency of the radio station is 1400 kHz. (*a*) What is the peak magnetic field strength of an electromagnetic wave of this minimum intensity? (*b*) What is the peak emf that it is capable of inducing in the antenna? (*c*) What would be the peak emf induced in a straight 2.00-m-long metal wire oriented parallel to the direction of the electric field?

54 •• The intensity of the sunlight striking Earth's upper atmosphere is 1.37 kW/m^2. (*a*) Find the rms values of the magnetic and electric fields of this light. (*b*) Find the average power output of the Sun. (*c*) Find the intensity and the radiation pressure at the surface of the Sun.

55 ••• A conductor in the shape of a long solid cylinder that has a length L, a radius a, and a resistivity ρ carries a steady current I that is uniformly distributed over its cross section. (*a*) Use Ohm's law to relate the electric field E in the conductor to I, ρ, and a. (*b*) Find the magnetic field $\vec{B}$ just outside the conductor. (*c*) Use the results from Part (*a*) and Part (*b*) to compute the Poynting vector $\vec{S} = (\vec{E} \times \vec{B})/\mu_0$ at $r = a$ (the edge of the conductor). In what direction is $\vec{S}$? (*d*) Find the flux $\oint S_n\, dA$ through the surface of the cylinder, and use the flux to show that the rate of energy flow into the conductor equals I^2R, where R is the resistance of the cylinder. SSM

56 ••• A long solenoid that has n turns per unit length carries a current that increases linearly with time. The solenoid has radius R, length L, and the current I in the windings is given by $I = at$. (*a*) Find the induced electric field at a distance $r < R$ from the central axis of the solenoid. (*b*) Find the magnitude and direction of the Poynting vector $\vec{S}$ at $r = R$ (just inside the solenoid windings). (*c*) Calculate the flux $\oint S_n\, dA$ into the region inside the solenoid, and show that the flux equals the rate of increase of the magnetic energy inside the solenoid.

57 ••• Small particles are blown out of the solar system by the radiation pressure of sunlight. Assume that each particle is spherical, has a radius r, has a density of 1.00 g/cm^3, and absorbs all the radiation in a cross-sectional area of πr^2. Assume the particles are located at some distance d from the Sun, which has a total power output of 3.83×10^{26} W. (*a*) What is the critical value for the radius r of the particle for which the radiation force of repulsion just balances the gravitational force of attraction to the Sun? (*b*) Do particles that have radii larger than the critical value get ejected from the solar system, or is it only particles that have radii smaller than the critical value that get ejected? Explain your answer.

58 ••• When an electromagnetic wave at normal incidence on a perfectly conducting surface is reflected, the electric field of the reflected wave at the reflecting surface is equal and opposite to the electric field of the incident wave at the reflecting surface. (*a*) Explain why this assertion is valid. (*b*) Show that the superposition of incident and reflected waves results in a standing wave. (*c*) Are the magnetic fields of the incident waves and reflected waves at the reflecting surface equal and opposite as well? Explain your answer.

59 ••• An intense point source of light radiates 1.00 MW isotropically (uniformly in all directions). The source is located 1.00 m above an infinite, perfectly reflecting plane. Determine the force that the radiation pressure exerts on the plane. SSM

PART V LIGHT

CHAPTER 31

LIGHT IS TRANSMITTED BY TOTAL INTERNAL REFLECTION THROUGH TINY GLASS FIBERS. *(© James L. Amos/Corbis.)*

? How large must the angle of incidence of the light on the wall of the tube be so that no light escapes? (See Example 31-4.)

Properties of Light

The human eye is sensitive to electromagnetic radiation with wavelengths from approximately 400 nm to 700 nm.* The shortest wavelengths in the visible spectrum correspond to violet light and the longest to red light. The perceived colors of light are the result of the physiological and psychological responses of the eyes and brain to the different frequencies of visible light. Although the correspondence between perceived color and frequency is quite good, there are many interesting deviations. For example, a mixture of red light and green light is perceived by the eyes and brain as yellow—even in the absence of light in the yellow region of the spectrum.

* Wavelengths as short as 380 nm and as long as 780 nm can be seen by some individuals.

In this chapter, we study how light is produced; how its speed is measured; and how light is scattered, reflected, refracted, and polarized.

31-1 THE SPEED OF LIGHT

Prior to the seventeenth century the speed of visible light was thought by many people to be infinite, and an effort to measure the speed of visible light was made by Galileo. He and a partner stood on hilltops about three kilometers apart, each with a lantern and a shutter to cover it. Galileo proposed to measure the time it took for visible light to travel back and forth between the experimenters. First, one would uncover his lantern, and when the other saw the light he would uncover his lantern. The time between the first partner's uncovering his lantern and his seeing the light from the other lantern would be the time it took for light to travel back and forth between the experimenters. Though this method is sound in principle, the speed of light is so great that the time interval to be measured is much smaller than variations in human response time, so Galileo was unable to obtain a value for the speed of light.

The first indication of the true magnitude of the speed of light came from astronomical observations of the period of Io, one of the moons of Jupiter. This period is determined by measuring the time between eclipses of Io. An eclipse occurs when Io enters the region behind Jupiter where no direct sunlight reaches. The eclipse period is about 42.5 h, but measurements made when Earth is moving away from Jupiter along path *ABC* in Figure 31-1 give a greater time for this period than do measurements made when Earth is moving toward Jupiter along path *CDA* in the figure. Because these measurements differ from the average value by only about 15 s, the discrepancies were difficult to measure accurately. In 1675, the astronomer Ole Römer attributed these discrepancies to the fact that the speed of light is finite, and that during the 42.5 h between eclipses of Jupiter's moon, the distance between Earth and Jupiter changes, making the path for the light longer or shorter. Römer devised the following method for measuring the cumulative effect of these discrepancies. Jupiter is moving much more slowly than Earth, so we can neglect its motion. When Earth is at point *A*, nearest to Jupiter, the distance between Earth and Jupiter is changing negligibly. The period of Io's eclipse is measured, providing the time between the beginnings of successive eclipses. Based on this measurement, the number of eclipses during 6 months is computed, and the time when an eclipse should begin a half-year later when Earth is at point *C* is predicted. When Earth is actually at point *C*, the observed beginning of the eclipse is about 16.6 min later than predicted. This is the time it takes light to travel a distance equal to the diameter of Earth's orbit. This calculation neglects the distance traveled by Jupiter toward Earth. However, because the orbital speed of Jupiter is so much slower than that of Earth, the distance Jupiter moves toward (or away from) Earth during the 6 months is much less than the diameter of Earth's orbit.

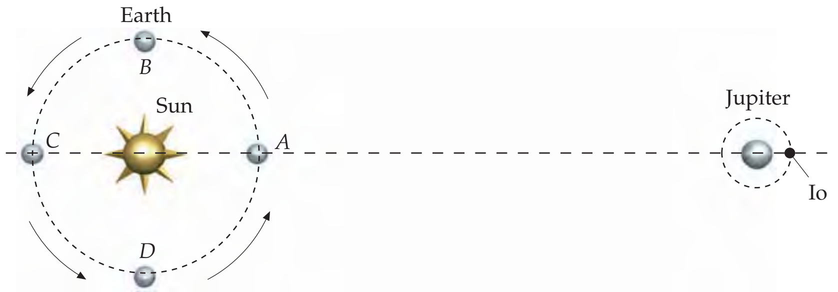

FIGURE 31-1 Römer's method of measuring the speed of light. The time between eclipses of Jupiter's moon Io appears to be greater when Earth is moving along path *ABC* than when Earth is moving along path *CDA*. The difference is due to the time it takes light to travel the distance traveled by Earth along the line of sight during one period of Io.

PRACTICE PROBLEM 31-1

Calculate (*a*) the distance traveled by Earth between successive eclipses of Io and (*b*) the speed of light, given that the time between successive eclipses is 15 s longer than average when Earth is moving directly away from Jupiter.

The French physicist Armand Fizeau made the first nonastronomical measurement of the speed of visible light in 1849. On a hill in Paris, Fizeau placed a light source and a system of lenses arranged so that the light reflected from a semitransparent mirror was focused on a gap in a toothed wheel, as shown in Figure 31-2.

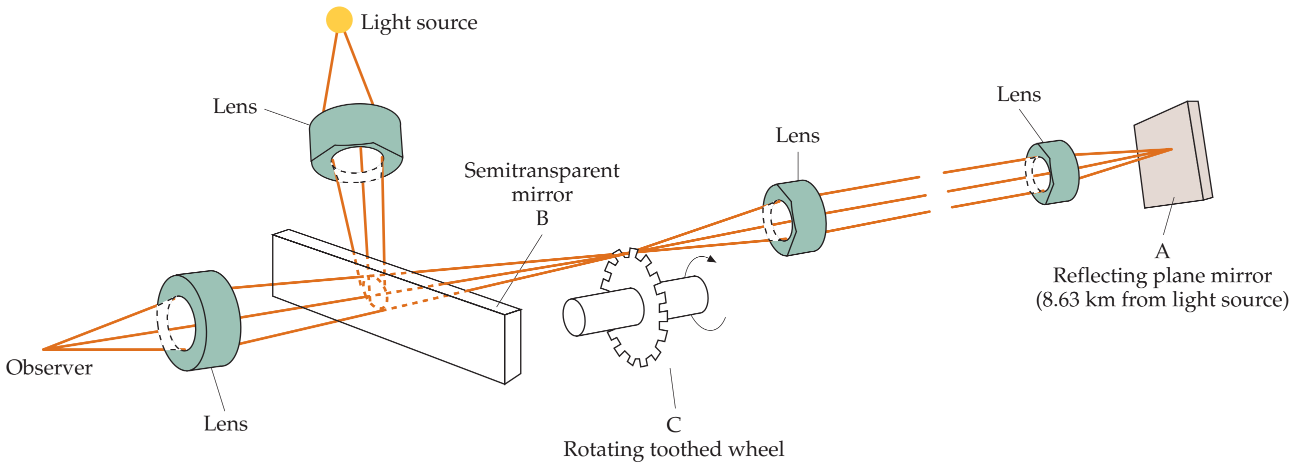

FIGURE 31-2 Fizeau's method of measuring the speed of light. Light from the source is reflected by mirror B and is transmitted through a gap in the toothed wheel to mirror A. The speed of light is determined by measuring the angular speed of the wheel that will permit the reflected light to pass through the next gap in the toothed wheel so that an image of the source is observed.

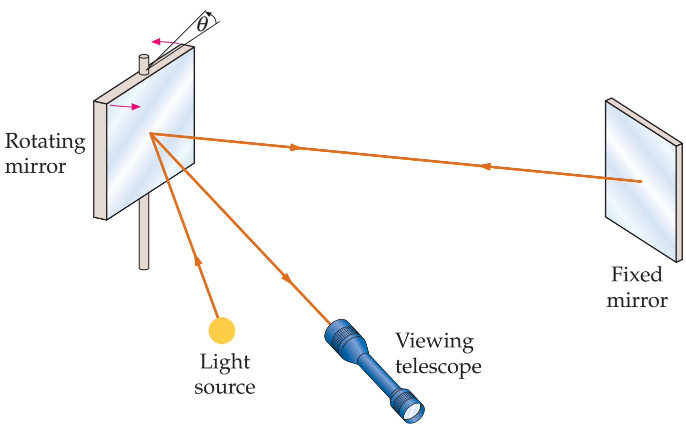
On a distant hill (about 8.63 km away) Fizeau placed a mirror to reflect the light back, to be viewed by an observer as shown. The toothed wheel was rotated, and the speed of rotation was varied. At low speeds of rotation, no light was visible because the light that passed through a gap in the rotating wheel and was reflected back by the mirror was obstructed by the next tooth of the wheel. The speed of rotation was then increased. The light suddenly became visible when the rotation speed was such that the reflected light passed through the next gap in the wheel. The time for the wheel to rotate through the angle between successive gaps equals the time for the light to make the round trip to the distant mirror and back.

Fizeau's method was improved upon by Jean Foucault, who replaced the toothed wheel with a rotating mirror, as shown in Figure 31-3. Light that strikes the rotating mirror is reflected toward a distant fixed mirror, where it is reflected back toward the rotating mirror. The light is then reflected toward the telescope by the rotating mirror. During the time taken for the light to travel from the rotating mirror to the distant fixed mirror and back, the mirror rotates through a small angle θ. By measuring the angle θ, the time for the light to travel to the distant mirror and back is determined. In approximately 1850, Foucault measured the speed of light in air and in water, and he showed that the speed of light in water is less than the speed of light in air. Using essentially the same method, the American physicist Albert Michelson made more precise measurements of the speed of light in approximately 1880. A half-century later, Michelson made even more precise measurements of the speed of light, using an octagonal rotating mirror (Figure 31-4). In these measurements, the mirror rotates through one-eighth of a turn during the time it takes for the light to travel to the fixed mirror and back. The rotation rate is varied until another face of the mirror is in the right position for the reflected light to enter the telescope.

FIGURE 31-3 Simplified drawing of Foucault's method of measuring the speed of light.



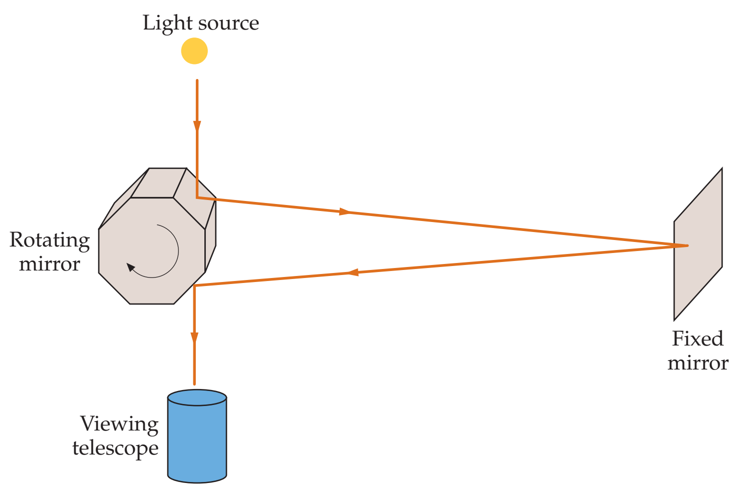


FIGURE 31-4 Simplified drawing of Michelson's method of measuring the speed of light at Mt. Wilson in the late 1920s.

Another method of determining the speed of light involves the measurement of the electrical constants ϵ_0 and μ_0 to determine c from $c = 1/\sqrt{\epsilon_0 \mu_0}$.

The various methods we have discussed for measuring the speed of light are all in agreement. Today, the speed of light is defined to be exactly

$$c = 299\,792\,458 \text{ m/s} \tag{31-1}$$

DEFINITION—SPEED OF LIGHT

and the standard unit of length, the meter, is defined in terms of this speed and the standard unit of time. The meter is the distance light travels (in a vacuum) in $1/299\,792\,458$ s. The value 3.00×10^8 m/s for the speed of light is accurate enough for nearly all calculations in this book. The speed of radio waves and all other electromagnetic waves (in a vacuum) is the same as the speed of visible light.

Example 31-1 The Speed of Light

What is the speed of light in feet per nanosecond?

PICTURE This is an exercise in unit conversions. There are ~ 30 cm $= 0.30$ m in 1.0 ft.

SOLVE

1. Convert m/s to ft/ns: $c = 3.0 \times 10^8 \text{ m/s} \times \left(\frac{1.0 \text{ ft}}{0.30 \text{ m}}\right) \times \left(\frac{1.0 \text{ s}}{10^9 \text{ ns}}\right) = \boxed{1.0 \text{ ft/ns}}$

Example 31-2 Fizeau's Determination of *c*

You are attempting to reproduce Fizeau's determination of the speed of light. Using a wheel that has 720 teeth, light is observed when the wheel rotates at 22.3 rev/s. If the distance from the wheel to the distant mirror is 8.63 km, what value do these numbers give for the speed of light?

PICTURE The time taken for the light to travel from the wheel to the mirror and back is the time for the wheel to rotate one Nth of a revolution, where $N = 720$ is the total number of teeth.

SOLVE

1. The speed is the distance divided by the time. The distance from the wheel to the mirror is L: $c = \frac{2L}{\Delta t}$
2. The angular displacement equals the angular speed multiplied by the time: $\Delta\theta = \omega\,\Delta t$
3. Solve for the time: $\Delta t = \frac{\Delta\theta}{\omega}$
4. Substitute for Δt and solve for c: $c = \frac{2L\omega}{\Delta\theta} = \frac{2(8.63 \times 10^3 \text{ m})(22.3 \text{ rev/s})}{\frac{1}{720} \text{ rev}} = \boxed{2.77 \times 10^8 \text{ m/s}}$

CHECK This result is slightly more than 7 percent too low for the speed of light. However, because it is only 7 percent off, it is a plausible answer.

PRACTICE PROBLEM 31-2 Space travelers on the moon use electromagnetic waves to communicate with the space control center on Earth. Use $c = 3.00 \times 10^8$ m/s to calculate the time delay for their signal to reach Earth, which is 3.84×10^8 m away.

CONCEPT CHECK 31-1

The step-4 result to Example 31-2 is 7 percent too low. What might account for this discrepancy between this measured value and the known value for the speed of light? An error in counting the number of teeth, in measuring the angular speed, or in measuring the distance to the mirror are possible sources of error, but they are unlikely sources of error. There is a more likely source of error. Can you find it?

Large distances are often given in terms of the distance traveled by light in a given time. For example, the distance to the Sun is 8.33 light-minutes, written 8.33 $c \cdot$ min. A light-year is the distance light travels in one year. We can easily find a conversion factor between light-years and meters. The number of seconds in one year is

$$1\text{ y} = 1\text{ y} \times \frac{365.24\text{ d}}{1\text{ y}} \times \frac{24\text{ h}}{1\text{ d}} \times \frac{3600\text{ s}}{1\text{ h}} = 3.156 \times 10^7\text{ s}$$

(*Note:* There are approximately π multiplied by 10^7 seconds per year, which is the mechanism by which some individuals remember the approximate value of the conversion.) The number of meters in one light-year is

$$1\, c \cdot y = (2.998 \times 10^8\text{ m/s})(3.156 \times 10^7\text{ s}) = 9.46 \times 10^{15}\text{ m} \qquad 31\text{-}2$$

31-2 THE PROPAGATION OF LIGHT

The propagation of light is governed by the wave equation discussed in Chapter 30. But long before Maxwell's theory of electromagnetic waves, the propagation of light and other waves was described empirically by two interesting and very different principles attributed to the Dutch physicist Christian Huygens (1629–1695) and the French mathematician Pierre de Fermat (1601–1665).

HUYGENS'S CONSTRUCTION

Figure 31-5 shows a portion of a spherical wavefront emanating from a point source. The wavefront is the locus of points of constant phase. If the radius of the wavefront is r at time t, its radius at time $t + \Delta t$ is $r + c\,\Delta t$, where c is the speed of the wave. However, if a part of the wave is blocked by some obstacle or if the wave passes through a different medium, as in Figure 31-6, the determination of the new wavefront position at time $t + \Delta t$ is much more difficult. The propagation of any wavefront through space can be described using a geometric construction invented by Huygens in approximately 1678, which is now known as **Huygens's construction** or **Huygens's principle:**

> Each point on a primary wavefront serves as the source of spherical secondary wavelets that advance at the wavespeed for the propagating medium. The primary wavefront at some later time is the envelope of these wavelets.
>
> HUYGENS'S CONSTRUCTION

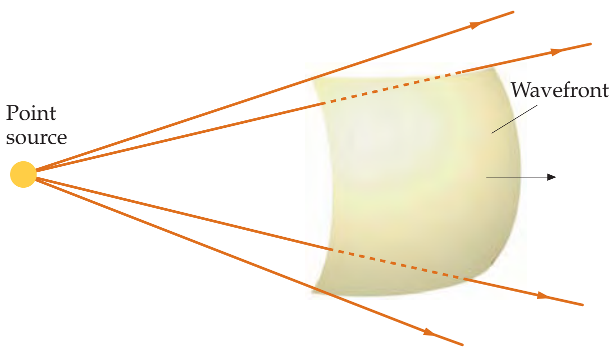

FIGURE 31-5 Spherical wavefront from a point source.

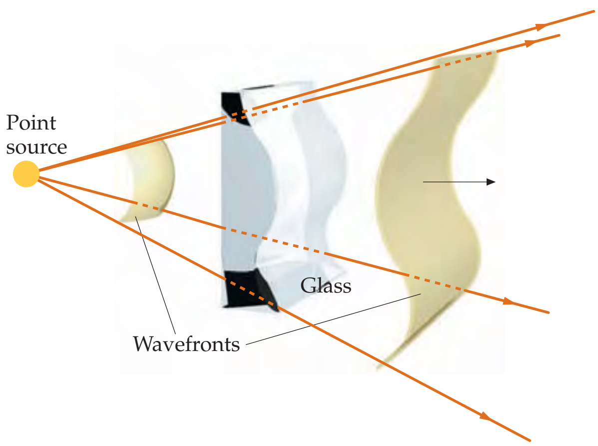

FIGURE 31-6 Wavefront from a point source before and after passing through a piece of glass of varied thickness.

Figure 31-7 shows the application of Huygens's construction to the propagation of a plane wave and the propagation of a spherical wave. Of course, if each point on a wavefront were really a point source, there would be waves in the backward direction as well. Huygens ignored those back waves.

Huygens's construction was later modified by Augustin Fresnel, so that the new wavefront was calculated from the old wavefront by superposition of the wavelets considering their relative amplitudes and phases. Kirchhoff later showed that the Huygens–Fresnel construction was a consequence of the wave equation (Equation 30-8*a*), thus putting it on a firm mathematical basis. Kirchhoff showed that the intensity of each wavelet depends on the angle and is zero at 180° (the backward direction).

We will use Huygens's construction to derive the laws of reflection and refraction in Section 31-5. In Chapter 33, we apply Huygens's construction with Fresnel's modification to calculate the diffraction pattern of a single slit. Because the wavelength of light is so small, we can often use the ray approximation to describe its propagation.

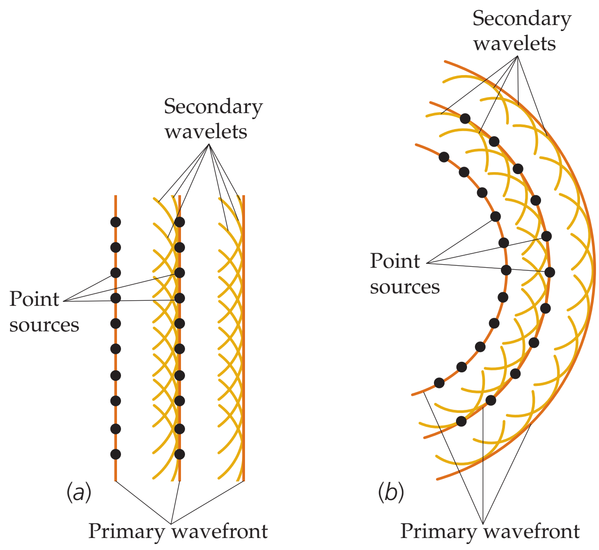

FIGURE 31-7 Huygens's construction for the propagation from left to right of a primary wavefront of (*a*) a plane wave and (*b*) an outgoing spherical, or circular, wave.

FERMAT'S PRINCIPLE

The propagation of light can also be described by Fermat's principle:

> The path taken by light traveling from one point to another is such that the time of travel is a minimum. That is, light travels along the path of least time.*
>
> FERMAT'S PRINCIPLE

The path of least time is not necessarily the path of shortest distance. For example, suppose you are a lifeguard at one end of a pool and a person needs immediate assistance at the far end of the pool. You could get to the person by swimming the entire length of the pool, but you would get to the person more quickly if you ran along the perimeter of the pool and entered the water only when you are near the person.

In Section 31-5, we will use Fermat's principle to derive the laws of reflection and refraction.

31-3 REFLECTION AND REFRACTION

The speed of light in a transparent medium such as air, water, or glass is less than the speed $c = 3 \times 10^8$ m/s in vacuum.† A transparent medium is characterized by an **index of refraction,** n, which is defined as the ratio of the speed of light in a vacuum, c, to the speed in the medium, v:

$$n = \frac{c}{v} \qquad 31\text{-}3$$

DEFINITION—INDEX OF REFRACTION

* A more complete and general statement is that the time of travel is stationary with respect to variations in path; that is, if t is expressed in terms of some parameter x, the path taken will be such that $dt/dx = 0$. The important characteristic of a stationary path is that the time taken along nearby paths will be approximately the same as that along the stationary path.

† It is not the case that the wave speed is never greater than c. In certain materials it is greater than c. However, this does not mean that information can travel at speeds greater than c.

For water, $n = 1.33$, whereas for glass n ranges from approximately 1.50 to 1.66, depending on the type of glass. Diamond has a very high index of refraction—approximately 2.4. The index of refraction of air is approximately 1.0003, so for most purposes we can assume that the speed of light in air is the same as the speed of light in vacuum.

When a beam of light strikes a boundary surface separating two different media, such as an air–glass interface, part of the light energy is reflected and part of the light energy enters the second medium. If the incident light is not perpendicular to the surface, then the transmitted beam is not parallel to the incident beam. The change in direction of the transmitted ray is called **refraction.** Figure 31-8 shows a light ray striking a smooth air–glass interface. The angle θ_1 between the incident ray and the normal (the line perpendicular to the surface) is called the **angle of incidence,** and the plane containing the incident ray and the normal is called the **plane of incidence.** The reflected ray lies in the plane of incidence and makes an angle θ_1' with the normal that is equal to the angle of incidence as shown in the figure:

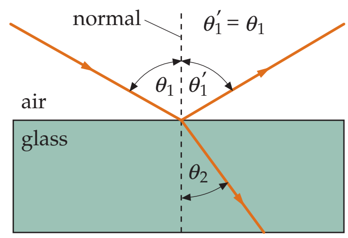

FIGURE 31-8 The angle of reflection θ_1' equals the angle of incidence θ_1. The angle of refraction θ_2 is less than the angle of incidence if the light speed in the second medium is less than that in the incident medium.

See **Math Tutorial** *for more information on* **Trigonometry**

$$\theta_1' = \theta_1 \qquad \text{31-4}$$

LAW OF REFLECTION

This result is known as the **law of reflection.** The law of reflection holds for any type of wave. Figure 31-9 illustrates the law of reflection for rays of light and for wavefronts of ultrasonic waves.

The ray that enters the glass in Figure 31-8 is called the *refracted ray*, and the angle θ_2 is called the angle of refraction. When a wave crosses a boundary where the wave speed is reduced, as in the case of light entering glass from air, the angle of refraction is less than the angle of incidence θ_1, as shown in Figure 31-8; that is, the refracted ray is bent toward the normal. If, on the other hand, the light beam originates in the glass and is refracted into the air, then the refracted ray is bent away from the normal.

The angle of refraction θ_2 depends on the angle of incidence and on the relative speed of light waves in the two mediums. If v_1 is the wave speed in the incident medium and v_2 is the wave speed in the transmission medium, the angles of incidence and refraction are related by

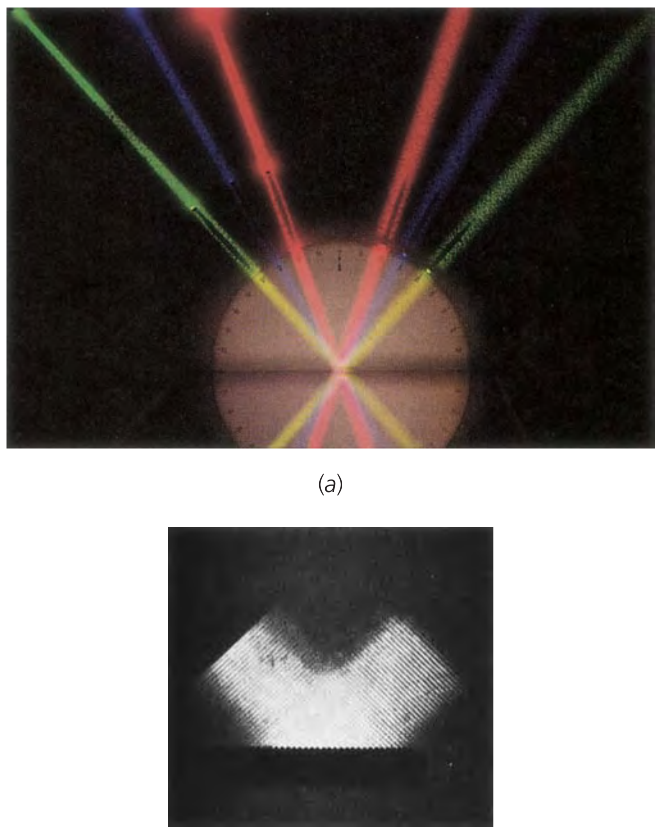
$$\frac{1}{v_1}\sin\theta_1 = \frac{1}{v_2}\sin\theta_2 \qquad \text{31-5}a$$

Equation 31-5*a* holds for the refraction of any kind of wave incident on a boundary separating two media.

The indices of refraction of the two media are n_1 and n_2. Combining Equations 31-3 and 31-5*a* gives

$$n_1 \sin\theta_1 = n_2 \sin\theta_2 \qquad \text{31-5}b$$

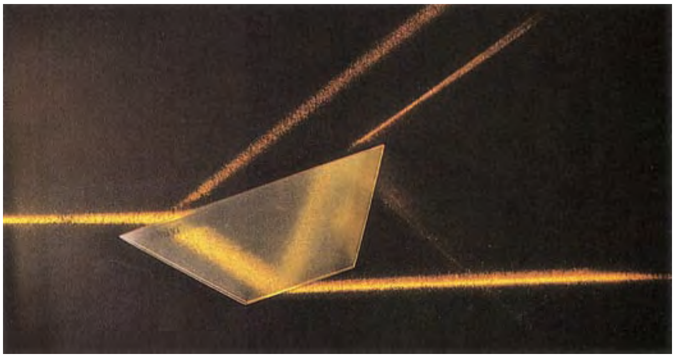
SNELL'S LAW OF REFRACTION



(*a*)

(*b*)

FIGURE 31-9 (*a*) Light rays reflecting from an air–glass interface showing equal angles of incidence and reflection. (*b*) Ultrasonic plane waves in water reflecting from a steel plate. *((a) Ken Kay/Fundamental Photographs. (b) Courtesy Battelle-Northwest Laboratories.)*



Reflection and refraction of a beam of light incident on a glass slab. *(Richard Megna/Fundamental Photographs.)*

This result was discovered experimentally in 1621 by the Dutch scientist Willebrord Snell and is known as **Snell's law** or the **law of refraction.** It was independently discovered a few years later by the French mathematician and philosopher René Descartes.

PHYSICAL MECHANISMS FOR REFLECTION AND REFRACTION

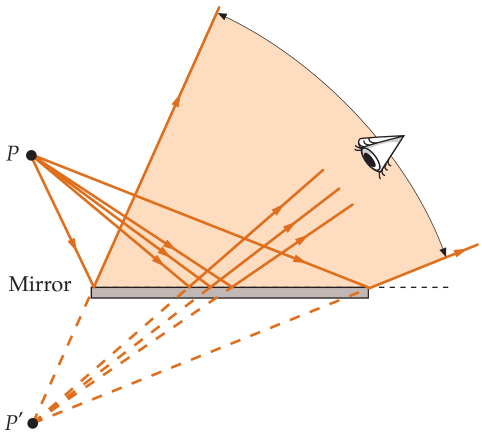
The physical mechanism of the reflection and refraction of light can be understood in terms of the absorption and reradiation of the light by the atoms in the reflecting or refracting medium. When light traveling in air strikes a glass surface, the atoms in the glass absorb the light and reradiate it at the same frequency in all directions. The waves radiated backward by the glass atoms interfere constructively at an angle equal to the angle of incidence to produce the reflected wave.

The transmitted wave is the result of the interference of the incident wave and the wave produced by the absorption and reradiation of light energy by the atoms in the medium. For light entering glass from air, a phase lag exists between the reradiated wave and the incident wave. Therefore, a phase lag also exists between the resultant wave and the incident wave. This phase lag means that the position of a wave crest of the transmitted wave is retarded relative to the position of a wave crest of the incident wave in the medium. As a result, a transmitted wave crest does not travel as far in a given time as the original incident wave crest; that is, the wave speed of the transmitted wave is less than that of the incident wave. The index of refraction is therefore greater than 1. The frequency of the light in the second medium is the same as the frequency of the incident light—the atoms absorb and reradiate the light at the same frequency—but the wave speed is different, so the wavelength of the transmitted light is different from that of the incident light. If λ is the wavelength of light in a vacuum, then $\lambda f = c$, and if λ_n is the wavelength in a medium that has an index of refraction n in which the wave has speed v, then $\lambda_n f = v$. Combining these two relations gives $\lambda/\lambda_n = c/v$, or

$$\lambda_n = \frac{\lambda}{c/v} = \frac{\lambda}{n} \qquad 31\text{-}6$$

SPECULAR REFLECTION AND DIFFUSE REFLECTION

Figure 31-10*a* shows a bundle of light rays from a point source P that are reflected from a flat surface. After reflection, the rays diverge exactly as if they came from a point P' behind the surface. (The point P' is called the *image point*. We will study the formation of images by reflecting and refracting surfaces in the next chapter.) When the rays enter the eye, they cannot be distinguished from rays actually diverging from a source at P'.

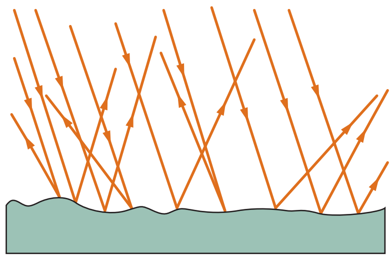


(a)

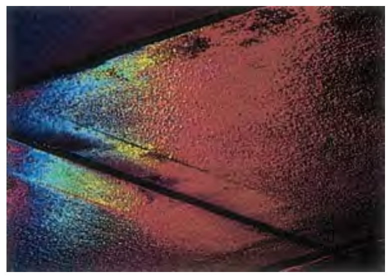
(b)

FIGURE 31-10 (*a*) Specular reflection from a smooth surface. (*b*) Specular reflection of trees from water. *(Macduff Everton/Corbis.)*

Reflection from a smooth surface is called **specular reflection.** It differs from **diffuse reflection,** which is illustrated in Figure 31-11. Here, because the surface is rough, the rays from a point reflect in random directions and do not diverge from any point, so no image exists. The reflection of light from the page of this book is diffuse reflection. The glass used in picture frames is sometimes ground slightly to give diffuse reflection and thereby cut down on glare from the light used to illuminate the picture. Diffuse reflection from the surface of a road allows you to see the road when you are driving at night because some of the light from your headlights reflects back toward you. In wet weather the reflection is mostly specular; therefore, little light is reflected back toward you, which makes the road difficult to see.



(a)



(b)

FIGURE 31-11 (*a*) Diffuse reflection from a rough surface. (*b*) Diffuse reflection of colored lights from a sidewalk. *((b) Pete Saloutos/The Stock Market.)*

RELATIVE INTENSITY OF REFLECTED AND TRANSMITTED LIGHT

The fraction of light energy reflected at a boundary, such as an air–glass interface, depends in a complicated way on the angle of incidence, the orientation of the electric field vector associated with the wave, and the indices of refraction of the two media. For the special case of normal incidence ($\theta_1 = \theta_1' = 0$), the reflected intensity can be shown to be

$$I = \left(\frac{n_1 - n_2}{n_1 + n_2}\right)^2 I_0 \qquad 31\text{-}7$$

where I_0 is the incident intensity and n_1 and n_2 are the indices of refraction of the two media.* For a typical case of reflection from a clean air–glass interface for which $n_1 = 1$ and $n_2 = 1.5$, Equation 31-7 gives $I = I_0/25$. Only about 4 percent of the energy is reflected; the remainder of the energy is transmitted.

* An equation for waves on a string that is similar to Equation 31-7 is presented in Section 4 of Chapter 15.

Example 31-3 Refraction from Air to Water

Light traveling in air enters water with an angle of incidence of 45.0°. If the index of refraction of water is 1.33, what is the angle of refraction?

PICTURE The angle of refraction is found using Snell's law of refraction. Let subscripts 1 and 2 refer to the air and water, respectively. Then $n_1 = 1.00$, $\theta_1 = 45.0°$, $n_2 = 1.33$, and θ_2 is the angle of refraction (Figure 31-12).

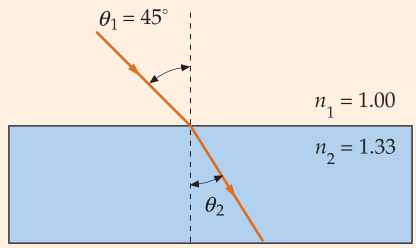


FIGURE 31-12

SOLVE

1. Use Snell's law of refraction to solve for $\sin\theta_2$, the sine of the angle of refraction:

$$n_1 \sin\theta_1 = n_2 \sin\theta_2$$

so

$$\sin\theta_2 = \frac{n_1}{n_2}\sin\theta_1$$

2. Find the angle whose sine is 0.532:

$$\theta_2 = \sin^{-1}\left(\frac{n_1}{n_2}\sin\theta_1\right) = \sin^{-1}\left(\frac{1.00}{1.33}\sin 45.0°\right)$$

$$= \sin^{-1}(0.532) = \boxed{32.1°}$$

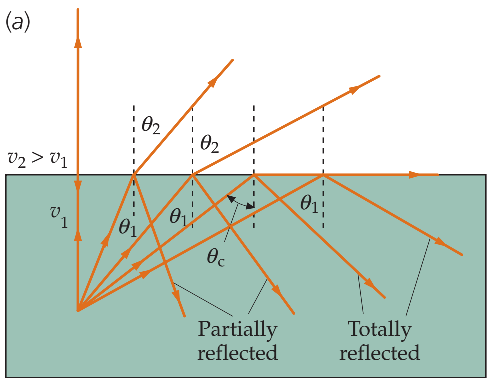
CHECK When entering a medium in which light travels more slowly, light bends toward the normal; so we expect θ_2 to be less than θ_1. The step-2 result meets this expectation.

TAKING IT FURTHER Note that the light is bent toward the normal as the light travels into the medium with the larger index of refraction.

TOTAL INTERNAL REFLECTION

Figure 31-13 shows a point source in glass and rays striking the glass–air interface at various angles. All the rays not perpendicular to the interface are bent away from the normal. As the angle of incidence is increased, the angle of refraction increases until a critical angle of incidence θ_c is reached for which the angle of refraction is 90°. For incident angles greater than the critical angle, no refracted ray exists. All the energy is reflected. This phenomenon is called **total internal reflection.** The critical angle can be found in terms of the indices of refraction of the two media by solving Equation 31-5*b* ($n_1 \sin\theta_1 = n_2 \sin\theta_2$) for $\sin\theta_1$ and setting θ_2 equal to 90°.

(*a*)



(*b*)

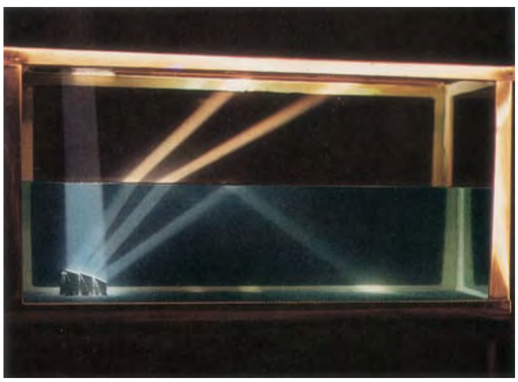


FIGURE 31-13 (*a*) Total internal reflection. As the angle of incidence is increased, the angle of refraction is increased until, at a critical angle of incidence θ_c, the angle of refraction is 90°. For angles of incidence greater than the critical angle, there is no refracted ray. (*b*) A photograph of refraction and total internal reflection from a water–air interface. *(Ken Kay/Fundamental Photographs.)*

That is,

$$\sin\theta_c = \frac{n_2}{n_1}\sin 90° = \frac{n_2}{n_1} \qquad 31\text{-}8$$

CRITICAL ANGLE FOR TOTAL INTERNAL REFLECTION

Note that total internal reflection occurs only when the incident light is in the medium that has the higher index of refraction. Mathematically, if n_2 is greater than n_1, Snell's law of refraction cannot be satisfied because there is no angle whose sine is greater than 1.

Example 31-4 Total Internal Reflection

Try It Yourself

A particular glass has an index of refraction of $n = 1.50$. What is the critical angle for total internal reflection for light leaving the glass and entering air, for which $n = 1.00$?

PICTURE Apply the law of refraction (Equation 31-5*b*) with the angle of refraction equal to 90°.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. Make a diagram (Figure 31-14) showing the incident and refracted rays. For the critical angle, the angle of refraction is 90°.	
2. Apply the law of refraction (Equation 31-5*b*). The critical angle is the angle of incidence.	$\theta_c = \boxed{41.8°}$

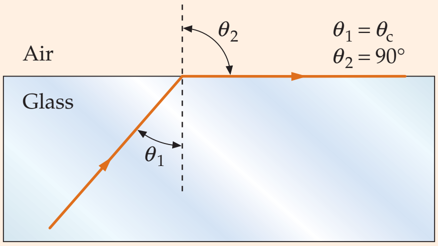

FIGURE 31-14

CHECK Figure 31-13*b* shows that the critical angle for a water-air boundary is a bit larger than 45°. Because the index of refraction for glass is somewhat larger than the index for water, we expect a critical angle for a glass-water boundary to be a bit less than 45°. An angle of 41.8° meets this expectation.

Example 31-5 How Deep Are You?

Context-Rich

You are spending time at the pool. While under the water, you look up and notice that you see objects above water level in a circle of light of radius approximately 2.0 m, and the rest of your vision is the color of the sides of the pool. How deep are you below the surface of the water?

PICTURE We can determine the depth of the pool from the radius of the light and the angle at which the light is entering your eye from the edge of the circle. At the edge of the circle the light is entering the water at 90.0°, so the angle of refraction at the air–water surface is the critical angle for total internal reflection at the water–air surface. From Figure 31-15, we see that the depth y is related to this angle and the radius of the circle R by $\tan\theta_c = R/y$. The critical angle is found from Equation 31-8 with $n_2 = 1.00$ and $n_1 = 1.33$.

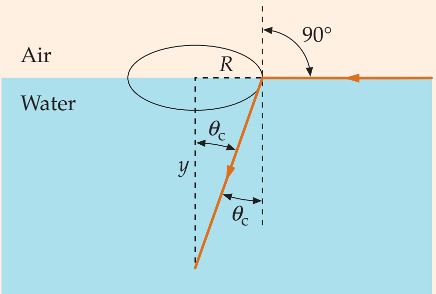

FIGURE 31-15

SOLVE

1. The depth y is related to the radius of the circle R and the critical angle θ_c: $\tan\theta_c = R/y$

2. Solve for the depth y: $y = \dfrac{R}{\tan\theta_c}$

3. Find the critical angle for total internal reflection at a water–air surface: $\sin\theta_c = \dfrac{n_2}{n_1} = \dfrac{1.00}{1.33} = 0.752$

   $\theta_c = 48.8°$

4. Solve for the depth y: $y = \dfrac{R}{\tan\theta_c} = \dfrac{2.0\text{ m}}{\tan 48.8°} = \boxed{1.7\text{ m}}$

CHECK The step-4 result seems like a plausible value. Most swimming pools are at least that deep.

Figure 31-16*a* shows light reaching one of the short sides of a 45–45–90° glass prism at normal incidence. If the index of refraction of the glass is 1.5, the critical angle for total internal reflection is 41.8°, as we calculated in Example 31-4. Because the angle of incidence of the ray on the glass–air interface is 45°, the light will be totally reflected and will exit perpendicular to the other face of the prism, as shown. In Figure 31-16*b*, the light is incident perpendicular to the hypotenuse of the prism and is totally reflected twice so that it emerges at 180° to its original direction. Prisms are used to change the directions of light rays. In binoculars, two prisms are used on each side. These prisms reflect the light, thus shortening the required length, and reinvert the image (first inverted by a lens).* Diamonds have a very large index of refraction ($n \approx 2.4$), so nearly all the light that enters a diamond is eventually reflected back out, giving the diamond its sparkle.

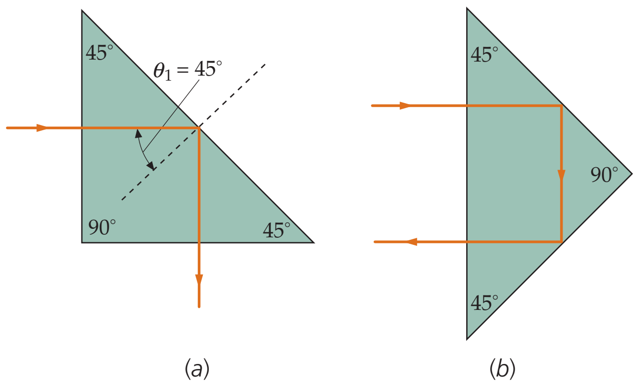

FIGURE 31-16 (*a*) Light entering through one of the short sides of a 45–45–90° glass prism is totally reflected. (*b*) Light entering through the long side of the prism is totally reflected twice.

Fiber optics An interesting application of total internal reflection is the transmission of a beam of light down a long, narrow, transparent glass fiber (Figure 31-17*a*). If the beam begins approximately parallel to the axis of the fiber, it will strike the walls of the fiber at angles greater than the critical angle (if the bends in the fiber are not too sharp) and no light energy will be lost through the walls of the fiber. A bundle of such fibers can be used for imaging, as illustrated in Figure 31-17*b*.

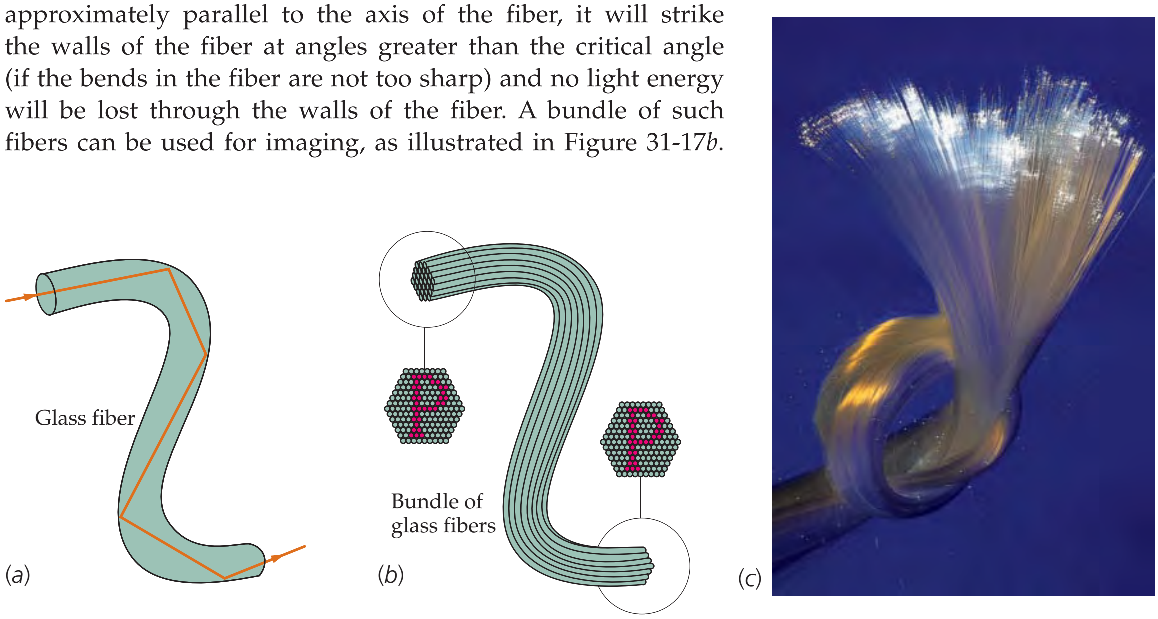

FIGURE 31-17 (*a*) A light pipe. Light inside the pipe is always incident at an angle greater than the critical angle, so no light escapes the pipe by refraction. (*b*) Light from the object is transported by a bundle of glass fibers to form an image of the object at the other end of the pipe. (*c*) Light emerging from a bundle of glass fibers. *((c) Ted Horowitz/The Stock Market.)*

Fiber optics has many applications in medicine and in communications. In medicine, light is transmitted along tiny fibers to visually probe various internal organs without surgery. In communications, the rate at which information can be transmitted is related to the signal frequency. A transmission system using light of frequencies of the order of 10^{14} Hz can transmit information at a much greater rate than one using radio waves, which have frequencies of the order of 10^6 Hz. In telecommunication systems, a single glass fiber that is the thickness of a human hair can transmit audio or video information equivalent to 32 000 voices speaking simultaneously.

* The image produced by the objective lens of a telescope is discussed in Section 32-4.

MIRAGES

When the index of refraction of a medium changes gradually, the refraction is continuous, leading to a gradual bending of the light. An interesting example of this is the formation of a mirage. On a hot and sunny day, the surface of exposed rocks, pavement, and sand often gets very hot. In this case there is often a layer of air near the ground that is warmer, and therefore less dense, than the air just above it. The speed of any light wave is slightly greater in this less dense layer, so a light beam passing from the cooler layer into the warmer layer is bent. Figure 31-18*a* shows the light from a tree when all the surrounding air is at the same temperature. The wavefronts are spherical, and the rays are straight lines. In Figure 31-18*b*, the air near the ground is warmer, resulting in the wavefronts traveling faster there. The portions of the wavefronts near the hot ground get ahead of the higher portions, creating a nonspherical wavefront and causing a curving of the rays. Thus, the ray shown initially heading for the ground is bent upward. As a result, the viewer sees an image of the tree looking as if it were reflected off a water surface on the ground. When driving on a hot sunny day, you may have noticed apparent wet spots on the highway ahead that disappear as you approach them. These mirages are due to the refraction of light from the sky by a layer of air that has been heated due to its proximity to the hot pavement.

DISPERSION

The index of refraction of a material has a slight dependence on wavelength. For many materials, n decreases slightly as the wavelength increases, as shown in Figure 31-19. The dependence of the index of refraction on wavelength (and therefore on frequency) is called **dispersion.** When a beam of white light is incident at some angle on the surface of a glass prism, the angle of refraction (which is measured relative to the normal) for the shorter wavelengths is slightly smaller than the angle of refraction for the longer wavelengths. The light of shorter wavelength (toward the violet end of the spectrum) is therefore bent more toward the normal than that of longer wavelength. The beam of white light is thus spread out or dispersed into its component colors or wavelengths (Figure 31-20).

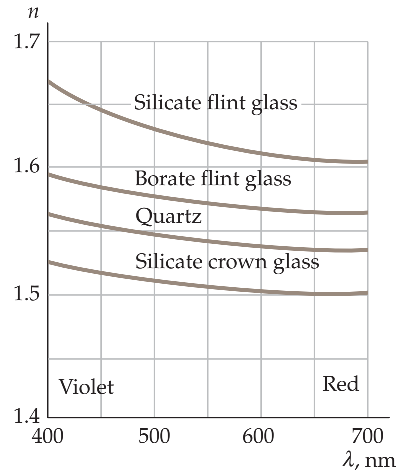

FIGURE 31-19 Index of refraction versus wavelength for various materials.

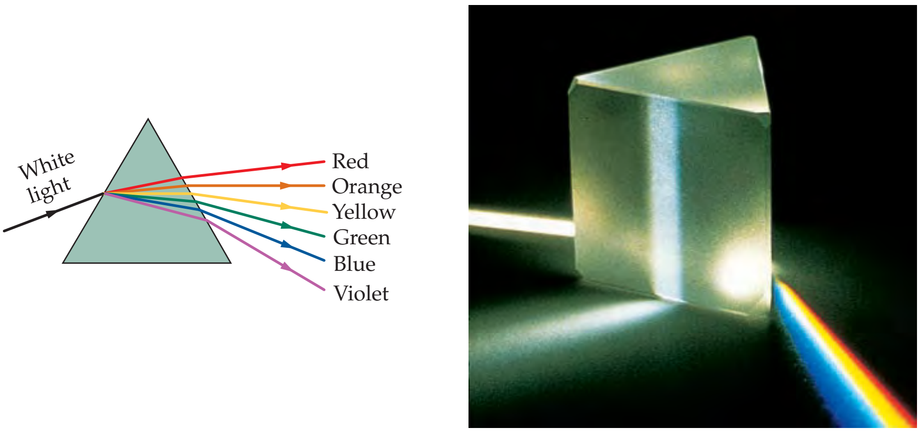

FIGURE 31-20 A beam of white light incident on a glass prism is dispersed into its component colors. The index of refraction decreases as the wavelength increases so that the longer wavelengths (red) are bent less than the shorter wavelengths (blue). *(David Parker/ Science Photo Library/Photo Researchers.)*

Rainbows The rainbow is a familiar example of dispersion, in this case the dispersion of sunlight. Figure 31-21 is a diagram originally drawn by Descartes, showing parallel rays of light from the Sun entering a spherical water drop. First, the rays are refracted as they enter the drop. The rays are then reflected from the water–air interface on the other side of the drop and finally are refracted again as they leave the drop.

From Figure 31-21, we can see that the angle made by the emerging rays and the diameter (along ray 1) reaches a maximum around ray 7 and then decreases. The concentration of rays emerging at approximately the maximum angle gives rise to the rainbow. By construction, using the law of refraction, Descartes showed that the maximum angle is about 42°. To observe a rainbow, we must therefore look at the water drops at an angle of 42° relative to the line back to the Sun, as shown in Figure 31-22. The angular radius of the rainbow is therefore 42°.

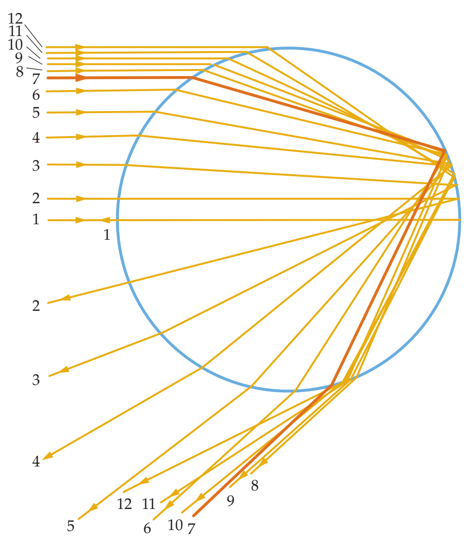

FIGURE 31-21 Descartes's construction of parallel rays of light entering a spherical water drop. Ray 1 enters the drop along a diameter and is reflected back along its incident path. Ray 2 enters slightly above the diameter and emerges below the diameter at a small angle with the diameter. The rays entering farther and farther away from the diameter emerge at greater and greater angles up to ray 7, shown as the heavy line. Rays entering above ray 7 emerge at smaller and smaller angles with the diameter.

The separation of the colors in the rainbow results from the fact that the index of refraction of water depends slightly on the wavelength of light. The angular radius of the rainbow will therefore depend slightly on the wavelength of the light. The observed rainbow is made up of light rays from many different droplets of water (Figure 31-23). The color seen at a particular angular radius corresponds to the wavelength of light that allows the light to reach the eye from the droplets at that angular radius. Because n_{water} is smaller for red light than for blue light, the red part of the rainbow is at a slightly greater angular radius than the blue part of the rainbow, so red is at the outer side of the rainbow.

When a light ray strikes a surface separating water and air, part of the light is reflected and part of the light is refracted. A secondary rainbow results from the light rays that are reflected twice within a droplet (Figure 31-24). The secondary rainbow has an angular radius of 51°, and its color sequence is the reverse of that of the primary rainbow; that is, the violet is on the outside in the secondary rainbow. Because of the small fraction of light reflected from a water–air interface, the secondary rainbow is considerably fainter than the primary rainbow.

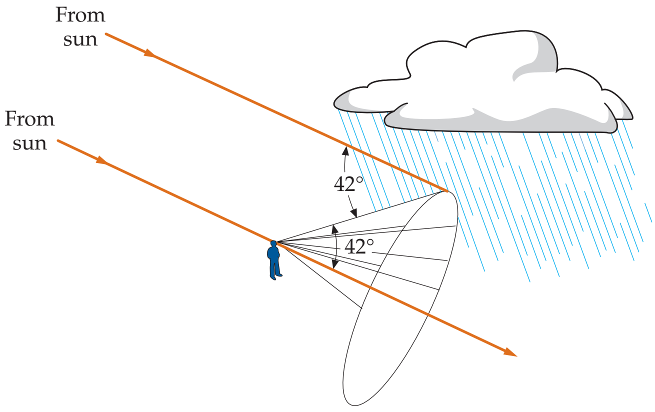

FIGURE 31-22 A rainbow is viewed at an angle of 42° from the line to the Sun, as predicted by Descartes's construction, as shown in Figure 31-21.

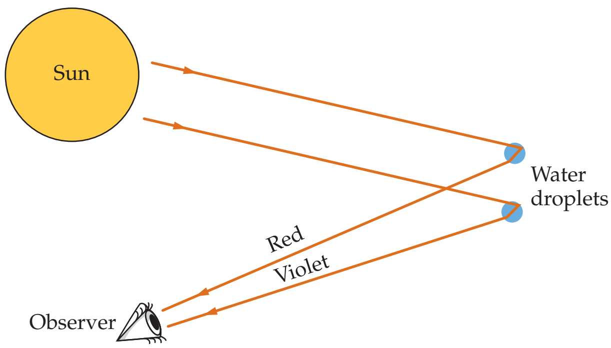

FIGURE 31-23 The rainbow results from light rays from many different water droplets.

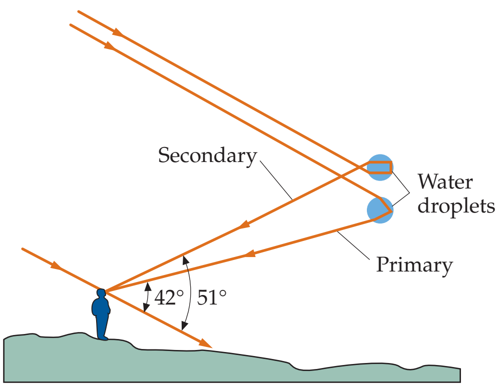

FIGURE 31-24 The secondary rainbow results from light rays that are reflected twice within a water droplet.

(*a*)

(*b*)

(*a*) This 22° halo around the Sun results from refraction by hexagonal ice crystals that are randomly oriented in the upper atmosphere. (*b*) When the ice crystals are not randomly oriented but are falling with their flat bases horizontal, only parts of the halo to the left and to the right of the Sun, called *sun dogs*, are seen. *((a) Robert Greenler. (b) Giovanni DeAmici, NSF, Lawrence Berkeley Laboratory.)*

*Calculating the angular radius of the rainbow

We can calculate the angular radius of the rainbow from the laws of reflection and refraction. Figure 31-25 shows a ray of light incident on a spherical water droplet at point *A*. The angle of refraction θ_2 is related to the angle of incidence θ_1 by Snell's law of refraction:

$$n_{\text{air}} \sin\theta_1 = n_{\text{water}} \sin\theta_2 \qquad \text{31-9}$$

Point *P* in Figure 31-25 is the intersection of the line of the incident ray and the line of the emerging ray. The angle ϕ_d is called the angle of deviation of the ray, and ϕ_d and 2β form a straight angle. Thus,

$$\phi_d + 2\beta = \pi \qquad \text{31-10}$$

We wish to relate the angle of deviation ϕ_d to the angle of incidence θ_1. From the triangle *AOB*, we have

$$2\theta_2 + \alpha = \pi \qquad \text{31-11}$$

Similarly, from the triangle *AOP*, we have

$$\theta_1 + \beta + \alpha = \pi \qquad \text{31-12}$$

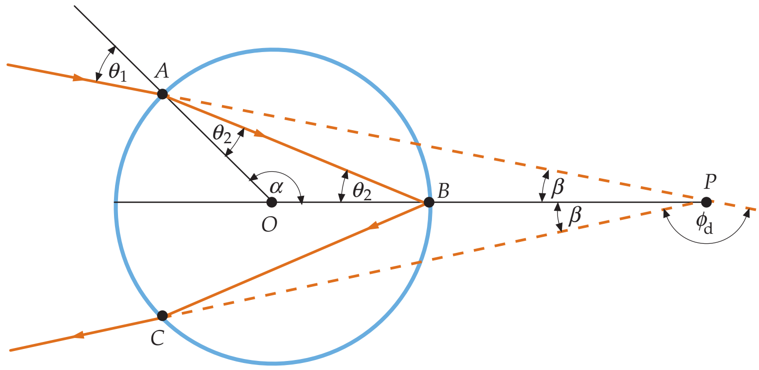

FIGURE 31-25 Light ray incident on a spherical water drop. The refracted ray strikes the back of the water droplet at point *B*. It makes an angle θ_2 with the radial line *OB* and is reflected at an equal angle. The ray is refracted again at point *C*, where it leaves the droplet.

Eliminating α from Equations 31-11 and 31-12 and solving for β gives

$$\beta = \pi - \theta_1 - \alpha = \pi - \theta_1 - (\pi - 2\theta_2) = 2\theta_2 - \theta_1$$

Substituting this value for β into Equation 31-10 gives the angle of deviation:

$$\phi_d = \pi - 2\beta = \pi - 4\theta_2 + 2\theta_1 \qquad \text{31-13}$$

Equation 31-13 can be combined with Equation 31-9 to eliminate θ_2 and give the angle of deviation ϕ_d in terms of the angle of incidence θ_1:

$$\phi_d = \pi + 2\theta_1 - 4\sin^{-1}\left(\frac{n_{\text{air}}}{n_{\text{water}}}\sin\theta_1\right) \qquad \text{31-14}$$

Figure 31-26 shows a plot of ϕ_d versus θ_1. The angle of deviation ϕ_d has its minimum value when $\theta_1 \approx 60°$. At an angle of incidence of 60°, the angle of deviation is $\phi_{d,\,\min} = 138°$. This angle is called the **angle of minimum deviation.** At incident angles that are slightly greater or slightly smaller than 60°, the angle of deviation is approximately the same. Therefore, the intensity of the light reflected by the water droplet will be a maximum at the angle of minimum deviation. We can see from Figure 31-25 that the maximum value of β corresponds to the minimum value of ϕ_d. Thus, the angular radius of the intensity maximum, given by $2\beta_{\max}$, is

$$2\beta_{\max} = \pi - \phi_{d,\,\min} = 180° - 138° = 42° \qquad \text{31-15}$$

The index of refraction of water varies slightly with wavelength. Thus, for each wavelength (color), the intensity maximum occurs at an angular radius slightly different than that of neighboring wavelengths.

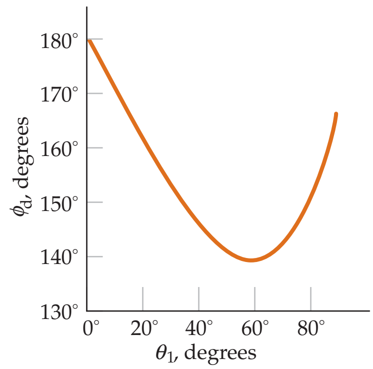

FIGURE 31-26 Plot of the angle of deviation ϕ_d as a function of incident angle θ_1. The angle of deviation has its minimum value of 138° when the angle of incidence is 60°. Because $d\phi_d/d\theta_1 = 0$ at minimum deviation, the deviation of rays with incident angles slightly less or slightly greater than 60° will be approximately the same.

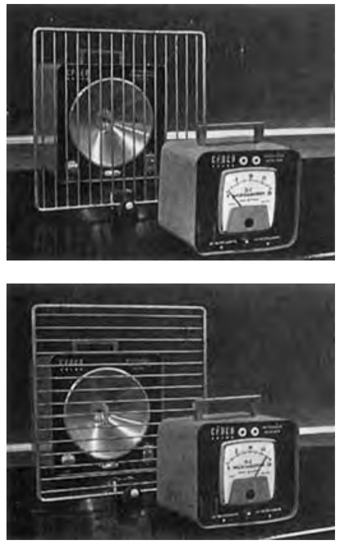
31-4 POLARIZATION

In an electromagnetic wave, the direction of the electric field is perpendicular to the direction of propagation of the wave. If the electric field remains parallel to a line perpendicular to the direction of propagation, the wave is said to be **linearly polarized.** A wave produced by an electric dipole antenna is polarized with the electric field vector at any field point remaining in the plane containing the field point and the antenna axis. Waves produced by numerous sources are usually not polarized. An incandescent light source, for example, contains millions of atoms acting independently. The electric field for such a wave can be resolved into x and y components that vary randomly, because there is no correlation between the individual atoms producing the light.

The polarization of electromagnetic waves can be demonstrated with microwaves, which have wavelengths on the order of centimeters. In a typical microwave generator, polarized waves are radiated by an electric dipole antenna. In Figure 31-27, the electric dipole antenna is vertical, so the electric field vector $\vec{E}$ of the horizontally radiated waves is also vertical. An absorber can be made of a screen of parallel straight wires. When the wires are vertical, as in Figure 31-27*a*, the electric field parallel to the wires sets up currents in the wires and energy is absorbed. When the wires are horizontal and therefore perpendicular to $\vec{E}$, as in Figure 31-27*b*, no currents are set up and the waves are transmitted.

There are four phenomena that produce polarized electromagnetic waves from unpolarized waves: (1) absorption, (2) reflection, (3) scattering, and (4) birefringence (also called double refraction), each of which is examined in the upcoming sections.



(*a*)

(*b*)

FIGURE 31-27 Demonstration showing the polarization of microwaves. The electric field of the microwaves is vertical, parallel to the vertical dipole antenna. (*a*) When the metal wires of the absorber are vertical, electric currents are set up in the wires and energy is absorbed, as indicated by the low reading on the microwave detector. (*b*) When the wires are horizontal, no currents are set up and the microwaves are transmitted, as indicated by the high reading on the detector. *(Larry Langrill.)*

POLARIZATION BY ABSORPTION

Several naturally occurring crystals, when cut into appropriate shapes, absorb and transmit light differently depending on the polarization of the light. These crystals can be used to produce linearly polarized light. In 1938, E. H. Land invented a simple commercial polarizing sheet called Polaroid. This material contains long-chain hydrocarbon molecules that are aligned when the sheet is stretched in one direction during the manufacturing process. These chains become conducting at optical frequencies when the sheet is dipped in a solution containing iodine. When light is incident with its electric field vector parallel to the chains, electric currents are set up along the chains, and the light energy is absorbed, just as the microwaves are absorbed by the wires in Figure 31-27. If the electric field is perpendicular to the chains, the light is transmitted. The direction perpendicular to the chains is called the **transmission axis.** We will make the simplifying assumption that all the light is transmitted when the electric field is parallel to the transmission axis and all the light is absorbed when it is perpendicular to the transmission axis. (In reality, polarizing sheets absorb some of the light, even when the electric field is parallel to the transmission axis.)

Consider an unpolarized light beam incident on a polarizing sheet with its transmission axis along the x direction, as shown in Figure 31-28. The beam is incident on a second polarizing sheet, the analyzer, whose transmission axis makes an angle θ with the x axis. If E is the electric field amplitude of the incident beam, the component parallel with the transmission axis is $E_{\parallel} = E\cos\theta$, and the component perpendicular to the transmission axis is $E_{\perp} = E\sin\theta$. The sheet absorbs $E_{\perp}$ and transmits $E_{\parallel}$, so the transmitted beam has an electric field amplitude of $E_{\parallel} = E\cos\theta$ and is linearly polarized in the direction of the transmission axis. Because the intensity of light is proportional to the square of the magnitude of the electric field amplitude, the intensity I of light transmitted by the sheet is given by

$$I = I_0\cos^2\theta \qquad 31\text{-}16$$

LAW OF MALUS

where I_0 is the intensity of the incident beam. If we have an incident beam of unpolarized light of intensity I_0 incident on a polarizing sheet, the direction of the incident electric field varies from location to location on the sheet, and at each location it fluctuates in time. At each location, the average value of $\cos^2\theta$ is one-half, so applying Equation 31-16 gives $I = I_0(\cos^2\theta)_{\text{av}} = \frac{1}{2}I_0$, where I is the intensity of the transmitted beam.

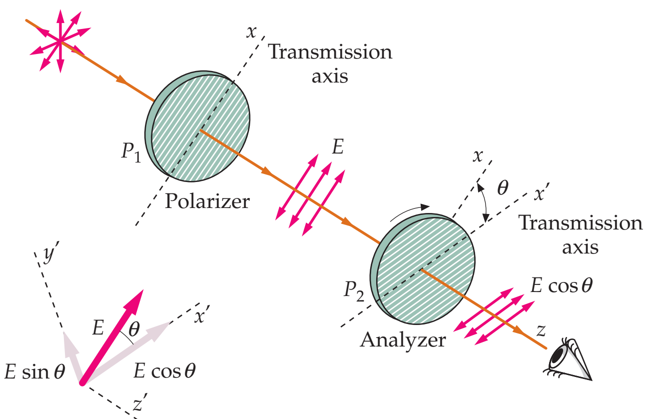


FIGURE 31-28 A vertically polarized beam is incident on a polarizing sheet with its transmission axis x' making an angle θ with the vertical. Only the component $E\cos\theta$ is transmitted through the second sheet, and the transmitted beam is linearly polarized in the direction of the transmission axis x'. If the intensity between the sheets is I_0, the intensity transmitted by the second sheet is $I_0\cos^2\theta$.

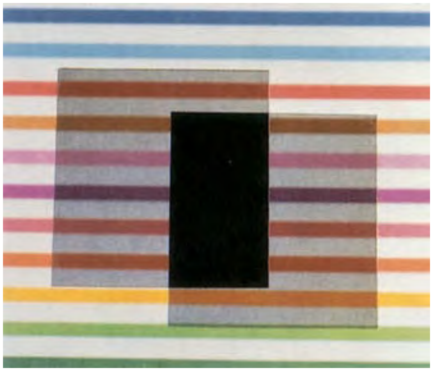
When two polarizing elements are placed in succession in a beam of unpolarized light, the first polarizing element is called the **polarizer** and the second polarizing element is called the **analyzer.** If the polarizer and the analyzer are crossed, that is, if their transmission axes are perpendicular to each other, no light gets through. Equation 31-16 is known as the **law of Malus** after its discoverer, E. L. Malus (1775–1812). It applies to any two polarizing elements whose transmission axes make an angle θ with each other.



(*a*)

(*b*)

(*a*) Crossed polarizers block out all of the light. (*b*) In a liquid crystal display, the crystal is between crossed polarizers. Light incident on the crystal is transmitted because the crystal rotates the direction of polarization of the light 90°. The light is reflected back out through the crystal by a mirror behind the crystal, and a uniform background is seen. When a voltage is applied across a small segment of the crystal, the polarization is not rotated, so no light is transmitted and the segment appears black. *((a) Fundamental Photographs. (b) 1990 PAR/NYC, Inc./Photo by Elizabeth Algieri.)*

Example 31-6 Intensity Transmitted

Unpolarized light of intensity $3.0\ \mathrm{W/m^2}$ is incident on two polarizing sheets whose transmission axes make an angle of 60° (Figure 31-29). What is the intensity of light transmitted by the second sheet?

PICTURE The incident light is unpolarized, so the intensity transmitted by the first polarizing sheet is half the incident intensity. The second sheet further reduces the intensity by a factor of $\cos^2\theta$, with $\theta = 60°$.

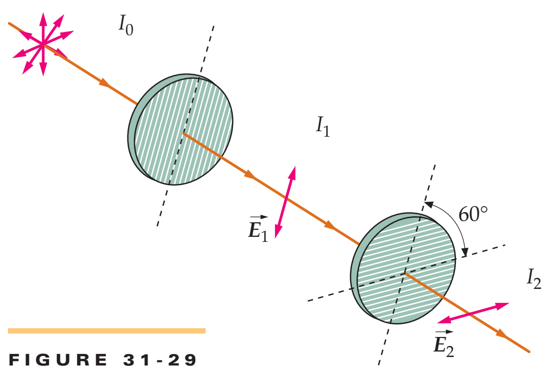


FIGURE 31-29

SOLVE

1. The intensity I_1 transmitted by the first sheet is half the intensity I_0 of unpolarized light incident on the first sheet: $\quad I_1 = \frac{1}{2}I_0$
2. The intensity I_2 transmitted by the second sheet is related to the intensity I_1 of the light incident on the second sheet by Equation 31-16: $\quad I_2 = I_1\cos^2\theta$
3. Combine these results and substitute the given data: $\quad I_2 = \frac{1}{2}I_0\cos^2 60° = \frac{1}{2}(3.0\ \mathrm{W/m^2})(0.500)^2 = \boxed{0.38\ \mathrm{W/m^2}}$

CHECK The first polarizer cuts the intensity in half, so we should expect the intensity transmitted through both sheets to be less than half the incident intensity of 3.0 W. The step-3 result meets this expectation.

TAKING IT FURTHER Note that the second sheet rotates the plane of polarization by 60°.

POLARIZATION BY REFLECTION

When unpolarized light is reflected from a plane surface boundary between two transparent media, such as air and glass or air and water, the reflected light is partially polarized. The degree of polarization depends on the angle of incidence and on the ratio of the wave speeds in the two media. For a certain angle of incidence called the polarizing angle θ_p, the reflected light is completely polarized. At the polarizing angle, the reflected and refracted rays are perpendicular to each other. David Brewster (1781–1868), a Scottish scientist and an inventor of numerous instruments (including the kaleidoscope), discovered this experimentally in 1812. The polarizing angle is also referred to as the Brewster angle.

Figure 31-30 shows light incident at the polarizing angle θ_p for which the reflected light is completely polarized. The electric field of the incident light can be resolved into components parallel and perpendicular to the plane of incidence. The reflected light is linearly polarized with its electric field perpendicular to the plane of incidence. We can relate the polarizing angle to the indices of refraction of the media using Snell's law (the law of refraction). If n_1 is the index of refraction of the first medium and n_2 is the index of refraction of the second medium, the law of refraction gives

$$n_1 \sin\theta_p = n_2 \sin\theta_2$$

where θ_2 is the angle of refraction. From Figure 31-30, we can see that the sum of the angle of reflection and the angle of refraction is 90°. Because the angle of reflection equals the angle of incidence, we have

$$\theta_2 = 90° - \theta_p$$

Then

$$n_1 \sin\theta_p = n_2 \sin(90° - \theta_p) = n_2 \cos\theta_p$$

or

$$\tan\theta_p = \frac{n_2}{n_1} \qquad 31\text{-}17$$

POLARIZING ANGLE

Although the reflected light is completely polarized for this angle of incidence, the transmitted light is only partially polarized (because only a small fraction of the incident light is reflected). If the incident light itself is polarized with the electric field in the plane of incidence, no reflected light exists when the angle of incidence is θ_p. We can qualitatively understand this result by using Figure 31-31. If we consider the charges in the atoms next to the surface of the second medium to be driven, by the electric field of the refracted light, to oscillate parallel to the direction of electric field, no reflected ray can exist because for an electric dipole antenna, no energy is radiated along the line of oscillation. (Each of the oscillating atoms is a small electric dipole antenna.)

Because of the polarization of reflected light, sunglasses that contain a polarizing sheet can be very effective in cutting out glare. If light is reflected from a horizontal surface, such as a lake surface or snow on the ground, the electric field of the reflected light will be predominantly horizontal. Polarizing sunglasses with a vertical transmission axis will then reduce glare by absorbing much of the reflected light. If you have polarizing sunglasses, you can observe this effect by looking through the glasses at reflected light and then rotating the glasses 90°; much more of the light will be transmitted.

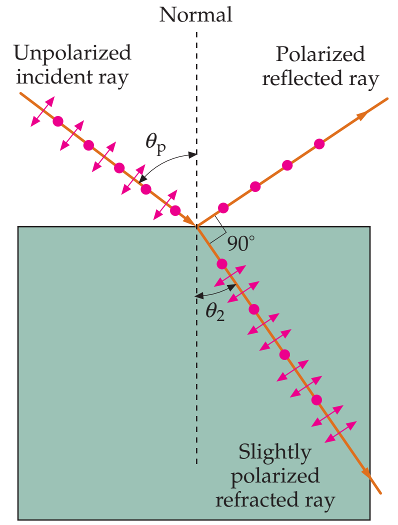

FIGURE 31-30 Polarization by reflection. The incident wave is unpolarized and has components of the electric field parallel to the plane of incidence (arrows) and components perpendicular to that plane (dots). For incidence at the polarizing angle, the reflected wave is completely polarized, with its electric field perpendicular to the plane of incidence.

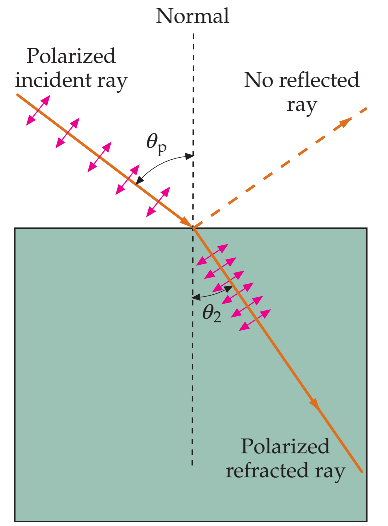

FIGURE 31-31 Polarized light incident at the polarizing angle. When the incident light is polarized with $\vec{E}$ in the plane of incidence, there is no reflected ray.

POLARIZATION BY SCATTERING

The phenomenon of absorption and reradiation is called **scattering.** Scattering can be demonstrated by passing a light beam through a container of water to which a small amount of powdered milk has been added. The milk particles scatter the light, making the light beam visible. Similarly, laser beams can be made visible by introducing chalk or smoke particles into the air to scatter the light. A familiar example of light scattering is that from air molecules, which tend to scatter short wavelengths more than long wavelengths, thereby giving the sky its blue color.

We can understand polarization by scattering if we think of the charges in a scattering atom as electric dipole antennas that radiate waves that have maximum intensities in directions perpendicular to the antenna axes and intensities of zero in the direction along the antenna axis. The electric field vector of the scattered light perpendicular to the direction of propagation is in the plane of the long axis of the antenna and the field point. Figure 31-32 shows a beam of unpolarized light that initially travels along the z axis, striking a particle at the origin. The electric field in the light beam has components in both the x and y directions perpendicular to the direction of motion of the light beam. These fields set up oscillations of the charges within the molecule in the $z = 0$ plane, and no oscillation exists along the z direction. These oscillations can be thought of as a superposition of an oscillation along the x axis and another along the y axis, and each of these oscillations produce dipole radiation. Thus, the oscillation along the x axis produces no radiation along the x axis, which means the light radiated along the x axis is produced only by the oscillation along the y axis. It follows that the light radiated along the x axis is polarized with its electric field parallel with the y axis. There is nothing special about the choice of axes for this discussion, so the result can be generalized. That is, the light scattered in a direction perpendicular to the incident light beam is polarized with its electric field perpendicular to both the incident beam and the direction of propagation of the scattered light. This can be seen easily by examining the scattered light with a piece of polarizing sheet.

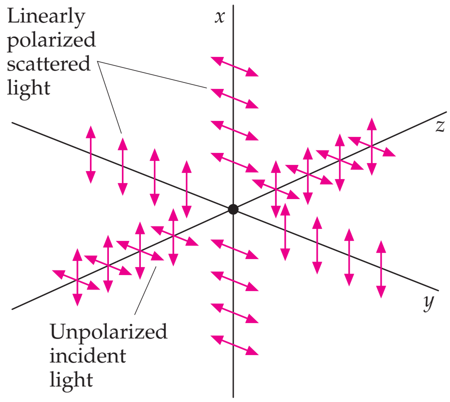

FIGURE 31-32 Polarization by scattering. Unpolarized light propagating in the $+z$ direction is incident on a scattering center at the origin. The light scattered in the $z = 0$ plane along the $\pm x$ direction is polarized parallel with the y axis (and the light scattered in the $\pm y$ direction is polarized parallel with the x axis).

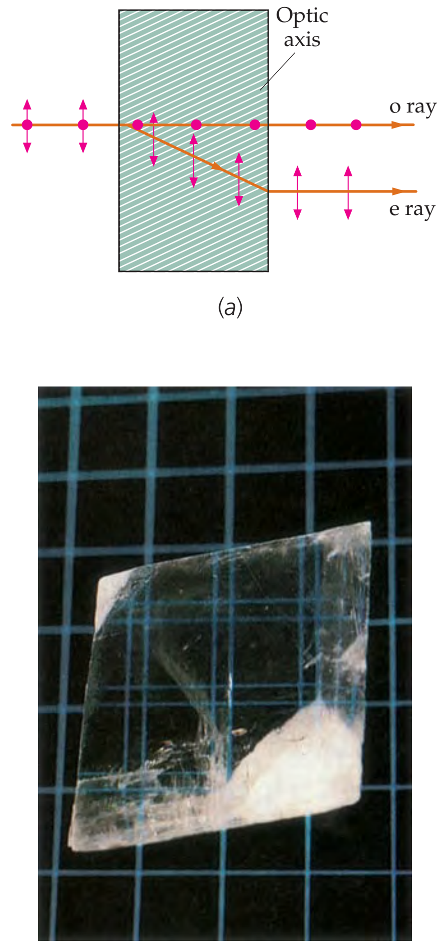
POLARIZATION BY BIREFRINGENCE

Birefringence is a complicated phenomenon that occurs in calcite and other noncubic crystals and in some stressed plastics, such as cellophane. Most materials are **isotropic,** that is, the speed of light passing through the material is independent of the polarization of the light. Because of their microscopic structure, birefringent materials are **anisotropic.** The speed of light depends on the polarization and on the direction of propagation of the light. When a light ray is incident on such materials, it may be separated into two rays called the *ordinary ray* and the *extraordinary ray*. These rays are polarized in mutually perpendicular directions, and they travel with different speeds. Depending on the relative orientation between the material and the incident light beam, the two rays may also travel in different directions.

There is one particular direction in a birefringent material in which both rays propagate with the same speed. This direction is called the **optic axis** of the material. (The optic axis is actually a *direction* rather than a line in the material.) Nothing unusual happens when light travels in the direction of the optic axis. However, when light is incident at an angle to the optic axis, as shown in Figure 31-33, the



(b)

FIGURE 31-33 (*a*) A narrow beam of light incident on a birefringent crystal such as calcite is split into two beams, called the ordinary ray (o ray) and the extraordinary ray (e ray), that have mutually perpendicular polarizations. If the crystal is rotated, the extraordinary ray rotates in space. (*b*) A double image of the cross-hatching is produced by this birefringent crystal of calcium carbonate. *(Paul Silverman Photographs.)*

rays travel in different directions and emerge separated in space. If the material is rotated, the extraordinary ray (the e ray in the figure) revolves in space around the ordinary ray (o ray).

If light is incident on a birefringent plate perpendicular to its crystal face and perpendicular to the optic axis, the two rays travel in the same direction but at different speeds. The number of wavelengths in the two rays in the plate is different because the wavelengths ($\lambda = v/f$) of the rays differ. The rays emerge with a phase difference that depends on the thickness of the plate and on the wavelength of the incident light. In a **quarter-wave plate,** the thickness is such that a 90° phase difference exists between the waves of a particular wavelength when they emerge. In a **half-wave plate,** the rays emerge with a phase difference of 180°.

Suppose that the incident light is linearly polarized so that the electric field vector is at 45° to the optic axis, as illustrated in Figure 31-34. The ordinary and extraordinary rays start out in phase and have equal amplitudes. With a quarter-wave plate, the waves emerge with a phase difference of 90°, so the resultant electric field has components $E_x = E_0 \sin \omega t$ and $E_y = E_0 \sin(\omega t + 90°) = E_0 \cos \omega t$. The electric field vector thus rotates in a circle and has constant magnitude. Such a wave is said to be **circularly polarized.**

With a half-wave plate, the waves that emerge have a phase difference of 180°, so the resultant electric field is linearly polarized with components $E_x = E_0 \sin \omega t$ and $E_y = E_0 \sin(\omega t + 180°) = -E_0 \sin \omega t$. The net effect is that the direction of polarization of the wave is rotated by 90° relative to that of the incident light, as shown in Figure 31-35.

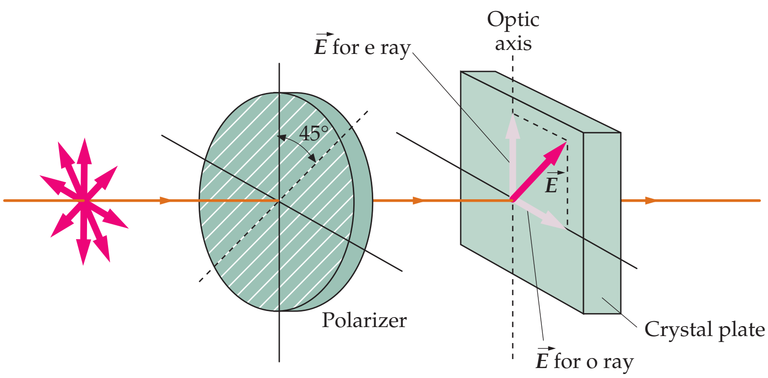


FIGURE 31-34 Polarized light emerging from the polarizer is incident on a birefringent crystal so that the electric field vector makes a 45° angle with the optic axis, which is perpendicular to the light beam. The ordinary and extraordinary rays travel in the same direction but at different speeds. The polarization of the emerging light depends on the thickness of the crystal and the wavelength of the light.

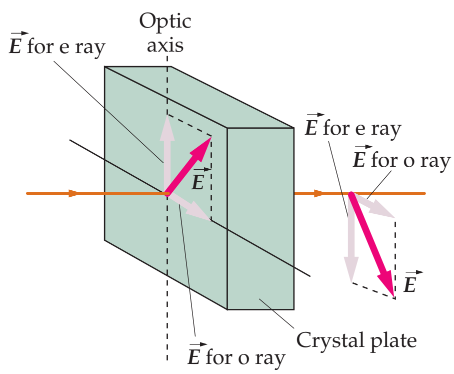

FIGURE 31-35 If the birefringent crystal in Figure 31-34 is a half-wave plate, and if the electric field vector of the incident light makes an angle of 45° with the optic axis, then the direction of polarization of the emerging light is rotated by 90°.

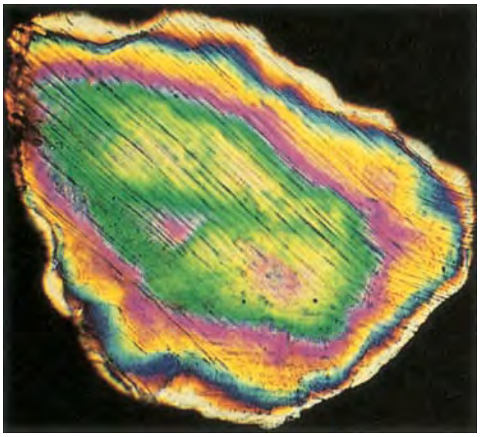
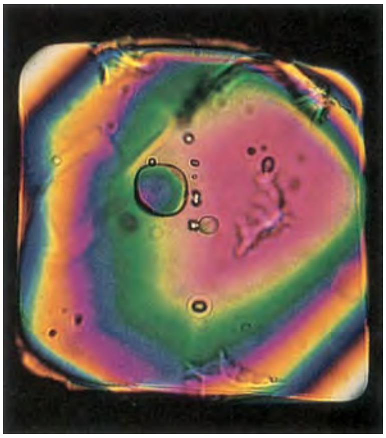
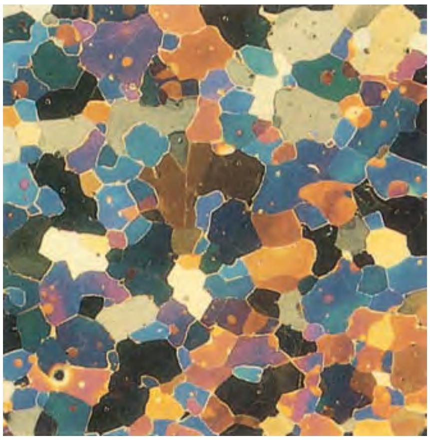
Interesting and beautiful patterns can be observed by placing birefringent materials, such as cellophane or stressed plastic, between two polarizing sheets with their transmission axes perpendicular to each other. Ordinarily, no light is transmitted through crossed polarizing sheets. However, if we place a birefringent material between the crossed polarizing sheets, the material acts as a half-wave plate for light of a certain color depending on the material's thickness. The direction of polarization is rotated and some light gets through both sheets. Various glasses and plastics become birefringent when under stress. The stress patterns can be observed when the material is placed between crossed polarizing sheets.



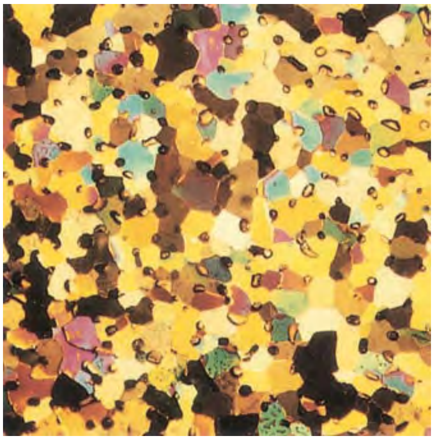
(*a*)



(*b*)



(*c*)



(*d*)

(*e*)

When the transmission axes of two polarizing sheets are perpendicular, the polarizers are said to be crossed and no light is transmitted. However, many materials are birefringent or become so under stress. Such materials rotate the direction of polarization of the light so that light of a particular wavelength is transmitted through both polarizers. When a birefringent material is viewed between crossed polarizers, information about its internal structure is revealed. (*a*) A shocked quartz grain from the site of a meteorite crater. The layered structure, evidenced by the parallel lines, arises from the shock of the impact of the meteor. (*b*) A grain of quartz typically found in silicic volcanic rocks. No shock lines are seen. (*c*) Thin sections of an ice core from the Antarctic ice sheet reveal bubbles of trapped CO_2, which appear amber-colored. The sample was taken from a depth of 194 m, corresponding to air trapped 1600 years ago, whereas the sample in (*d*) is from a depth of 56 m, corresponding to air trapped 450 years ago. Ice core measurements have replaced the less reliable technique of analyzing carbon in tree rings to compare current atmospheric CO_2 levels with those of the recent past. (*e*) Robert Mark of the Princeton School of Architecture examines the stress patterns in a plastic model of the nave structure of Chartres Cathedral. *((a, b) Glen A. Izett, US Geological Survey. 31-5 DERIVATION OF THE LAWS OF REFLECTION AND REFRACTION

The laws of reflection and refraction can be derived from either Huygens's principle or Fermat's principle.

HUYGENS'S CONSTRUCTION

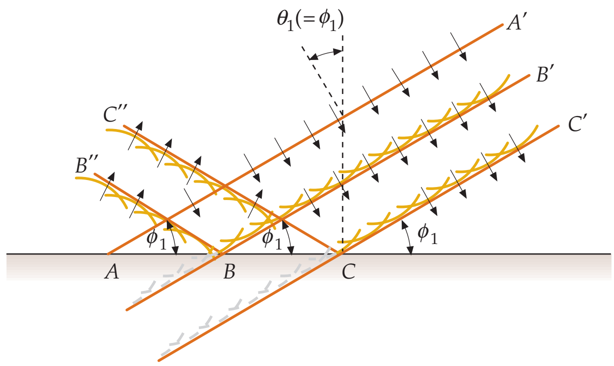

FIGURE 31-36 Plane wave reflected at a plane mirror. The angle θ_1 between the incident ray and the normal to the mirror is the angle of incidence. It is equal to the angle ϕ_1 between the incident wavefront and the mirror.

Reflection Figure 31-36 shows a plane wavefront AA' striking a mirror at point A. As can be seen from the figure, the angle ϕ_1 between the wavefront and the mirror is the same as the angle of incidence θ_1, which is the angle between the normal to the mirror and the rays (which are perpendicular to the wavefronts). According to Huygens's construction, each point on a given wavefront can be considered a point source of secondary wavelets. The position of the wavefront after a time t is found by constructing wavelets of radius ct with their centers on the wavefront AA'. Wavelets that have not yet reached the mirror form the portion of the new wavefront BB'. Wavelets that have already reached the mirror are reflected and form the portion of the new wavefront $B''B$. By a similar construction, the wavefront $C''C$ is obtained from the Huygens's wavelets originating on the wavefront $B''B$. Figure 31-37 is an enlargement of a portion of Figure 31-36 showing AP, which is part of the initial position of the wavefront. During the time t, the wavelet from point P reaches the mirror at point B, and the wavelet from point A reaches point B''. The reflected wavefront $B''B$ makes an angle ϕ_1' with the mirror that is equal to the angle of reflection θ_1' between the reflected ray and the normal to the mirror. The triangles $AB''B$ and APB are both right triangles that have a common side AB and equal sides $AB'' = BP = ct$. Hence, these triangles are congruent, and the angles ϕ_1 and ϕ_1' are equal, implying that the angle of reflection θ_1' equals the angle of incidence θ_1.

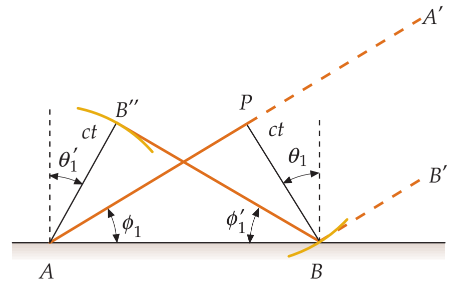

FIGURE 31-37 Geometry of Huygens's construction for the calculation of the law of reflection. The wavefront AP initially strikes the mirror at point A. After a time t, the Huygens wavelet from P strikes the mirror at point B, and the Huygens wavelet from point A reaches point B''.

Refraction Figure 31-38 shows a plane wave incident on an air–glass interface. We apply Huygens's construction to find the wavefront in the transmitted wave. Line AP indicates a portion of the wavefront in medium 1 that strikes the glass surface at an angle ϕ_1. In time t, the wavelet from P travels the distance v_1t and reaches the point B on the line AB separating the two media, while the wavelet from point A travels a shorter distance v_2t into the second medium. The new wavefront BB' is not parallel to the original wavefront AP because the speeds v_1 and v_2 are different. From the triangle APB,

$$\sin\phi_1 = \frac{v_1t}{AB}$$

or

$$AB = \frac{v_1t}{\sin\phi_1} = \frac{v_1t}{\sin\theta_1}$$

using the fact that the angle ϕ_1 equals the angle of incidence θ_1. Similarly, from triangle $AB'B$,

$$\sin\phi_2 = \frac{v_2t}{AB}$$

or

$$AB = \frac{v_2t}{\sin\phi_2} = \frac{v_2t}{\sin\theta_2}$$

where $\theta_2 = \phi_2$ is the angle of refraction. Equating the reciprocals of the two values for AB, we obtain

$$\frac{1}{v_1}\sin\theta_1 = \frac{1}{v_2}\sin\theta_2 \qquad \text{31-18}$$

Multiplying both sides by c, and then substituting n_1 for c/v_1 and n_2 for c/v_2, we obtain $n_1\sin\theta_1 = n_2\sin\theta_2$, which is Snell's law.

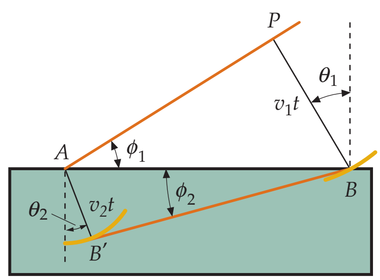

FIGURE 31-38 Application of Huygens's principle to the refraction of plane waves at the surface separating a medium in which the wave speed is v_1 from a medium in which the wave speed v_2 is less than v_1. The angle of refraction θ_2 is less than the angle of incidence θ_1.

FERMAT'S PRINCIPLE

Reflection Figure 31-39 shows two paths in which light leaves point A, strikes the plane surface, which we can consider to be a mirror, and travels to point B. The problem for the application of Fermat's principle to reflection can be stated as follows: At what point P in the figure must the light strike the mirror so that it will travel from point A to point B in the least time? Because the light is traveling in the same medium for this problem, the time will be minimum when the distance is minimum. In Figure 31-39 the distance APB is the same as the distance $A'PB$, where point A' lies along the perpendicular from A to the mirror and is equidistant behind the mirror. As we vary point P, the distance $A'PB$ is least when the points A', P, and B lie on a straight line. We can see from the figure that this occurs when the angle of incidence equals the angle of reflection.

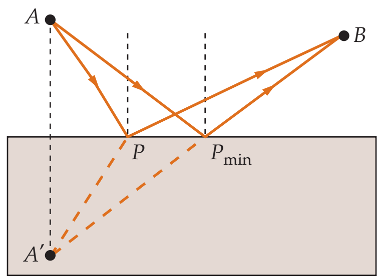

FIGURE 31-39 Geometry for deriving the law of reflection from Fermat's principle. The time it takes for the light to travel from point A to the surface and then on to point B is a minimum for the light striking the surface at point P_{min}.

Refraction The derivation of Snell's law of refraction from Fermat's principle is slightly more complicated. Figure 31-40 shows several possible paths for light traveling from point A in air to point B in glass. Point P_1 is on the straight line between A and B, but this path is not the one for the shortest travel time because light travels at a slower speed in the glass. If we move slightly to the right of P_1, the total path length is longer, but the distance traveled in the slower medium is less than for the path through P_1. It is not apparent from the figure which path is the path of least time. However, it is not surprising that a path slightly to the right of the straight-line path takes less time because the time gained by traveling a shorter distance in the glass more than compensates for the time lost traveling a longer distance in the air. As we move the point of intersection of the possible path to the right of point P_1, the total time of travel from point A to point B decreases until we reach a minimum at point P_{min}. Beyond this point, the time saved by traveling a shorter distance in the glass is not enough to compensate for the additional time spent by traveling the greater distance in the air.

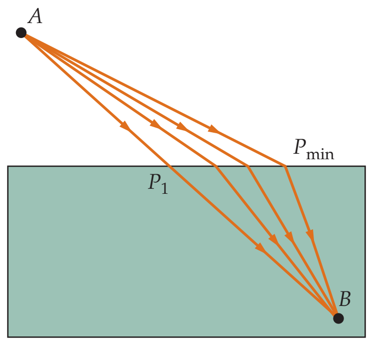

FIGURE 31-40 Geometry for deriving Snell's law from Fermat's principle. The point P_{min} is the point at which light must strike the glass in order that the travel time from point A to point B is a minimum.

Figure 31-41 shows the geometry for finding the path of least time. If L_1 is the distance traveled in medium 1 that has an index of refraction n_1, and L_2 is the distance traveled in medium 2 that has an index of refraction n_2, the time for light to travel the total path AB is

$$t = \frac{L_1}{v_1} + \frac{L_2}{v_2} = \frac{L_1}{c/n_1} + \frac{L_2}{c/n_2} = \frac{n_1 L_1}{c} + \frac{n_2 L_2}{c} \qquad \text{31-19}$$

We wish to find the point P_{min} for which this time is a minimum. We do this by expressing the time in terms of a single parameter x, as shown in the figure, indicating the position of point P_{min}. In terms of the distance x,

$$L_1^2 = a^2 + x^2 \quad \text{and} \quad L_2^2 = b^2 + (d - x)^2 \qquad \text{31-20}$$

Figure 31-42 shows the time t as a function of x. At the value of x for which the time is a minimum, the slope of the graph of t versus x is zero:

$$\frac{dt}{dx} = 0$$

Differentiating each term in Equation 31-19 with respect to x and setting the result equal to zero, we obtain

$$\frac{dt}{dx} = \frac{1}{c}\left(n_1 \frac{dL_1}{dx} + n_2 \frac{dL_2}{dx}\right) = 0 \qquad \text{31-21}$$

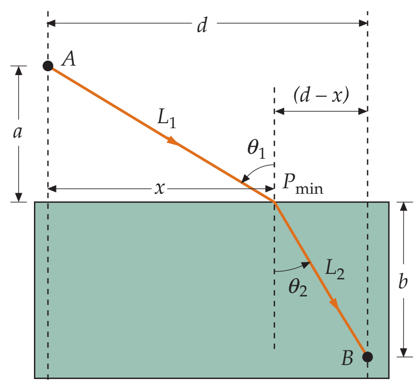

FIGURE 31-41 Geometry for calculating the minimum time in the derivation of Snell's law from Fermat's principle.

We can compute these derivatives from Equations 31-20. We have

$$2L_1 \frac{dL_1}{dx} = 2x \quad \text{or} \quad \frac{dL_1}{dx} = \frac{x}{L_1}$$

where x/L_1 is just $\sin\theta_1$, and where θ_1 is the angle of incidence. Thus,

$$\frac{dL_1}{dx} = \sin\theta_1 \qquad \text{31-22}$$

Similarly,

$$2L_2\frac{dL_2}{dx} = 2(d - x)(-1)$$

or

$$\frac{dL_2}{dx} = -\frac{d - x}{L_2} = -\sin\theta_2 \qquad \text{31-23}$$

where θ_2 is the angle of refraction. From Equation 31-21,

$$n_1\frac{dL_1}{dx} + n_2\frac{dL_2}{dx} = 0 \qquad \text{31-24}$$

Substituting the results of Equations 31-22 and 31-23 for dL_1/dx and dL_2/dx gives

$$n_1 \sin\theta_1 + n_2(-\sin\theta_2) = 0$$

or

$$n_1 \sin\theta_1 = n_2 \sin\theta_2$$

which is Snell's law.

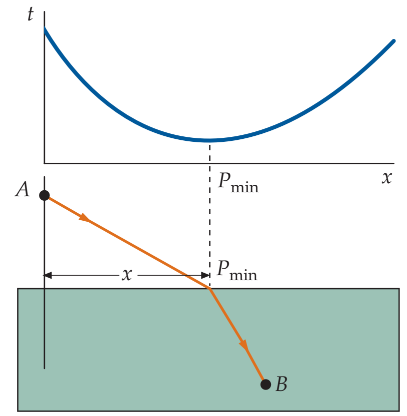

FIGURE 31-42 Graph of the time it takes for light to travel from point A to point B versus x, measured along the refracting surface. The time is a minimum at the point at which the angles of incidence and refraction obey Snell's law.

31-6 WAVE–PARTICLE DUALITY

The wave nature of light was first demonstrated by Thomas Young, who in 1801 observed the interference pattern of two coherent light sources produced by illuminating a pair of narrow, parallel slits with a single source. (Young's experiment is presented in Section 3 of Chapter 33.) The wave theory of light culminated in 1860 with Maxwell's prediction of electromagnetic waves. The particle nature of light was first proposed by Albert Einstein in 1905 in his explanation of the photoelectric effect.* A particle of light called a **photon** has energy E that is related to the frequency f and wavelength λ of the light wave by the Einstein equation

$$E = hf = \frac{hc}{\lambda} \qquad \text{31-25}$$

EINSTEIN'S EQUATION FOR PHOTON ENERGY

where c is the speed of light and h is Planck's constant:

$$h = 6.626 \times 10^{-34}\,\text{J}\cdot\text{s} = 4.136 \times 10^{-15}\,\text{eV}\cdot\text{s}$$

Because energies are often given in electron volts and wavelengths are given in nanometers, it is convenient to express the combination hc in eV · nm. We have

$$hc = (4.1357 \times 10^{-15}\,\text{eV}\cdot\text{s})(2.9979 \times 10^{8}\,\text{m/s}) = 1.2398 \times 10^{-6}\,\text{eV}\cdot\text{m}$$

or

$$hc = 1240\,\text{eV}\cdot\text{nm} \qquad \text{31-26}$$

The propagation of light is governed by its wave properties, whereas the exchange of energy between light and matter is governed by its particle properties. This wave–particle duality is a general property of nature. For example, the propagation of electrons (and other so-called particles) is also governed by wave properties, whereas the exchange of energy between the electrons and other particles is governed by particle properties.

* The photoelectric effect is discussed in Chapter 34.

31-7 LIGHT SPECTRA

Newton was the first to recognize that white light is a mixture of light of all colors of approximately equal intensity. He demonstrated this by letting sunlight fall on a glass prism and observing the spectrum of the refracted light (Figure 31-43). Because the angle of refraction produced by a glass prism depends on the wavelength of the light, the refracted beam is spread out in space into its component colors or wavelengths, like a rainbow. Figure 31-44 shows a spectroscope, which is a device for analyzing the spectra of light sources. Light from the source passes through a narrow slit, traverses a lens that makes the beam parallel, and falls on a glass prism, where it is refracted twice (once as it enters the glass and again as it leaves the glass). The refracted beam is viewed with a telescope, which is mounted on a rotating platform so that the angle of the refracted beam, which depends on the wavelength of the light, can be measured. The spectrum of the light source can thus be analyzed in terms of its component wavelengths. The spectrum of sunlight has a continuous range of wavelengths and is therefore called a **continuous spectrum.** The light emitted by the atoms in low-pressure gases, such as mercury atoms in a fluorescent lamp, contains only a discrete set of wavelengths. Each wavelength emitted by the source produces a separate image of the collimating slit in the spectroscope. Such a spectrum is called a **line spectrum.** The continuous visible spectrum and the line spectra from several elements are shown in the photograph.

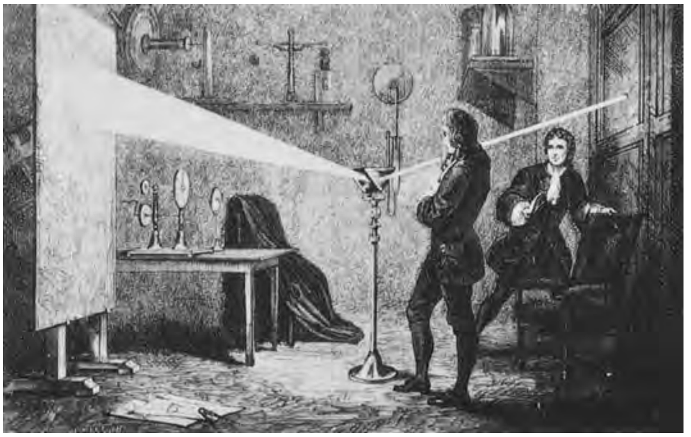

FIGURE 31-43 Newton demonstrating the spectrum of sunlight with a glass prism. *(Corbis/Bettmann.)*

* 31-8 SOURCES OF LIGHT

LINE SPECTRA

The most common sources of visible light are transitions of the valence electrons in atoms. Normally, an atom is in its ground state where its electrons are at their lowest allowed energy levels consistent with the exclusion principle. (The exclusion principle, which was first proposed by Wolfgang Pauli in 1925 to explain the electronic structure of atoms, states that no two electrons in an atom can have the same quantum state.) The lowest energy electrons are tightly bound to the nucleus, forming a stable core of electrons. The one or two electrons in the highest energy states are much less tightly bound to the nucleus and are relatively easily excited to vacant higher energy states. These outer electrons are responsible for the energy changes in the atom that result in the emission or absorption of visible light.

When an atom collides with another atom or with a free electron, or when the atom absorbs electromagnetic energy, the valence electrons can be excited to higher energy states. After a time of approximately 10 ns (1 ns = 10^{-9} s), the valence electrons spontaneously make transitions to lower energy states with the emission of a photon. This process, called **spontaneous emission,** is random; the photons emitted from two different atoms are not correlated. The emitted light is thus incoherent. By conservation of energy, the energy of an emitted photon is the energy difference $|\Delta E|$ between the initial state and the final state of the atom. The frequency of the light wave is related to the energy by the Einstein equation, $|\Delta E| = hf$ (Equation 31-25). The wavelength of the emitted light is then

$$\lambda = \frac{c}{f} = \frac{hc}{hf} = \frac{hc}{|\Delta E|} \qquad \text{31-27}$$

The photon energies corresponding to shortest wavelengths (400 nm) and longest (700 nm) wavelengths in the visible spectrum are

$$E_{400\text{ nm}} = \frac{hc}{\lambda} = \frac{1240\text{ eV}\cdot\text{nm}}{400\text{ nm}} = 3.10\text{ eV} \qquad \text{31-28}a$$

and

$$E_{700\text{ nm}} = \frac{hc}{\lambda} = \frac{1240\text{ eV}\cdot\text{nm}}{700\text{ nm}} = 1.77\text{ eV} \qquad \text{31-28}b$$

Because the energy levels in atoms form a discrete set, the emission spectrum of light from single atoms or from atoms in low-pressure gases consists of a set of sharp discrete lines that are characteristic of the element. These narrow lines are broadened somewhat by Doppler shifts, due to the motion of the atom relative to the observer and by collisions with other atoms; generally, however, if the gas density is low enough, the lines are narrow and well separated from one another. The study of the line spectra of hydrogen and other atoms led to the first understanding of the energy levels of atoms.

Continuous spectra When atoms are close together and interact strongly, as in liquids and solids, the energy levels of the individual atoms are spread out into energy bands, resulting in essentially continuous bands of energy levels. When the bands overlap, as they often do, the result is a continuous spectrum of possible energies and a continuous emission spectrum. In an incandescent material such as a hot metal filament, electrons are randomly accelerated by frequent collisions, resulting in a broad spectrum of thermal radiation. The rate at which an object radiates thermal energy is proportional to the fourth power of its absolute temperature.*

* This is known as the Stefan–Boltzmann law. This property and other properties of thermal radiation, such as Wien's displacement law, are discussed more fully in Section 20-4.

The radiation emitted by an object at temperatures below approximately 600°C is concentrated in the infrared and is not visible. As an object is heated, the energy radiated extends to shorter and shorter wavelengths. Between approximately 600°C and 700°C, enough of the radiated energy is in the visible spectrum for the object to glow a dull red. At higher and higher temperatures, the object becomes bright red and then white. For a given temperature, the wavelength λ_{peak} at which the emitted power is a maximum varies inversely with the temperature, a result known as Wien's displacement law. The surface of the Sun at $T = 6000$ K emits a continuous spectrum of approximately constant intensity over the visible range of wavelengths.

ABSORPTION, SCATTERING, SPONTANEOUS EMISSION, AND STIMULATED EMISSION

When radiation is emitted, an atom (the words atom and molecule are used interchangeably in this section) makes a transition from an excited state to a state of lower energy; when radiation is absorbed, an atom makes a transition from a lower state to a higher state. When atoms are irradiated with a continuous spectrum of radiation, the transmitted spectrum shows dark lines corresponding to the absorption of light at discrete wavelengths. The absorption spectra of atoms were the first line spectra observed. Because atoms at normal temperatures are in either their ground states or low-energy excited states, only transitions from a ground state (or a near ground state) to a more highly excited state are observed. Thus, absorption spectra usually have far fewer lines than do emission spectra.

Figure 31-45 illustrates several interesting phenomena that can occur when a photon is incident on an atom. In Figure 31-45*a*, the energy of the incoming photon is too small to excite the atom to an excited state, so the atom remains in its ground state and the photon is said to be scattered. Because the incoming and outgoing or scattered photons have the same energy, the scattering is said to be elastic. If the wavelength of the incident light is large compared with the size of the atom, the scattering can be described in terms of classical electromagnetic theory and is called **Rayleigh scattering** after Lord Rayleigh, who worked out the theory in 1871. The probability of Rayleigh scattering varies as $1/\lambda^4$. This means that blue light is scattered much more readily than red light, which accounts for the bluish color of the sky. The removal of blue light by Rayleigh scattering also accounts for some of the reddish color of the light transmitted through the atmosphere at sunrise and sunset.

Inelastic scattering, also called **Raman scattering,** occurs when an incident photon that has just the right amount of energy is absorbed and the atom undergoes a transition to a more energetic state. Then, the atom emits a photon as it undergoes a transition to a less energetic state, whose energy differs from that of the initial state. If the energy of the scattered photon hf' is less than that of the incident photon hf (Figure 31-45*b*), it is called **Stokes Raman scattering.** If the energy of the scattered photon is greater than that of the incident photon (Figure 31-45*c*), it is called **anti-Stokes Raman scattering.**

In Figure 31-45*d*, the energy of the incident photon is just equal to the difference in energy between the initial state and a more energetic state. The atom absorbs the photon and makes a transition to the more excited state in a process called **resonance absorption.**

In Figure 31-45*e*, an atom in an excited state spontaneously undergoes a transition to a less energetic state, in a process called **spontaneous emission.** Often an atom in an excited state undergoes transitions to one or more intermediate states as it returns to the ground state. A common example occurs when an atom is excited by ultraviolet light and emits visible light as it returns to its ground state by multiple transitions. This process, often called **fluorescence,** occurs in a thin film lining on the inside of the glass tubes of fluorescent lightbulbs. Because the lifetime of a typical excited atomic energy state is of the order of 10 ns, this process appears to occur instantaneously. However, some excited states have much longer lifetimes—of the

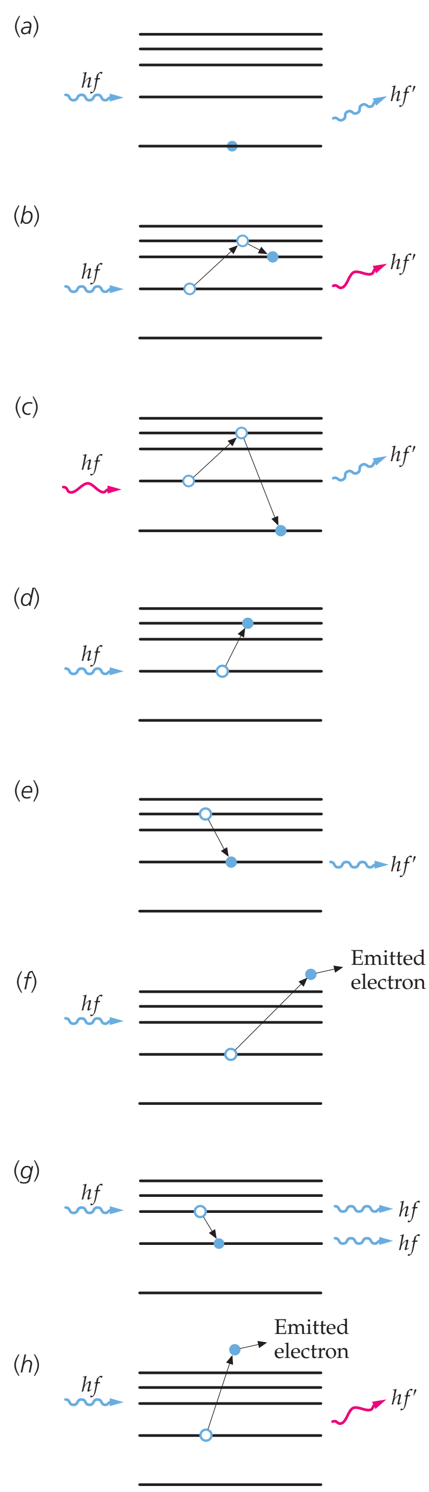

FIGURE 31-45 Photon–atom and photon–molecule interactions. (*a*) Elastic scattering. (*b*) Stokes Raman scattering. (*c*) Anti-Stokes Raman scattering. (*d*) Resonance absorption. (*e*) Spontaneous emission. (*f*) Photoelectric effect. (*g*) Stimulated emission. (*h*) Compton scattering.

order of milliseconds or occasionally seconds or even minutes. Such a state is called a **metastable state.** Materials that have very long-lived metastable states and emit light long after the original excitation are called **phosphorescent materials.**

Figure 31-45*f* illustrates the photoelectric effect, in which the absorption of the photon ionizes the atom by causing the emission of an electron. Figure 31-45*g* illustrates **stimulated emission.** This process occurs if the atom is initially in an excited state of energy E_H, and the energy of the incident photon is equal to $E_H - E_L$, where E_H and E_L are the energies of higher and lower energy states, respectively. In this case, the oscillating electromagnetic field associated with the incident photon can stimulate the excited atom, which then emits a photon in the same direction as the incident photon and in phase with it. The photons from the stimulated atoms can stimulate the emission of additional photons propagating in the same direction with the same phase. This process amplifies the initially emitted photon, yielding a beam of light originating from different atoms that is coherent. As a result, interference of the light from a large number of atoms can easily be observed.

Figure 31-45*h* illustrates **Compton scattering,** which occurs if the energy of the incident photon is much greater than the ionization energy. Note that in Compton scattering, a photon is absorbed and a photon is emitted, whereas in the photoelectric effect, a photon is absorbed with none emitted.

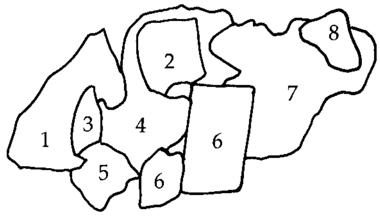
(*b*)



(*c*)

A collection of minerals in (*a*) daylight and in (*b*) ultraviolet light (sometimes called *black light*). Identified by number in the schematic (*c*), they are 1, powerllite; 2, willemite; 3, scheelite; 4, calcite; 5, calcite and willemite composite; 6, optical calcite; 7, willemite; and 8, opal. The change in color is due to the minerals fluorescing under the ultraviolet light. In optical calcite, both fluorescence and phosphorescence occur. *(Paul Silverman/Fundamental Photographs.)*

Example 31-7 Resonant Absorption and Emission

The energy level E_1 of the first excited state of a potassium atom is 1.62 eV above the energy level E_0 of the ground state. The energy levels E_2 and E_3 of the second and third excited states of a potassium atom are 2.61 eV and 3.07 eV, respectively, above the ground state energy E_0. (*a*) What is the longest wavelength of radiation that can be absorbed by a potassium atom in its ground state? Calculate the wavelength of the emitted photon when the atom makes a transition from (*b*) the third excited state (E_3) to the ground state and from (*c*) the third excited state (E_3) to the second excited state (E_2).

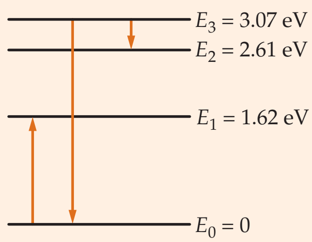


FIGURE 31-46

PICTURE The ground state and the first three excited energy levels are shown in Figure 31-46. (*a*) Because the wavelength is related to the energy of a photon by $\lambda = hc/\Delta E$, longer wavelengths correspond to smaller energy differences, and the smallest energy difference for a transition originating at the ground state is from the ground state to the first excited state. (*b*) The wavelengths of the photons emitted when the atom transitions to lower energy states are related to the energy differences by $\lambda = hc/|\Delta E|$.

SOLVE

(*a*) Calculate the wavelength of radiation absorbed in a transition from the ground state to the first excited state:

$$\lambda = \frac{hc}{\Delta E} = \frac{hc}{E_1 - E_0} = \frac{1240\text{ eV}\cdot\text{nm}}{1.62\text{ eV} - 0} = \boxed{765\text{ nm}}$$

(*b*) For the transition from E_3 to the ground state, the photon energy is $E_3 - E_0 = E_3$. Calculate the wavelength of radiation emitted in this transition:

$$\lambda = \frac{hc}{|\Delta E|} = \frac{hc}{E_3 - E_0} = \frac{1240\text{ eV}\cdot\text{nm}}{3.07\text{ eV} - 0} = \boxed{404\text{ nm}}$$

(*c*) For the transition from E_3 to E_2, the photon energy is $E_3 - E_2$. Calculate the wavelength of radiation emitted in this transition:

$$\lambda = \frac{hc}{|\Delta E|} = \frac{hc}{E_3 - E_2} = \frac{1240\ \text{eV}\cdot\text{nm}}{3.07\ \text{eV} - 2.61\ \text{eV}} = \boxed{2.70\ \mu\text{m}}$$

CHECK The Part (*b*) result is smaller than the Part (*a*) result. This result is expected because the more energy a photon has, the shorter the wavelength.

TAKING IT FURTHER The wavelength of radiation emitted in the transition from E_1 to the ground state E_0 is 765 nm, the same as the wavelength for radiation absorbed in the transition from the ground state to E_1. This transition and the transition from E_3 to the ground state both result in photons in the visible spectrum. The photon emitted during the transition from E_3 to E_2 is in the infrared region of the electromagnetic spectrum.

LASERS

The *laser* (*l*ight *a*mplification by *s*timulated *e*mission of *r*adiation) is a device that produces a strong beam of coherent photons by stimulated emission. Consider a system consisting of atoms that have a ground state of energy E_0 and an excited metastable state of energy E_1. If the atoms are irradiated by photons of energy $E_1 - E_0$, those atoms in the ground state can absorb a photon and make the transition to state E_1, whereas those atoms already in the excited state may be stimulated to decay back to the ground state. The relative probabilities of absorption and stimulated emission, first worked out by Einstein, are equal. Ordinarily, nearly all the atoms of the system at normal temperature will initially be in the ground state, so absorption will be the main effect. To produce more stimulated-emission transitions than absorption transitions, we must arrange to have more atoms in the excited state than in the ground state. This condition, called *population inversion*, can be achieved by a method called optical pumping in which atoms are *pumped* up to levels of energy greater than E_1 by the absorption of an intense auxiliary radiation. The atoms then decay down to state E_1 either by spontaneous emission or by nonradiative transitions, such as those transitions due to collisions.

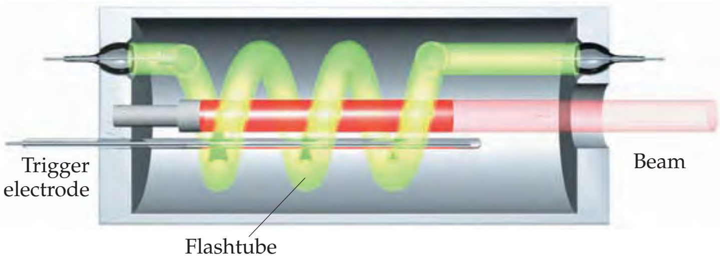

FIGURE 31-47 Schematic diagram of the first ruby laser.

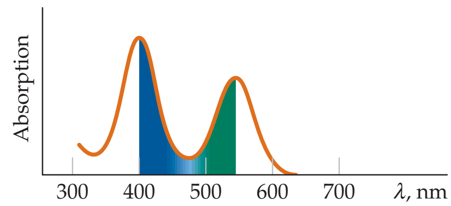

FIGURE 31-48 Absorption versus wavelength for Cr^{3+} in ruby. Ruby appears red because of the strong absorption of green and blue light by the chromium ions.

Figure 31-47 shows a schematic diagram of the first laser, a ruby laser built by Theodore Maiman in 1960. The laser consists of a ruby rod a few centimeters long surrounded by a helical gaseous flashtube that emits a broad spectrum of light. The ends of the ruby rod are flat and perpendicular to the axis of the rod. Ruby is a transparent crystal of Al_2O_3 that has a small amount (about 0.05 percent) of chromium. It appears red because the chromium ions (Cr^{3+}) have strong absorption bands in the blue and green regions of the visible spectrum, as shown in Figure 31-48. The energy levels of chromium—important for the operation of a ruby laser–are shown in Figure 31-49. When the flashtube is fired, there is an intense burst of light that lasts several milliseconds. Photon absorption excites many of the chromium ions to the bands of energy levels indicated by the shading in Figure 31-49. The excited chromium ions then rapidly drop down to a closely spaced pair of metastable states labeled E_1 in the figure. The metastable states are approximately 1.79 eV

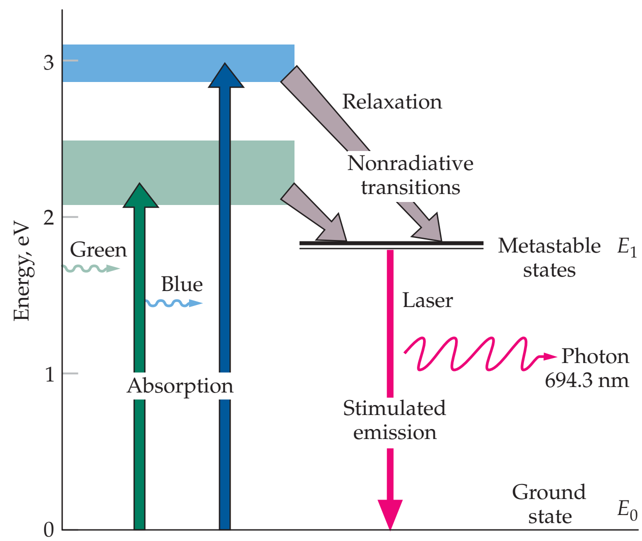

FIGURE 31-49 Energy levels in a ruby laser. To make the population of the metastable states greater than that of the ground state, the ruby crystal is subjected to intense radiation that contains energy in the green and blue wavelengths. This excites atoms from the ground state to the bands of energy levels indicated by the shading, from which the atoms decay to the metastable states by nonradiative transitions. Then, by stimulated emission, the atoms undergo the transition from the metastable states to the ground state.

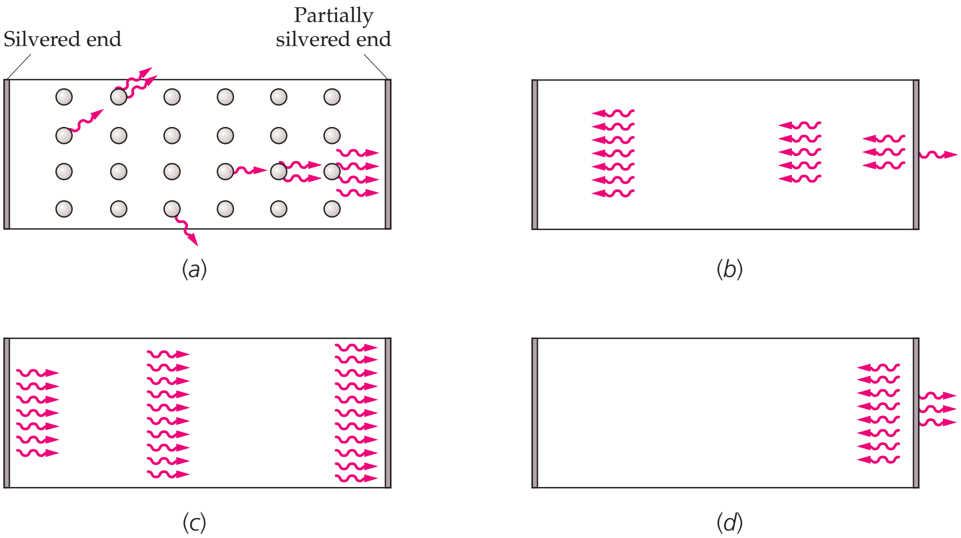

FIGURE 31-50 Buildup of a photon beam in a laser. (*a*) When irradiated, some atoms spontaneously emit photons, some of which travel to the right and stimulate other atoms to emit photons parallel to the axis of the crystal. (*b*) Of the four photons that strike the right face, one is transmitted and three are reflected. As the reflected photons traverse the lasing material, they stimulate other atoms to emit photons, and the beam builds up. By the time the beam reaches the right face again (*c*), it comprises many photons. (*d*) Some of the photons are transmitted, and the rest of the photons are reflected.

above the ground state. The expected lifetime for a chromium ion to remain in one of the metastable states is about 5 ms, after which the chromium ion spontaneously emits a photon and decays to the ground state. A millisecond is a long time for an atomic process. Consequently, if the flash is intense enough, the number of chromium ions populating the two metastable states will exceed the population of chromium ions in the ground state. It follows that during the time the flashtube is firing, the populations of ions in the ground state and in the metastable states are inverted. When the chromium ions in the state E_1 decay to the ground state by spontaneous emission, they emit photons of energy 1.79 eV and wavelength 694.3 nm. The photons have just the right energy to stimulate chromium ions in the metastable states to emit photons of the same energy (and wavelength) as they undergo the transition to the ground state. The photons also have just the right energy to stimulate chromium ions in the ground state to absorb a photon as they undergo the transition to one of the metastable states. These processes are competing processes, but the stimulated emission process dominates as long as the population of chromium ions in the metastable states exceeds the population in the ground state.

In the ruby laser, one end of the crystal is fully silvered, so it is 100 percent* reflecting; the other end of the crystal, called the output coupler, is partially silvered, leaving it about 85 percent reflecting. When photons traveling parallel to the axis of the crystal strike the silvered ends, all are reflected from the back face and 85 percent are reflected from the front face, with 15 percent of the photons escaping through the partially silvered front face. During each pass through the crystal, the photons stimulate more and more atoms so that an intense beam is emitted from the partially silvered end (Figure 31-50). Because the duration of each flash of the flashtube is between two and three seconds, the laser beam is produced in pulses lasting a few milliseconds. Modern ruby lasers generate intense light beams with energies ranging from 50 J to 100 J per pulse. The beam can have a diameter as small as 1 mm and an angular divergence as small as 0.25 mrad to about 7 mrad.

Population inversion is achieved somewhat differently in the continuous helium–neon laser. The energy levels of helium and neon that are important for the operation of the laser are shown in Figure 31-51. Helium has an excited energy state $E_{1\,\mathrm{He}}$ that is 20.61 eV above its ground state. Helium atoms are excited to state $E_{1\,\mathrm{He}}$ by an electric discharge. Neon has an excited state $E_{2\,\mathrm{Ne}}$ that is 20.66 eV above its ground state. This is just 0.05 eV above the first excited state of helium. The neon atoms are excited to state $E_{2\,\mathrm{Ne}}$ by collisions with excited helium atoms. The kinetic energy of the helium atoms provides the extra 0.05 eV of energy needed to excite the neon atoms. Another excited state of neon $E_{1\,\mathrm{Ne}}$ exists that is 18.70 eV above its ground state and 1.96 eV below state $E_{2\,\mathrm{Ne}}$. Because state $E_{1\,\mathrm{Ne}}$ is normally unoccupied, population

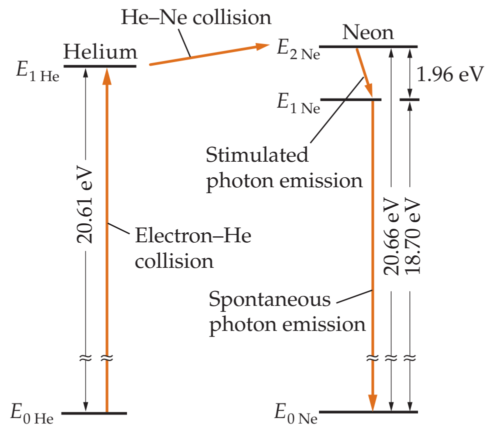

FIGURE 31-51 Energy levels of helium and neon that are important for the helium–neon laser. The helium atoms are excited by electrical discharge to an energy state 20.61 eV above the ground state. They collide with neon atoms, exciting some neon atoms to an energy state 20.66 eV above the ground state. Population inversion is thus achieved between this level and one 1.96 eV below it. The spontaneous emission of photons of energy 1.96 eV stimulates other atoms in the upper state to emit photons of energy 1.96 eV.

* In actuality, the light is only 99.7 percent reflected by a "fully silvered" end. In addition, the reflective coating consists of multiple dielectric layers, not silver.

inversion between states $E_{2\ \mathrm{Ne}}$ and $E_{1\ \mathrm{Ne}}$ is obtained immediately. The stimulated emission that occurs between these states results in photons of energy 1.96 eV and wavelength 632.8 nm, which produces a bright red light. After stimulated emission, the neon atoms in state $E_{1\ \mathrm{Ne}}$ decay to the ground state $E_{0\ \mathrm{Ne}}$ by spontaneous emission.

Note that stimulated emission involves transitions between two excited states of the neon atom in the helium–neon laser, whereas stimulated emission involves transitions between an excited state and the ground state of the chromium ion in the ruby laser. For stimulated emission between an excited state and a ground state, population inversion is difficult to achieve because more than half the atoms in the ground state must be excited. However, for stimulated emission between two excited states, population inversion is easily achieved because the state after stimulated emission is not the ground state but an excited state that is normally unpopulated.

Figure 31-52 shows a schematic diagram of a helium–neon laser commonly used for physics demonstrations. The helium–neon laser consists of a gas tube that contains 15 percent helium gas and 85 percent neon gas. A totally reflecting flat mirror is mounted at one end of the gas tube and a 99 percent reflecting concave mirror is placed at the other end of the gas tube. The concave mirror focuses parallel light at the flat mirror and also acts as a lens that transmits part of the light, so that the light emerges as a parallel beam.

A laser beam is coherent, very narrow, and intense. Its coherence makes the laser beam useful in the production of holograms, which we discuss in Chapter 33. The precise direction and small angular spread of the laser beam make it useful as a surgical tool for destroying cancer cells or reattaching a detached retina. Lasers are also used by surveyors for precise alignment over large distances. Distances can be accurately measured by reflecting a laser pulse from a mirror and measuring the time the pulse takes to travel to the mirror and back. The distance to the moon has been measured to within a few centimeters using an array of mirrors placed on the moon for that purpose. Laser beams are also used in fusion research. An intense laser pulse is focused on tiny pellets of deuterium–tritium in a combustion chamber. The beam heats the pellets to temperatures of the order of 10^8 K in a very short time, causing the deuterium and tritium to fuse and release energy.

Laser technology is advancing so quickly that it is possible to mention only a few of the recent developments. In addition to the ruby laser, many other solid-state lasers exist that have output wavelengths which range from approximately 170 nm to 3900 nm. Lasers that generate more than 1 kW of continuous power have been constructed. Pulsed lasers can now deliver nanosecond pulses of power exceeding 10^{14} W. Various gas lasers can now produce beams of wavelengths that range from the far infrared to the ultraviolet. Semiconductor lasers (also known as diode lasers or junction lasers) have shrunk in just 10 years from the size of a pinhead to mere billionths of a meter. Liquid lasers that use chemical dyes can be tuned over a range of wavelengths (approximately 70 nm for continuous lasers and more than 170 nm for pulsed lasers). A relatively new laser, the free-electron laser, extracts light energy from a beam of free electrons moving through a spatially varying magnetic field.

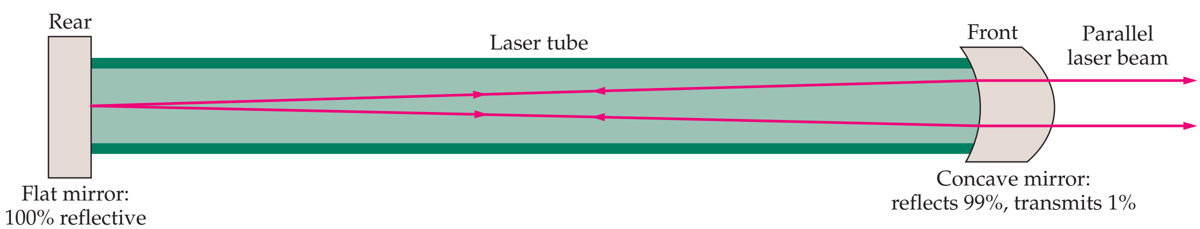

FIGURE 31-52 Schematic drawing of a helium–neon laser. The use of a concave mirror rather than a second plane mirror makes the alignment of the mirrors less critical than it is for the ruby laser. The concave mirror on the right also serves as a lens that focuses the emitted light into a parallel beam.

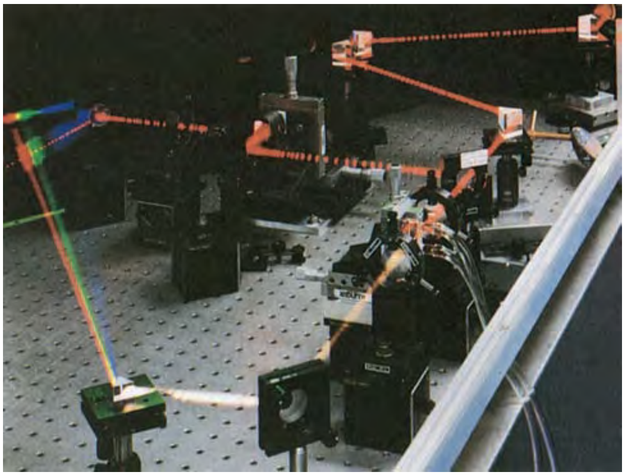
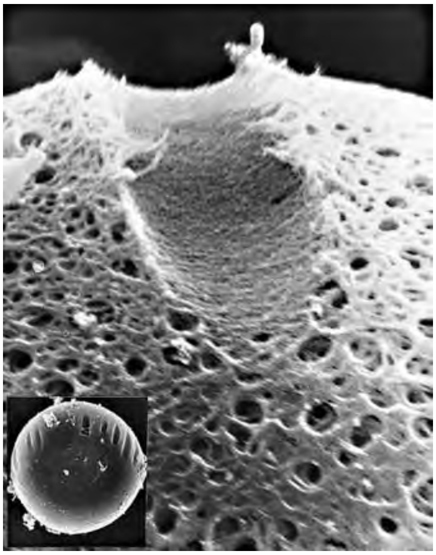
The free-electron laser has the potential to have very high power and large efficiency and can be tuned over a large range of wavelengths. There appears to be no limit to the variety and uses of modern lasers.

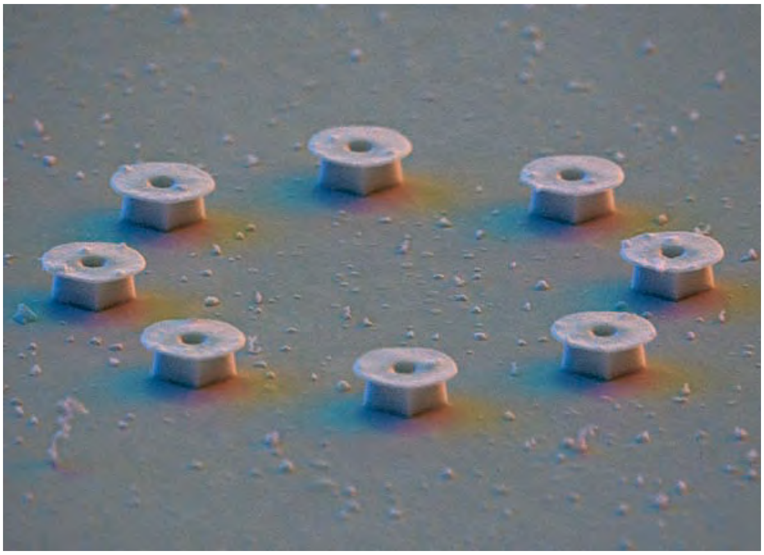


(*b*)

(*c*)



(*d*)



(*e*)

(*a*) Beams from a krypton laser and an argon laser, split into their component wavelengths. In these gas lasers, krypton and argon atoms have been stripped of multiple electrons, forming positive ions. The light-emitting energy transitions occur when excited electrons in the ions decay from one upper energy level to another. Here, several energy transitions are occurring at once, each corresponding to emitted light of a different wavelength. (*b*) A femtosecond pulsed laser. By a technique known as *modelocking*, different excited modes within a laser's cavity can be made to interfere with one another and create a series of ultrashort pulses, which are picoseconds long, that correspond to the time it takes light to bounce back and forth once within the cavity. Ultrashort pulses have been used as probes to study the behavior of atoms and molecules during chemical reactions. (*c*) A carbon dioxide laser takes just 2 minutes to cut out a steel saw blade. (*d*) A groove etched in the zona pellucida (protective outer covering) of a mouse egg by a *laser scissor* facilitates implantation. This technique has already been applied in human fertility therapies. Several effects contribute to the ability of the finely focused laser to cut on such a delicate scale—photon absorption may heat the target, break molecular bonds, or drive chemical reactions. (*e*) The so-called nanolasers shown are semiconductor disks mere microns in diameter and fractions of a micron in width. These tiny lasers work like their larger counterparts. Exploiting quantum effects that prevail on the microscopic scale, nanolasers promise great efficiency and they are being explored as ultrafast, low-energy switching devices. *((a, c) Chuck O'rear/ West Light. Physics Spotlight

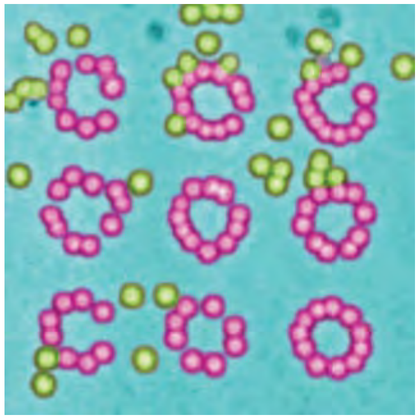
Optical Tweezers and Vortices: Light at Work



Silicon spheres in water are caught in a three by three array of optical vortices. The optical vortices trap the spheres and exert torques on them. *(Courtesy David G. Grier, from E. Curtis, B. A. Koss and D. G. Grier, "Dynamic holographic optical tweezers," Optics Communications 207, 169-175 (2002).)*

Light pressure has been used to measure the force exerted by biological molecules,[*] to unfold and refold proteins,[†] and even to assist in the trapping and study of atoms.[‡] Using the radiation pressure of light to hold microscopic particles in place is called *optical trapping*. Some optical traps, often called *optical tweezers*, can move and manipulate particles.

In the 1970s, a research group led by Arthur Ashkin at Bell Laboratories used radiation pressure of light to levitate droplets of water from 1 to 40 micrometers in diameter.[#] After many years of experimentation, this group demonstrated that a single laser could control the position of a virus in a solution on a microscope slide.[°] Molecular biologists and microbiologists quickly began to use optical tweezers in their studies.

Often, optical trapping is done using lasers that transmit light which has a wavelength near 1000 nanometers,[§] because many biological materials are relatively transparent to such near-infrared wavelengths. The liquid used for holding biological specimens absorbs scattered light near this wavelength.[¶,**] (This means that the trapped object is less likely to be cooked by the light.) Other wavelengths of light may be used, depending on the items to be trapped. The force used in optical traps for examining biological molecules is a few piconewtons.[††]

Optical trapping works both by light pressure and by taking advantage of the gradient of light intensity of a tightly focused laser beam. If a beam of light shines through a small translucent spherical object within the beam, the light will refract. The average of the pressure of refraction of an intense beam will act to keep the object centered in the beam. The more tightly the beam of light is focused, the closer a particle is trapped along the beam near the focus by the strength of the gradient of light intensity.[‡‡,##] This allows for positional control of an object in three dimensions. During the study of biological molecules, a molecule is usually attached to a polystyrene sphere that can be anywhere from 100 nm to 2 μm in diameter. Moving the sphere allows the molecule to be stretched, folded, and brought into focus with the help of optical tweezers. Much larger objects, such as entire cells, can also be moved by optical tweezers.[°°]

Specialized digital lenses can give laser light carefully calculated twists. The twisted light is called an *optical vortex*. Although they have many other potential uses, optical vortices can be used as specialized optical tweezers that have angular momentum.[§§] Different twists have different amounts of angular momentum and can be used to spin and rotate particles. Optical vortices have even been used to spin particles into one another to combine particles.

Physicists at the University of Chicago have come up with a method of generating hundreds of different optical tweezers from the same beam by passing laser beams through a digitally controlled lens.[¶¶] These tweezers can include optical vortices that exert different amounts of torque on particles. The holographic optical tweezers (HOT) method of creating optical vortices has been patented for manipulating particles, and for pumping, mixing, and sorting fluids and objects on a microscopic scale.[***,†††] Makers of miniature machines are enthusiastic about this technology because, unlike delicate tiny machines, light does not wear out.[‡‡‡]

Summary

TOPIC	RELEVANT EQUATIONS AND REMARKS	
1. Speed of Light	The SI unit of length, the meter, is defined so that the speed of light in vacuum is exactly $c = 299\,792\,458 \text{ m/s}$	31-1
v in a transparent medium	$v = \frac{c}{n}$ where n is the index of refraction.	31-3
2. Reflection and Refraction	When light is incident on a surface separating two media in which the speed of light differs, part of the light energy is transmitted and part of the light energy is reflected.	
Law of reflection	The reflected ray lies in the plane of incidence and makes an angle θ_1' with the normal that is equal to the angle of incidence. $\theta_1' = \theta_1$	31-4
Reflected intensity, normal incidence	$I = \left(\frac{n_1 - n_2}{n_1 + n_2}\right)^2 I_0$	31-7
Index of refraction	$n = \frac{c}{v}$	31-3
Law of refraction (Snell's law)	$n_1 \sin\theta_1 = n_2 \sin\theta_2$	31-5*b*
Total internal reflection Critical angle	When light is traveling in a medium that has an index of refraction n_1 and is incident on the boundary of a second medium that has a lower index of refraction $n_2 < n_1$, the light is totally reflected if the angle of incidence is greater than the critical angle θ_c given by $n_1 \sin\theta_c = n_2 \sin 90° \qquad n_1 > n_2$	31-8
Dispersion	The speed of light in a medium, and therefore the index of refraction of that medium, depends on the wavelength of light. Because of dispersion, a beam of white light incident on a refracting prism is dispersed into its component colors. Similarly, the reflection and refraction of sunlight by raindrops produce a rainbow.	
3. Polarization	Transverse waves can be polarized. The four phenomena that produce polarized electromagnetic waves from unpolarized waves are (1) absorption, (2) scattering, (3) reflection, and (4) birefringence.	
Malus's law	When two polarizers have their transmission axes at an angle θ, the intensity transmitted by the second polarizer is reduced by the factor $\cos^2\theta$: $I = I_0 \cos^2\theta$	31-16
4. Huygens's Construction	Each point on a primary wavefront serves as the source of spherical secondary wavelets that advance with a speed and frequency equal to that of the primary wave. The primary wavefront at some later time is the envelope of these wavelets.	
5. Wave-Particle Duality	Light propagates like a wave, but interacts with matter like a particle.	
Photon energy	$E = hf = \frac{hc}{\lambda}$	31-25
Planck's constant	$h = 6.626 \times 10^{-34} \text{ J}\cdot\text{s} = 4.136 \times 10^{-15} \text{ eV}\cdot\text{s}$	
hc	$hc = 1240 \text{ eV}\cdot\text{nm}$	31-26

TOPIC	RELEVANT EQUATIONS AND REMARKS
6. Emission of Light	Light is emitted when a valence electron makes a transition from an excited state to a state of lower energy.
Line spectra	Atoms in dilute gases emit a discrete set of wavelengths called a line spectrum. The photon energy $E = hf = hc/\lambda$ equals the difference in energy of the initial and final states of the atom.
Continuous spectra	Atoms in high-density gases, liquids, or solids have continuous bands of energy levels, so they emit a continuous spectrum of light. Thermal radiation is visible if the temperature of the emitting object is above approximately 600°C.
Spontaneous emission	An atom in an excited state will spontaneously make a transition to a lower state with the emission of a photon. This process is random, with a characteristic lifetime of about 10^{-8} s. The photons from two or more atoms are not correlated, so the light is incoherent.
Stimulated emission	Stimulated emission occurs if an atom is initially in an excited state and a photon of energy equal to the energy difference between that state and a lower state is incident on the atom. The oscillating electromagnetic field of the incident photon stimulates the excited atom to emit another photon in the same direction and in phase with the incident photon. The emitted light is coherent with the incident light.
7. Visible Light	The human eye is sensitive to electromagnetic radiation that has wavelengths from approximately 400 nm (violet) to 700 nm (red). The photon energies range from approximately 1.8 eV to 3.1 eV. A uniform distribution of wavelengths, such as the wavelengths emitted by the Sun, appears white to our eyes.
8. Lasers	A laser produces an intense, coherent, and narrow beam of photons as the result of stimulated emission. The operation of a laser depends on population inversion, in which there are more atoms in an excited state than in the ground state or a lower state.

Answers to Concept Check

31-1 There are 720 teeth, but there are also 720 gaps, so the width of a tooth is less than $\frac{1}{720}$ of the circumference of the wheel. Consequently, the wheel actually has to rotate through less than $\frac{1}{720}$ rev for the light from the distant mirror to be again observed.

Answers to Practice Problems

31-1 (*a*) 4.57×10^6 km (*b*) 3.05×10^8 m/s

31-2 1.28 s each way

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • A ray of light reflects from a plane mirror. The angle between the incoming ray and the reflected ray is 70°. What is the angle of reflection? (*a*) 70°, (*b*) 140°, (*c*) 35°, (*d*) Not enough information is given to determine the reflection angle. SSM

2 • A ray of light in air is incident on the surface of a piece of glass. The angle between the normal to the surface and the incident ray is 40°, and the angle between the normal and the refracted ray is 28°. What is the angle between the incident ray and the refracted ray? (*a*) 12°, (*b*) 28°, (*c*) 40°, (*d*) 68°

3 • **Engineering Application** During a physics experiment, you are measuring refractive indices of different transparent materials using a red helium–neon laser beam. For a given angle of incidence, the beam has an angle of refraction equal to 28° in material A, and an angle of refraction equal to 26° in material B. Which material has the larger index of refraction? (*a*) A, (*b*) B, (*c*) The indices of refraction are the same. (*d*) You cannot determine the relative magnitudes of the indices of refraction from the data given.

4 • A ray of light passes from air into water, striking the surface of the water at an angle of incidence of 45°. Which, if any, of the following four quantities changes as the light enters the water: (*a*) wavelength, (*b*) frequency, (*c*) speed of propagation, (*d*) direction of propagation, (*e*) none of the above?

5 • Earth's atmosphere decreases in density as the altitude increases. As a consequence, the index of refraction of the atmosphere also decreases as altitude increases. Explain how one can see the Sun when it is below the horizon. (The horizon is the extension of a plane that is tangent to the Earth's surface.) Why does the setting Sun appear flattened?

6 • A physics student playing pocket billiards wants to strike her cue ball so that it hits a cushion and then hits the eight ball squarely. She chooses several points on the cushion and then measures the distances from each point to the cue ball and to the eight ball. She aims at the point for which the sum of these distances is least. (*a*) Will her cue ball hit the eight ball? (*b*) How is her method related to Fermat's principle? Neglect any effects due to ball rotation.

7 • A swimmer at point *S* in Figure 31-53 develops a leg cramp while swimming near the shore of a calm lake and calls for help. A lifeguard at point *L* hears the call. The lifeguard can run 9.0 m/s and swim 3.0 m/s. She knows physics and chooses a path that will take the least time to reach the swimmer. Which of the paths shown in the figure does the lifeguard take? SSM

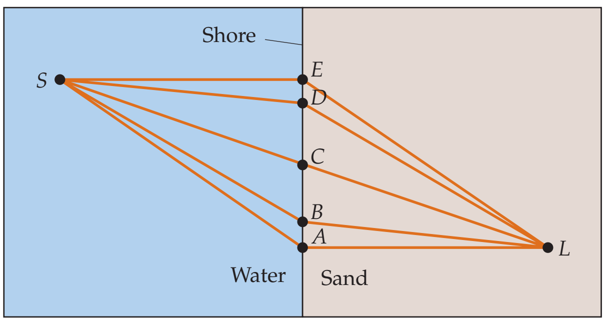

FIGURE 31-53 Problem 7

8 • Material A has a higher index of refraction than material B. Which material has the larger critical angle for total internal reflection when the material is in air? (*a*) A, (*b*) B, (*c*) The angles are the same. (*d*) You cannot compare the angles based on the data given.

9 • **Biological Application** A human eye perceives color using a structure which is called a *cone* that is located on the retina. Three types of molecules compose these cones and each type of molecule absorbs either red, green, or blue light by resonance absorption. Use this fact to explain why the color of an object that appears blue in air appears blue underwater, in spite of the fact that the wavelength of the light is shortened in accordance with Equation 31-6. SSM

10 • Let θ be the angle between the transmission axes of two polarizing sheets. Unpolarized light of intensity I is incident on the first sheet. What is the intensity of the light transmitted through both sheets? (*a*) $I\cos^2\theta$, (*b*) $(I\cos^2\theta)/2$, (*c*) $(I\cos^2\theta)/4$, (*d*) $I\cos\theta$, (*e*) $(I\cos\theta)/4$, (*f*) none of the above

11 •• Draw a diagram to explain how Polaroid sunglasses reduce glare from sunlight reflected from a smooth horizontal surface, such as the surface found on a pool of water. Your diagram should clearly indicate the direction of polarization of the light as it propagates from the Sun to the reflecting surface and then through the sunglasses into the eye. SSM

12 • **Biological Application** Why is it far less dangerous to stand in front of an intense beam of red light than in front of a very low-intensity beam of gamma rays?

13 • Three energy states of an atom are A, B, and C. State B is 2.0 eV above state A and state C is 3.00 eV above state B. Which atomic transition results in the emission of the shortest wavelength of light? (*a*) B → A, (*b*) C → B, (*c*) C → A, (*d*) A → C

14 • In Problem 13, if the atom is initially in state A, which transition results in the emission of the longest wavelength of light? (*a*) A → B, (*b*) B → C, (*c*) A → C, (*d*) B → A

15 • What role does the helium play in a helium–neon laser? SSM

16 • When a beam of visible white light that passes through a gas of atomic hydrogen at room temperature is viewed with a spectroscope, dark lines are observed at the wavelengths of the hydrogen atom emission series. The atoms that participate in the resonance absorption then emit light of same wavelength as they return to the ground state. Explain why the observed spectrum nevertheless exhibits pronounced dark lines.

17 • Which of the following types of light would have the highest energy photons? (*a*) red, (*b*) infrared, (*c*) blue, (*d*) ultraviolet SSM

ESTIMATION AND APPROXIMATION

18 • Estimate the time required for light to make the round trip during Galileo's experiment to measure the speed of light. Compare the time of the round trip to typical human response times. How accurate do you think this experiment is?

19 • Estimate the time delay in receiving a light on your retina when you are wearing eyeglasses compared to when you are not wearing your eyeglasses.

20 •• **Biological Application** Estimate the number of photons that enter your eye if you look for a tenth of a second at the Sun. What energy is absorbed by your eye during that time, assuming that all the photons are absorbed? The total power output of the Sun is 4.2×10^{2} W.

21 •• Römer was observing the eclipses of Jupiter's moon Io with the hope that they would serve as a highly accurate clock that would be independent of longitude. (Prior to GPS, such a clock was needed for accurate navigation.) Io eclipses (enters the umbra of Jupiter's shadow) every 42.5 h. Assuming an eclipse of Io is observed on Earth on June 1 at midnight when Earth is at location *A*

(as shown in Figure 31-54), predict the expected time of observation of an eclipse one-quarter of a year later when Earth is at location B, assuming (*a*) the speed of light is infinite and (*b*) the speed of light is 2.998×10^8 m/s.

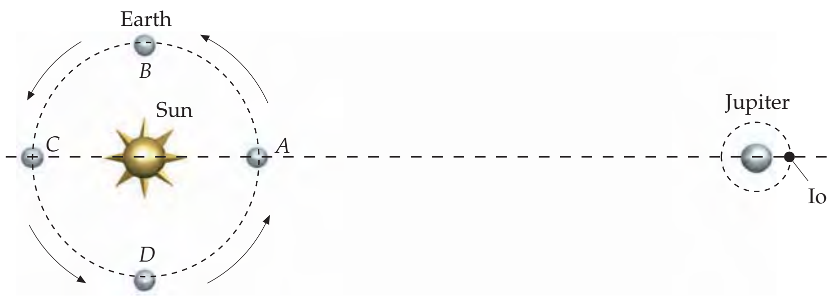

FIGURE 31-54 Problem 21

22 •• If the angle of incidence is small enough, the small angle approximation $\sin\theta \approx \theta$ may be used to simplify Snell's law of refraction. Determine the maximum value of the angle that would make the value for the angle differ by no more than one percent from the value for the sine of the angle. (This approximation will be used in connection with image formation by spherical surfaces in Chapter 32.)

THE SPEED OF LIGHT

23 • Mission Control sends a brief wake-up call to astronauts in a spaceship that is far from Earth. At a time 5.0 s after the call is sent, Mission Control can hear the groans of the astronauts. How far from Earth is the spaceship? (*a*) 7.5×10^8 m, (*b*) 15×10^8 m, (*c*) 30×10^8 m, (*d*) 45×10^8 m, (*e*) The spaceship is on the moon.

24 •• **ENGINEERING APPLICATION** The distance from a point on the surface of Earth to a point on the surface of the moon is measured by aiming a laser light beam at a reflector on the surface of the moon and measuring the time required for the light to make a round trip. The uncertainty in the measured distance Δx is related to the uncertainty in the measured time Δt by $\Delta x = \frac{1}{2}c\,\Delta t$. If the time intervals can be measured to ± 1.00 ns, (*a*) find the uncertainty of the distance. (*b*) Estimate the percentage uncertainty in the distance.

25 •• Ole Römer discovered the finiteness of the speed of light by observing Jupiter's moons. Approximately how sensitive would the timing apparatus need to be in order to detect a shift in the predicted time of the moon's eclipses that occur when the moon happens to be at perigee (3.63×10^5 km) and those that occur when the moon is at apogee (4.06×10^5 km)? Assume that an instrument should be able to measure to at least one-tenth the magnitude of the effect it is to measure. SSM

REFLECTION AND REFRACTION

26 • Calculate the fraction of light energy reflected from an air–water interface at normal incidence.

27 • A ray of light is incident on one of two mirrors that are set at right angles to each other. The plane of incidence is perpendicular to both mirrors. Show that after reflecting from each mirror, the ray will emerge traveling in the direction opposite to the incident direction, regardless of the angle of incidence.

28 •• **SPREADSHEET** (*a*) A ray of light in air is incident on an air–water interface. Using a spreadsheet or graphing program, plot the angle of refraction as a function of the angle of incidence from 0° to 90°. (*b*) Repeat Part (*a*), but for a ray of light in water that is incident on a water–air interface. [For Part (*b*), there is no reflected ray for angles of incidence that are greater than the critical angle.]

29 •• The red light from a helium–neon laser has a wavelength of 632.8 nm in air. Find the (*a*) speed, (*b*) wavelength, and (*c*) frequency of helium–neon laser light in air, water, and glass. (The glass has an index of refraction equal to 1.50.)

30 •• The index of refraction for silicate flint glass is 1.66 for violet light that has a wavelength in air equal to 400 nm and 1.61 for red light that has a wavelength in air equal to 700 nm. A ray of 700-nm-wavelength red light and a ray of 400-nm-wavelength violet light both have angles of refraction equal to 30° upon entering the glass from air. (*a*) Which is greater, the angle of incidence of the ray of red light or the angle of incidence of the ray of violet light? Explain your answer. (*b*) What is the difference between the angles of incidence of the two rays?

31 •• A slab of glass that has an index of refraction of 1.50 is submerged in water that has an index of refraction of 1.33. Light in the water is incident on the glass. Find the angle of refraction if the angle of incidence is (*a*) 60°, (*b*) 45°, and (*c*) 30°. SSM

32 •• Repeat Problem 31 for a beam of light initially in the glass that is incident on the glass–water interface at the same angles.

33 •• A beam of light in air strikes a glass slab at normal incidence. The glass slab has an index of refraction of 1.50. (*a*) Approximately what percentage of the incident light intensity is transmitted through the slab (in one side and out the other)? (*b*) Repeat Part (*a*) if the glass slab is immersed in water.

34 •• This problem is a refraction analogy. A band is marching down a football field with a constant speed v_1. About midfield, the band comes to a section of muddy ground that has a sharp boundary making an angle of 30° with the 50-yd line, as shown in Figure 31-55. In the mud, each marcher moves at a speed equal to $\frac{1}{2}v_1$ in a direction perpendicular to the row of marchers they are in. (*a*) Diagram how each line of marchers is bent as it encounters the muddy section of the field so that the band is eventually marching in a different direction. Indicate the original direction by a ray and the final direction by a second ray. (*b*) Find the angles between these rays and the line normal to the boundary. Is their direction of motion "bent" toward the normal or away from it? Explain your answer in terms of refraction.

35 •• In Figure 31-56, light is initially in a medium that has an

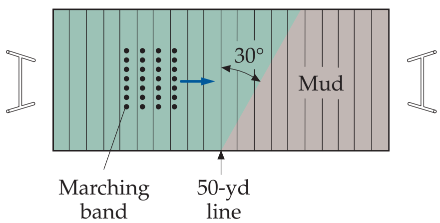

FIGURE 31-55 Problem 34

index of refraction n_1. It is incident at angle θ_1 on the surface of a liquid that has an index of refraction n_2. The light passes through the layer of liquid and enters glass that has an index of refraction n_3. If θ_3 is the angle of refraction in the glass, show that $n_1 \sin\theta_1 = n_3 \sin\theta_3$. That is, show that the second medium can be neglected when finding the angle of refraction in the third medium. SSM

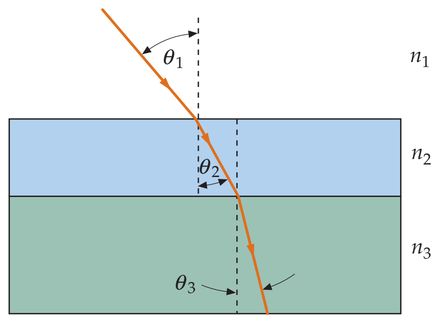

FIGURE 31-56 Problem 35

36 •• On a safari, you are spearfishing while wading in a river. You observe a fish gliding by you. If your line of sight to the fish is 64.0° below the horizontal in air, and assuming the spear follows a straight-line path through the air and water after it is released, determine the angle below the horizontal that you should aim your spear gun in order to catch dinner. Assume the spear gun barrel is 1.50 m above the water surface, the fish is 1.20 m below the surface, and the spear travels in a straight line all the way to the fish.

37 ••• You are standing on the edge of a swimming pool and looking directly across at the opposite side. You notice that the bottom edge of the opposite side of the pool appears to be at an angle of 28° below the horizontal. However, when you sit on the pool edge, the bottom edge of the opposite side of the pool appears to be at an angle of only 14° below the horizontal. Use these observations to determine the width and depth of the pool. *Hint: You will need to estimate the height of your eyes above the surface of the water when standing and sitting.*

38 ••• Figure 31-57 shows a beam of light incident on a glass plate of thickness d and index of refraction n. (*a*) Find the angle of incidence so that the separation b between the ray reflected from the top surface and the ray reflected from the bottom surface and exiting the top surface is a maximum. (*b*) What is this angle of incidence if the index of refraction of the glass is 1.60? (*c*) What is the separation of the two beams if the thickness of the glass plate is 4.0 cm?

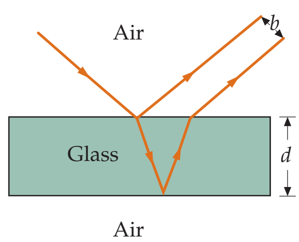

FIGURE 31-57 Problems 38 and 48

TOTAL INTERNAL REFLECTION

39 • What is the critical angle for light traveling in water that is incident on a water–air interface? SSM

40 • A glass surface ($n = 1.50$) has a layer of water ($n = 1.33$) on it. Light in the glass is incident on the glass–water interface. Find the critical angle for total internal reflection.

41 • A point source of light is located 5.0 m below the surface of a large pool of water. Find the area of the largest circle on the pool's surface through which light coming directly from the source can emerge.

42 •• Light traveling in air strikes the largest face of an isosceles-right-triangle prism at normal incidence. What is the speed of light in this prism if the prism is just barely able to produce total internal reflection?

43 •• A point source of light is located at the bottom of a steel tank, and an opaque circular card of radius 6.00 cm is placed horizontally over it. A transparent fluid is gently added to the tank so that the card floats on the fluid surface with its center directly above the light source. No light is seen by an observer above the surface until the fluid is 5.00 cm deep. What is the index of refraction of the fluid?

44 •• ENGINEERING APPLICATION An optical fiber allows rays of light to propagate long distances by using total internal reflection. Optical fibers are used extensively in medicine and in digital communications. As shown in Figure 31-58 the fiber consists of a core material that has an index of refraction n_2 and radius b surrounded by a cladding material that has an index of refraction $n_3 < n_2$. The *numerical aperture* of the fiber is defined as $\sin\theta_1$, where θ_1 is the angle of incidence of a ray of light that impinges on the center of the end of the fiber and then reflects off the core-cladding interface just at the critical angle. Using the figure as a guide, show that the numerical aperture is given by $\sin\theta_1 = \sqrt{n_2^2 - n_3^2}$ assuming the ray is initially in air. *Hint: Use of the Pythagorean theorem may be required.*

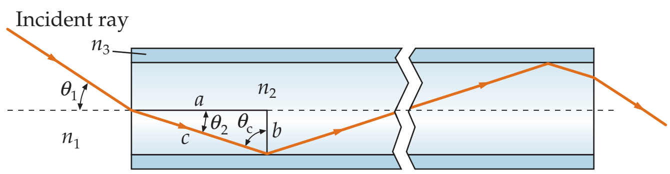

FIGURE 31-58 Problems 44, 45, and 46

45 •• ENGINEERING APPLICATION Find the maximum angle of incidence θ_1 of a ray that would propagate through an optical fiber that has a core index of refraction of 1.492, a core radius of 50.00 μm, and a cladding index of 1.489. See Problem 44. SSM

46 •• ENGINEERING APPLICATION Calculate the difference in time needed for two pulses of light to travel down 15.0 km of the fiber that is described in Problem 44. Assume that one pulse enters the fiber at normal incidence and the second pulse enters the fiber at the maximum angle of incidence calculated in Problem 45. In fiber optics, this effect is known as *modal dispersion*.

47 ••• Investigate how a thin film of water on a glass surface affects the critical angle for total reflection. Use $n = 1.50$ for glass and $n = 1.33$ for water. (*a*) What is the critical angle for total internal reflection at the glass–water interface? (*b*) Does a range of incident angles exist such that the angles are greater than θ_c for glass-to-air refraction and for which the light rays will leave the glass, travel through the water, and then pass into the air?

48 •• A laser beam is incident on a plate of glass that is 3.0 cm thick (Figure 31-57). The glass has an index of refraction of 1.5 and the angle of incidence is 40°. The top and bottom surfaces of the glass are parallel. What is the distance b between the beam formed by reflection off the top surface of the glass and the beam reflected off the bottom surface of the glass.

DISPERSION

49 • A beam of light strikes the plane surface of silicate flint glass at an angle of incidence of 45°. The index of refraction of the glass varies with wavelength (see Figure 31-59). How much smaller is the angle of refraction for violet light of wavelength 400 nm than the angle of refraction for red light of wavelength 700 nm?

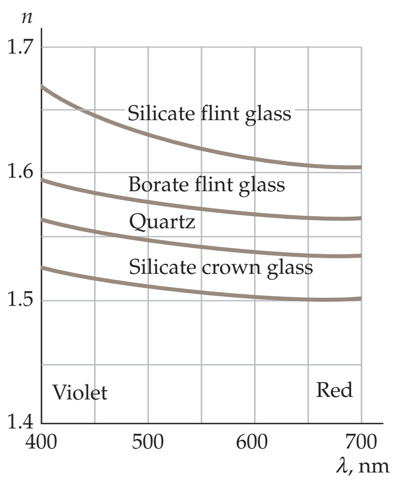

FIGURE 31-59 Problems 49, 50, 73, and 77

50 •• **ENGINEERING APPLICATION** In many transparent materials, dispersion causes different colors (wavelengths) of light to travel at different speeds. This can cause problems in fiber-optic communications systems where pulses of light must travel very long distances in glass. Assuming a fiber is made of silicate crown glass (see Figure 31-59), calculate the difference in travel times that two short pulses of light take to travel 15.0 km in the fiber if the first pulse has a wavelength of 700 nm and the second pulse has a wavelength of 500 nm.

POLARIZATION

51 • What is the polarizing angle for light in air that is incident on (*a*) water ($n = 1.33$) and (*b*) glass ($n = 1.50$)? SSM

52 • Light that is horizontally polarized is incident on a polarizing sheet. It is observed that only 15 percent of the intensity of the incident light is transmitted through the sheet. What angle does the transmission axis of the sheet make with the horizontal?

53 • Two polarizing sheets have their transmission axes crossed so that no light gets through. A third sheet is inserted between the first two so that its transmission axis makes an angle θ with the transmission axis of the first sheet. Unpolarized light of intensity I_0 is incident on the first sheet. Find the intensity of the light transmitted through all three sheets if (*a*) $\theta = 45°$ and (*b*) $\theta = 30°$.

54 • A horizontal 5.0 mW laser beam that is vertically polarized is incident on a polarizing sheet that is oriented with its transmission axis vertical. Behind the first sheet is a second sheet that is oriented so that its transmission axis makes an angle of 27° with respect to vertical. What is the power of the beam transmitted through the second sheet?

55 •• The polarizing angle for light in air that is incident on a certain substance is 60°. (*a*) What is the angle of refraction of light incident at this angle? (*b*) What is the index of refraction of this substance? SSM

56 •• Two polarizing sheets have their transmission axes crossed so that no light is transmitted. A third sheet is inserted so that its transmission axis makes an angle θ with the transmission axis of the first sheet. (*a*) Derive an expression for the intensity of the transmitted light as a function of θ. (*b*) Show that the intensity transmitted through all three sheets is maximum when $\theta = 45°$.

57 •• If the middle polarizing sheet in Problem 56 is rotating at an angular speed ω about an axis parallel with the light beam, find an expression for the intensity transmitted through all three sheets as a function of time. Assume that $\theta = 0°$ at time $t = 0$.

58 •• **SPREADSHEET** A stack of $N + 1$ ideal polarizing sheets is arranged so that each sheet is rotated by an angle of $\pi/(2N)$ rad with respect to the preceding sheet. A linearly polarized light wave of intensity I_0 is incident normally on the stack. The incident light is polarized along the transmission axis of the first sheet and is therefore perpendicular to the transmission axis of the last sheet in the stack. (*a*) Show that the intensity of the light transmitted through the entire stack is given by $I_0 \cos^{2N}[\pi/(2N)]$. (*b*) Using a spreadsheet or graphing program, plot the transmitted intensity as a function of N for values of N from 2 to 100. (*c*) What is the direction of polarization of the transmitted beam in each case?

59 •• **SPREADSHEET, ENGINEERING APPLICATION** The device described in Problem 58 could serve as a *polarization rotator*, which changes the linear plane of polarization from one direction to another. The efficiency of such a device is measured by taking the ratio of the output intensity at the desired polarization to the input intensity. The result of Problem 58 suggests that the highest efficiency is achieved by using a large value for the number N. A small amount of intensity is lost regardless of the input polarization when using a real polarizer. For each polarizer, assume the transmitted intensity is 98 percent of the amount predicted by the law of Malus and use a **spreadsheet** or graphing program to determine the optimum number of sheets you should use to rotate the polarization 90°. SSM

60 •• Show mathematically that a linearly polarized wave can be thought of as a superposition of a right and a left circularly polarized wave.

61 •• Suppose that the middle sheet in Problem 53 is replaced by two polarizing sheets. If the angles between the transmission axes of the second, third and fourth sheets in the stack make angles of 30°, 60° and 90°, respectively, with the transmission axis of the first sheet, (*a*) what is the intensity of the transmitted light? (*b*) How does this intensity compare with the intensity obtained in part (*a*) of Problem 53?

62 •• Show that the electric field of a circularly polarized wave propagating parallel to the x axis can be expressed by $\vec{E} = E_0 \sin(kx + \omega t)\hat{j} + E_0 \cos(kx + \omega t)\hat{k}$.

63 •• A circularly polarized wave is said to be *right circularly polarized* if the electric and magnetic fields rotate clockwise when viewed along the direction of propagation and *left circularly polarized* if the fields rotate counterclockwise. (*a*) What is the sense of the circular polarization for the wave described by the expression in Problem 62? (*b*) What would be the expression for the electric field of a circularly polarized wave traveling in the same direction as the wave in Problem 60, but with the fields rotating in the opposite sense? SSM

SOURCES OF LIGHT

64 • A helium–neon laser emits light that has a wavelength equal to 632.8 nm and has a power output of 4.00 mW. How many photons are emitted per second by this laser?

65 •• The first excited state of an atom of a gas is 2.85 eV above the ground state. (*a*) What is the maximum wavelength of radiation for resonance absorption by atoms of the gas that are in the ground state? (*b*) If the gas is irradiated with monochromatic light that has a wavelength of 320 nm, what is the wavelength of the Raman scattered light?

66 •• A gas is irradiated with monochromatic ultraviolet light that has a wavelength of 368 nm. Scattered light that has a wavelength equal to 368 nm is observed, and scattered light that has a wavelength of 658 nm is also observed. Assuming that the gas atoms were in their ground state prior to irradiation, find the energy difference between the ground state and the excited state obtained by the irradiation.

67 •• Sodium has excited states 2.11 eV, 3.20 eV, and 4.35 eV above the ground state. Assume that the atoms of the gas are all in the ground state prior to irradiation. (*a*) What is the maximum wavelength of radiation that will result in resonance fluorescence? What is the wavelength of the fluorescent radiation? (*b*) What wavelength will result in excitation of the state 4.35 eV above the ground state? If that state is excited, what are the possible wavelengths of resonance fluorescence that might be observed? SSM

68 •• Singly ionized helium is a hydrogen-like atom that has a nuclear charge of $+2e$. Its energy levels are given by $E_n = -4E_0/n^2$, where $n = 1, 2, \ldots$ and $E_0 = 13.6$ eV. If a beam of visible white light is sent through a gas of singly ionized helium, at what wavelengths will dark lines be found in the spectrum of the transmitted radiation? (Assume that the ions of the gas are all in the state with energy E_1 prior to irradiation.)

69 • A pulse from a ruby laser has an average power of 10 MW and lasts 1.5 ns. (*a*) What is the total energy of the pulse? (*b*) How many photons are emitted in the pulse? SSM

GENERAL PROBLEMS

70 • A beam of red light that has a wavelength of 700 nm in air travels in water. (*a*) What is the wavelength in water? (*b*) Does a swimmer underwater observe the same color or a different color for this light?

71 • The critical angle for total internal reflection for a substance is 48°. What is the polarizing angle for the substance? SSM

72 •• Show that when a flat mirror is rotated through an angle θ about an axis in the plane of the mirror, a reflected beam of light (from a fixed incident beam) that is perpendicular to the rotation axis is rotated through 2θ.

73 •• Use Figure 31-59 to calculate the critical angles for light initially in silicate flint glass that is incident on a glass–air interface if the light is (*a*) violet light of wavelength 400 nm and (*b*) red light of wavelength 700 nm. SSM

74 •• Light is incident on a slab of transparent material at an angle θ_1, as shown in Figure 31-60. The slab has a thickness t and an index of refraction n. Show that $n = \sin(\theta_1)/\sin[\tan^{-1}(d/t)]$, where d is the distance shown in the figure.

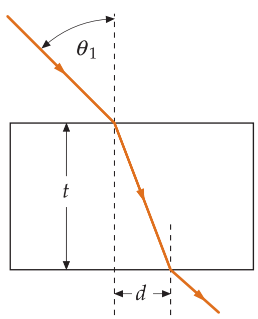

FIGURE 31-60 Problem 74

75 •• A ray of light begins at the point (−2.00 m, 2.00 m, 0.00 m), strikes a mirror in the $y = 0$ plane at some point (x, 0, 0), and reflects through the point (2.00 m, 6.00 m, 0.00 m). (*a*) Find the value of x that makes the total distance traveled by the ray a minimum. (*b*) What is the angle of incidence on the reflecting plane? (*c*) What is the angle of reflection?

76 •• **Engineering Application** To produce a polarized laser beam, a plate of transparent material (Figure 31-61) is placed in the laser cavity and oriented so the light strikes it at the polarizing angle. Such a plate is called a Brewster window. Show that if θ_{P1} is the polarizing angle for the n_1 to n_2 interface, then θ_{P2} is the polarizing angle for the n_2 to n_1 interface.

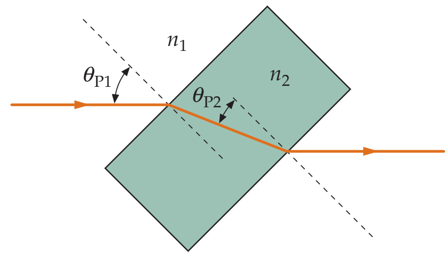

FIGURE 31-61 Problem 76

77 •• From the data provided in Figure 31-59, calculate the polarization angle for an air–glass interface, using light of wavelength 550 nm in each of the four types of glass shown. SSM

78 •• A light ray passes through a prism with an apex angle of α, as shown in Figure 31-62. The ray and the bisector of the apex angle intersect at right angles. Show that the *angle of deviation* δ is related to the apex angle and the index of refraction of the prism material by $\sin\left[\frac{1}{2}(\alpha + \delta)\right] = n \sin\left(\frac{1}{2}\alpha\right)$.

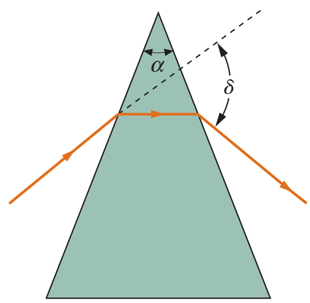

FIGURE 31-62 Problems 78 and 84

79 •• (*a*) For light rays inside a transparent medium that is surrounded by a vacuum, show that the polarizing angle and the critical angle for total internal reflection satisfy $\tan\theta_p = \sin\theta_c$. (*b*) Which angle is larger, the polarizing angle or the critical angle for total internal reflection? SSM

80 •• Light in air is incident on the surface of a transparent substance at an angle of 58° with the normal. The reflected and refracted rays are observed to be mutually perpendicular. (*a*) What is the index of refraction of the transparent substance? (*b*) What is the critical angle for total internal reflection in this substance?

81 •• A light ray in dense flint glass that has an index of refraction of 1.655 is incident on the glass surface. An unknown liquid condenses on the surface of the glass. Total internal reflection on the glass–liquid interface occurs for a minimum angle of incidence on the glass–liquid interface of 53.7°. (*a*) What is the refractive index of the unknown liquid? (*b*) If the liquid is removed, what is the minimum angle of incidence for total internal reflection? (*c*) For the angle of incidence found in Part (*b*), what is the angle of refraction of the ray into the liquid film? Does a ray emerge from the liquid film into the air above? Assume the glass and liquid have parallel planar surfaces.

82 ••• (*a*) Show that for normally incident light, the intensity transmitted through a glass slab that has an index of refraction of n and is surrounded by air is approximately given by $I_T = I_0[4n/(n+1)^2]^2$. (*b*) Use the Part (*a*) result to find the ratio of the transmitted intensity to the incident intensity through N parallel slabs of glass for light of normal incidence. (*c*) How many slabs of a glass that has an index of refraction of 1.5 are required to reduce the intensity to 10 percent of the incident intensity?

83 ••• Equation 31-14 gives the relation between the angle of deviation ϕ_d of a light ray incident on a spherical drop of water in terms of the incident angle θ_1 and the index of refraction of water. (*a*) Assume that $n_{air} = 1$ and derive an expression for $d\phi_d/d\theta_1$. *Hint:* If $y = \sin^{-1}x$, then $dy/dx = (1 - x^2)^{-1/2}$. (*b*) Use the result to show that the angle of incidence for minimum deviation θ_{lm} is given by $\cos\theta_{lm} = \sqrt{\frac{1}{3}(n^2 - 1)}$. (*c*) The index of refraction for a certain red light in water is 1.3318 and the index of refraction for a certain blue light in water is 1.3435. Use the result of Part (*a*) to find the angular separation of these colors in the primary rainbow.

84 ••• Show that the angle of deviation δ is a minimum if the angle of incidence is such that the ray and the bisector of the apex angle α (Figure 31-62) intersect at right angles.

CHAPTER 32

THIS IMAGE IS OF A FEMALE MOSQUITO AND WAS PRODUCED BY A MICROSCOPE. *(Nuridsany & Perennou/ Photo Researchers.)*

Optical Images

? How do you determine the magnifying power of a compound microscope? (See Example 32-15.)

Because the wavelength of light is very small compared with most obstacles and openings, diffraction—the bending of waves around corners—is often negligible, and the ray approximation, in which waves are considered to propagate in straight lines, accurately describes observations.

In this chapter, we apply the laws of reflection and refraction to the formation of images by mirrors and lenses.

32-1 MIRRORS

PLANE MIRRORS

Figure 32-1 shows a bundle of light rays emanating from a point source P and reflected from a plane mirror. After reflection, the rays diverge exactly as if they came from a point P' behind the plane of the mirror. The point P' is called the **image** of the **object** P. When the reflected rays enter the eye, they cannot be distinguished from rays diverging from a source at P' when no mirror is present. This image at P' is called a **virtual image,** virtual because the light does not really emanate from it.

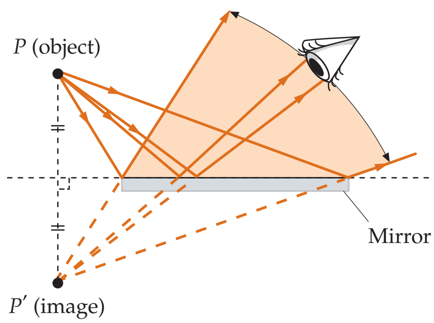

FIGURE 32-1 Image formed by a plane mirror. The rays from point P that strike the mirror and enter the eye appear to come from the image point P' behind the mirror. The image can be seen by an eye located anywhere in the shaded region.

The plane of the mirror is the perpendicular bisector of the line from the object point P to the image point P' as shown. The image can be seen by an eye located anywhere in the shaded region indicated, in which a straight line from the image to the eye passes through the mirror. The object need not be directly in front of the mirror. As long as the object is not located behind the plane of the mirror, some location exists at which the eye can be positioned so as to view the image.

If you stand in front of a mirror and hold up your right hand, the image you see is neither magnified nor reduced, but it looks like a left hand (Figure 32-2). This right-to-left reversal is a result of **depth inversion**—the hand is transformed from a right hand to a left hand because the front and the back of the hand are reversed by the mirror. Depth inversion is also illustrated in Figure 32-3. Figure 32-4 shows the image of a simple rectangular coordinate system. The mirror transforms a right-handed coordinate system, for which $\hat{i} \times \hat{j} = \hat{k}$, into a left-handed coordinate system, for which $\hat{i} \times \hat{j} = -\hat{k}$.

Figure 32-5 shows an arrow of height y standing parallel to a plane mirror a distance s from the mirror. We can locate the image of the tip of the arrowhead (and of any other point on the arrow) by drawing two rays. One ray, drawn perpendicular to the mirror, hits the mirror at point A and is reflected back onto itself. The other ray, making an angle θ with the normal to the mirror, is reflected, making an equal angle θ with the x axis. The extension of these two rays back behind the mirror locates the image of the arrowhead, as shown by the dashed lines in the figure. We can see from this figure that the image is the same distance behind the mirror as the object is in front of the mirror, and that the image is upright (the image of the arrow points in the same direction as the object) and is the same size as the object.

The formation of multiple images by two flat mirrors whose planes make an angle with each other is illustrated in Figure 32-6. We frequently see multiple images like this in clothing stores that provide mirrors for this purpose. The light from source point P that is reflected from mirror 1 strikes mirror 2 just as if it came from the image point P'_1. The image P'_1 is the object for mirror 2. Its image is behind the plane of mirror 2 at point P''_{12}. This image will be formed as long as the image point P'_1 is in front of the plane of mirror 2. The image at point P'_2 is due to rays from P that reflect directly from mirror 2. Because P'_2 is behind the plane of mirror 1, it cannot serve as an object point for an additonal image in mirror 1. The image at point P'_2 cannot serve as an object for mirror 1 because the geometry dictates that none of the rays from P that reflect directly from mirror 2 can then strike mirror 1.

FIGURE 32-2 The image of a right hand in a plane mirror is transformed to a left hand. This right-to-left reversal is a result of depth inversion. *(Demitrios Zangos.)*

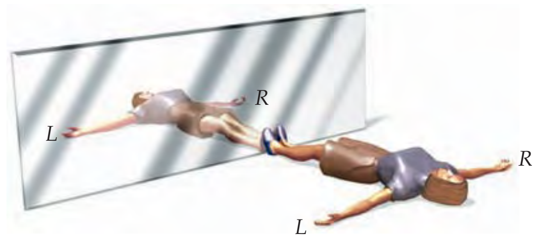

FIGURE 32-3 A person lying down with her feet against the mirror. The image is depth inverted.

! Do not make the mistake of thinking that a mirror is an inversion in the left to right direction. Instead, it is an inversion in the front to back direction.

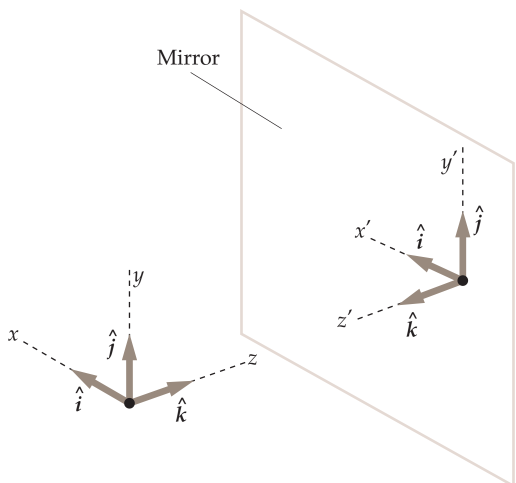

FIGURE 32-4 Image of a rectangular coordinate system in a plane mirror. The arrow along the z axis is reversed in the image. The image of the original right-handed coordinate system, for which $\hat{i} \times \hat{j} = \hat{k}$, is a left-handed coordinate system, for which $\hat{i} \times \hat{j} = -\hat{k}$.

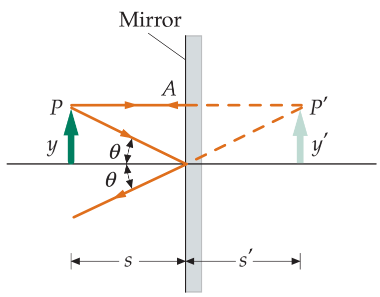

FIGURE 32-5 Ray diagram for locating the image of an arrow in a plane mirror.

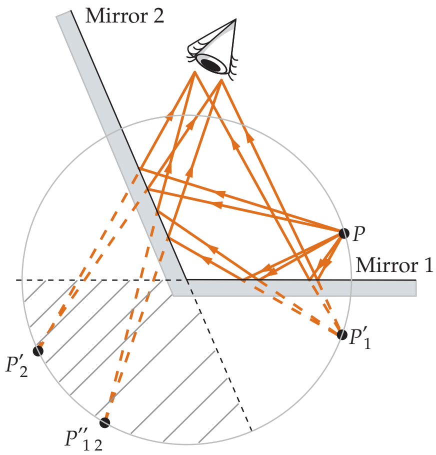

FIGURE 32-6 Images formed by two plane mirrors. P'_1 is the image of the object P in mirror 1, and P'_2 is the image of the object in mirror 2. Point P''_{12} is the image of P'_1 in mirror 2, which is seen when light rays from the object reflect first from mirror 1 and then from mirror 2. The image P'_2 does not have an image in mirror 1 because it is behind that mirror.

CONCEPT CHECK 32-1

Show that a source point and all consequent image points formed by two flat mirrors are equidistant from the intersection of the planes of the two mirrors. (The circle shown in Figure 32-6 is equidistant from such an intersection.)

CONCEPT CHECK 32-2

Which of the images of himself can Ben see?

An alternative way of stating this is that because P'_2 is behind the plane of mirror 1, the image at P'_2 cannot serve as an object for mirror 1. The number of images formed by two mirrors depends on the angle between the mirrors and the position of the object.

Suppose your friend Ben is standing at point P (Figure 32-6) and is wearing a sweatshirt with BEN printed on it. In addition, suppose Ben is facing the intersection of the two mirrors and waving his right hand. Also, suppose that you are standing at the location of the eye. You can see an image of Ben at all three image locations. For the images at P'_1 and P'_2, Ben is waving his left hand and the printing on his sweatshirt appears as ИƎB. However, for the image at P''_{12} Ben is waving his right hand and the printing appears as BEN. For the image at P''_{12} depth inversion occurs twice, once for each reflection, so the result is as if no depth inversion occurs.

Figure 32-7 illustrates the fact that a horizontal ray reflected from two mutually perpendicular vertical mirrors is reflected back along a parallel path no matter what angle the ray makes with the mirrors. If three mirrors are mutually perpendicular to each other, like the sides of an inside corner of a box, any ray incident on any one of the mirrors from any direction is reflected back on a path parallel to the incident ray. A set of three mirrors arranged in this manner is called a corner-cube reflector. An array of corner-cube reflectors was placed on the moon in the Sea of Tranquility by the Apollo 11 astronauts in 1969. A laser beam from Earth that is directed at the mirrors is reflected back to the same place on Earth. Such a beam has been used to measure the distance from the laser to the mirrors to within a few centimeters by measuring the time it takes for the light to travel to the mirrors and return.

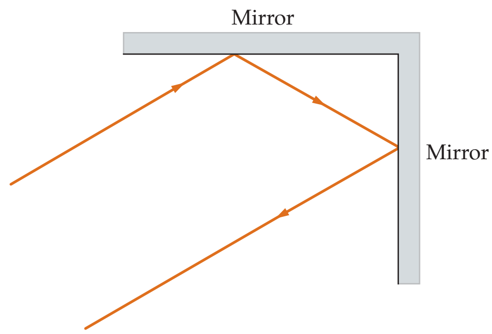

FIGURE 32-7 A ray striking one of two perpendicular plane mirrors is reflected from the second mirror in the direction opposite the original direction for any angle of incidence. The plane of the rays is perpendicular to both mirrors.

SPHERICAL MIRRORS

Figure 32-8 shows a bundle of rays from a point source P on the axis of a concave spherical mirror reflecting from the mirror and converging at point P'. (A concave mirror is shaped like a cave when you look into it.) The rays then diverge from point P', just as if there were an object at the point P'. This image is called a **real image,** because light really does emanate from the image point. The image can be seen by an eye at the left of the image looking into the mirror. It can also be observed on a small viewing screen* or on a small piece of photographic film placed at the image point.

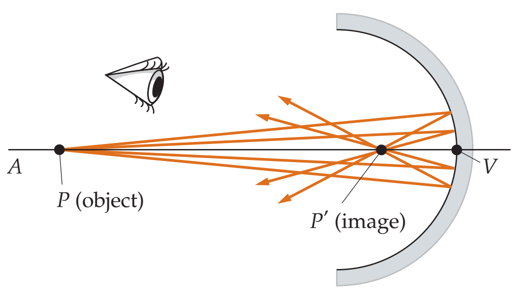

FIGURE 32-8 Rays from a point object P on the axis AV of a concave spherical mirror form an image at P'. The image is sharp if the rays strike the mirror near the axis and if the rays are almost parallel with the axis.

* A viewing screen must produce either diffuse reflection or diffuse transmission of the light. Ground glass is commonly used for this purpose. The screen must be relatively small, so that some of the light from the source reaches the mirror without being blocked by the screen.

A virtual image, such as that formed by a plane mirror as discussed in the previous section, cannot be observed on a screen at the image point because no light from the object point exists at the image point. Despite this distinction between real and virtual images, the eye makes no distinction between them. The light rays diverging from a real image and those appearing to diverge from a virtual image are the same to the eye.

From Figure 32-9, we can see that only rays that strike the spherical mirror at points near the axis (line AV) are reflected through the image point. Rays that are almost parallel with the axis and are near to the axis are called **paraxial rays.** Rays that strike the mirror at points far from the axis upon reflection pass near the image point, but not through it. Such rays cause the image to appear blurred, an effect called **spherical aberration.** The image can be sharpened by blocking off all but the central part of the mirror, so that rays far from the axis do not strike it. The image is then sharper, but its brightness is reduced because less light is reflected to the image point.

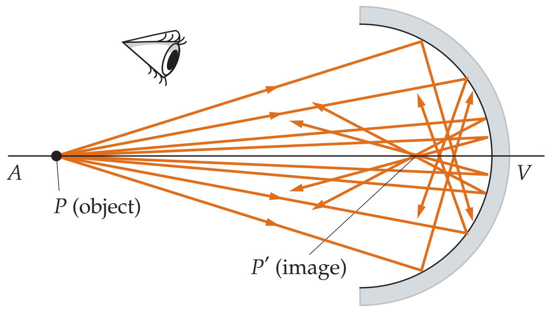

FIGURE 32-9 Spherical aberration of a mirror. Nonparaxial rays that strike the mirror at points far from the axis AV are not reflected through the image point P' formed by the paraxial rays. The nonparaxial rays blur the image.

In order to describe image formation, we wish to obtain an equation relating the position of the image point to the position of the object point. To do this, we draw two rays (Figure 32-10*a*) from an arbitrarily positioned object point P. One ray passes through point C, the center of curvature of the mirror, and the other ray strikes point A, an arbitrarily positioned point on the mirror. The image point P' is where these two rays intersect after reflecting off the mirror. Using the law of reflection, we obtain the location of P'. The ray passing through point C strikes the mirror at normal incidence, so the ray reflects back upon itself. The ray striking the mirror at A makes angle θ with the normal, so, as shown, the reflected ray also makes angle θ with the normal. (Any line normal to a spherical surface passes through the center of curvature.) The image distance s' and object distance s are measured from the plane tangent to the mirror at its vertex V. The angle β is an exterior angle to the triangle PAC, therefore, $\beta = \alpha + \theta$. Similarly, from the triangle PAP', $\gamma = \alpha + 2\theta$. Eliminating θ from these equations gives

$$\alpha + \gamma = 2\beta$$

See **Math Tutorial** *for more information on*
Geometry and Trigonometry

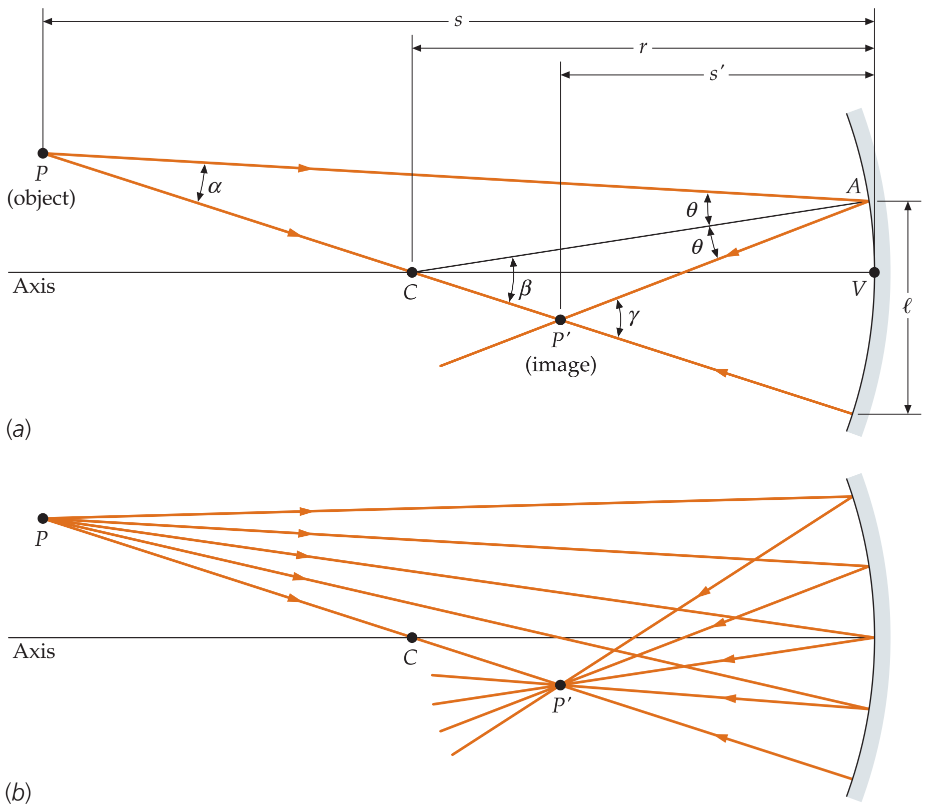

FIGURE 32-10 (a) Geometry for calculating the image distance s' from the object distance s and the radius of curvature r. The angle β is an exterior angle to the triangle PAC; therefore, $\beta = \alpha + \theta$. Similarly, from the triangle PAP', $\gamma = \alpha + 2\theta$. Eliminating θ from these equations gives $2\beta = \alpha + \gamma$. Equation 32-1 follows directly, if we assume the following small-angle approximations: $\alpha \approx \ell/s$, $\beta \approx \ell/r$, and $\gamma \approx \ell/s'$. (b) All paraxial rays from object point P pass through image point P' after reflecting off the mirror.

By assuming all rays are paraxial, we can substitute using the small-angle approximations: $\alpha \approx \ell/s$, $\beta \approx \ell/r$, and $\gamma \approx \ell/s'$. Equation 32-1 follows directly:

$$\frac{1}{s} + \frac{1}{s'} = \frac{2}{r} \qquad \text{32-1}$$

This equation relates the object and image distances with the radius of curvature. The striking thing about this equation is that it has absolutely no information about the location of point A. Therefore, the equation is valid for *any* choice for the location of point A, as long as point A is on the surface of the mirror and all rays are paraxial. That is, as shown in Figure 32-10*b*, *all* paraxial rays emanating from an object point will, upon reflection, pass through a *single* image point.

Equation 32-1 specifies the image position in terms of its distance from the mirror. We now specify the image position in terms of its distance from the axis. We first draw a single ray (Figure 32-11) that reflects off the mirror at its vertex. The two right triangles formed are similar. Corresponding sides of similar triangles are equal, so

$$\frac{y'}{y} = -\frac{s'}{s} \qquad \text{32-2}$$

The minus sign takes into account that y'/y is negative as P and P' are on opposite sides of the axis. Thus, if y is positive, y' is negative and if y is negative, y' is positive.

PRACTICE PROBLEM 32-1

For the image point and object point shown in Figure 32-11, show that

$$\frac{y'}{y} = -\frac{r/2}{s - (r/2)}$$

Hint: Solve Equation 32-1 for s' and substitute your result into Equation 32-2.

When the object distance is large compared with the radius of curvature of the mirror, the term $1/s$ in Equation 32-1 is much smaller than $2/r$ and can be neglected. That is, as $s \rightarrow \infty$, $s' \rightarrow \frac{1}{2}r$, where s' is the image distance. This distance is called the **focal length** f of the mirror, and the plane on which parallel rays incident on the mirror are focused is called the **focal plane.** The intersection of the axis with the focal plane is called the **focal point** F, as illustrated in Figure 32-12*a*. (Again, only paraxial rays are focused at a single point.)

$$f = \tfrac{1}{2}r \qquad \text{32-3}$$

FOCAL LENGTH FOR A MIRROR

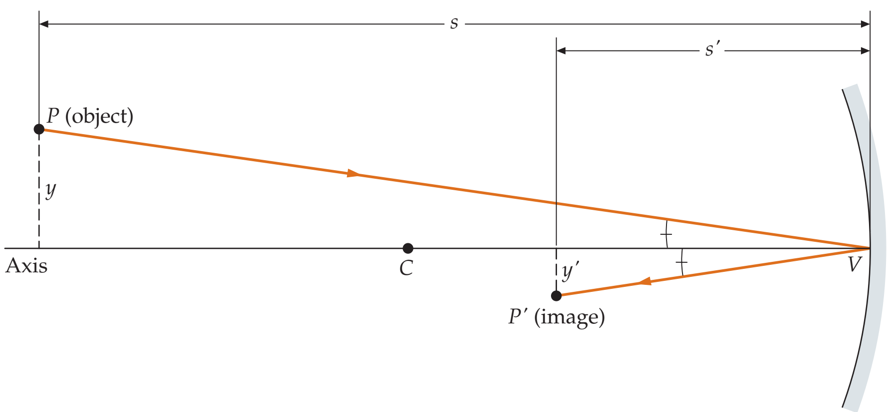

FIGURE 32-11 Geometry for calculating the position y' of the image point with respect to its distance from the axis.

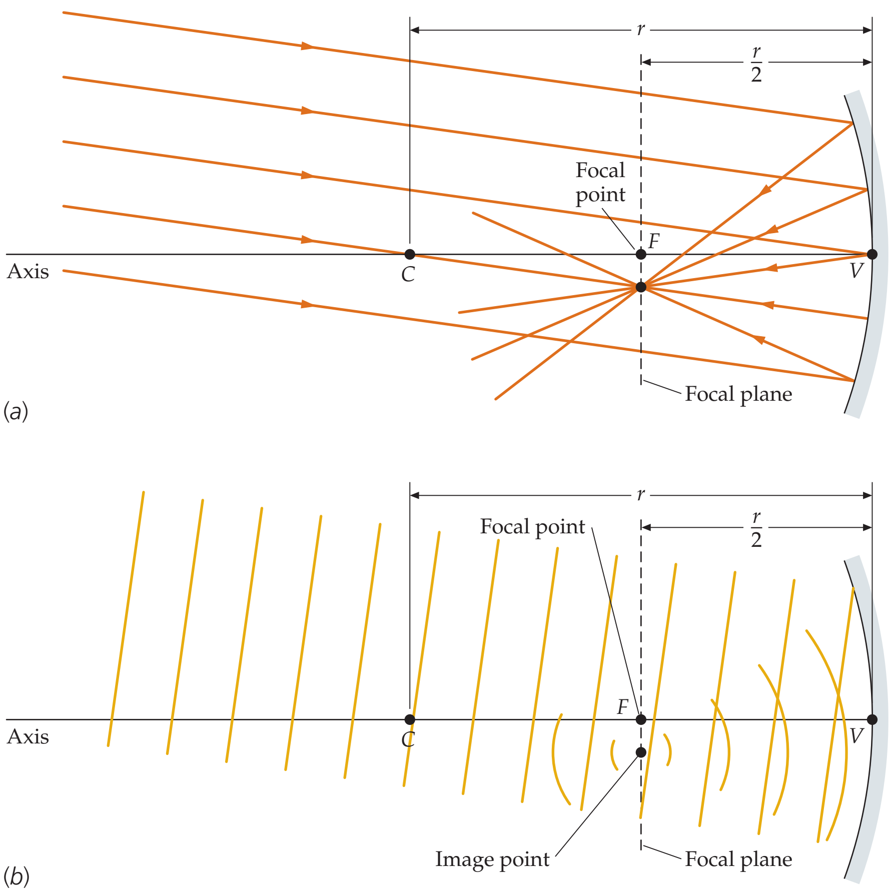

(a)

(b)

FIGURE 32-12 (a) Parallel rays strike a concave mirror and are reflected to a point on the focal plane a distance $\frac{1}{2}r$ to the left of the mirror. (b) The incoming wavefronts are planes; upon reflection, they become spherical wavefronts that converge to, and then diverge from, the image point.

PRACTICE PROBLEM 32-2

Show that solving Equation 32-1 for s' gives

$$s' = \frac{r}{2 - \dfrac{r}{s}}$$

Then show that as $s \to \infty$, $s' \to \frac{1}{2}r$.

The focal length of a spherical mirror is half the radius of curvature. In terms of the focal length f, Equation 32-1 is

$$\frac{1}{s} + \frac{1}{s'} = \frac{1}{f} \qquad 32\text{-}4$$

MIRROR EQUATION

Equation 32-4 is called the **mirror equation.**

When an object point is very far from the mirror, the rays reaching the mirror are approximately parallel, and the wavefronts are approximately planes (Figure 32-12*b*). In Figure 32-12*b*, note that the last part of each wavefront to reflect from the concave mirror surface is the part just below the vertex V. This results in a spherical wavefront upon reflection. Figure 32-13 shows both the wavefronts and the rays for plane waves striking a convex mirror. In this case, the central part of the wavefront strikes the mirror first, and the reflected waves appear to come from the focal point behind the mirror.

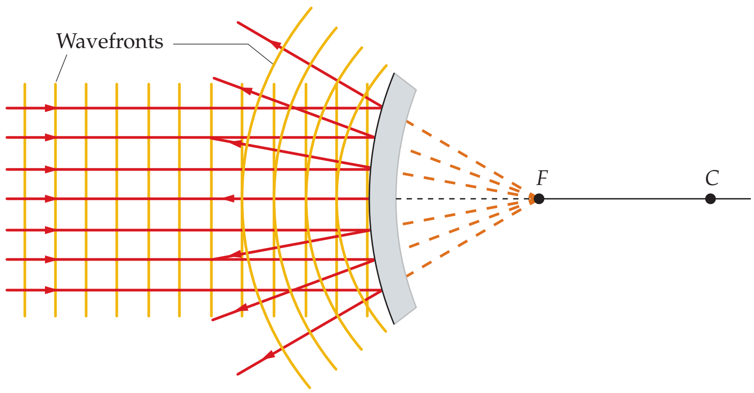

FIGURE 32-13 Reflection of plane waves from a convex mirror. The outgoing wavefronts are spherical, as if emanating from the focal point F behind the mirror. The rays are normal to the wavefronts and appear to diverge from F.

Figure 32-14 illustrates a property of waves called **reversibility.** If we reverse the direction of a reflected ray, the law of reflection assures us that the reflected ray will be along the original incoming ray, but in the opposite direction. (Reversibility also holds for refracted rays, which are discussed in later sections.) Thus, if we have a real image of an object formed by a reflecting (or refracting) surface, we can place an object at the image point and a new, real image will be formed at the position of the original object.

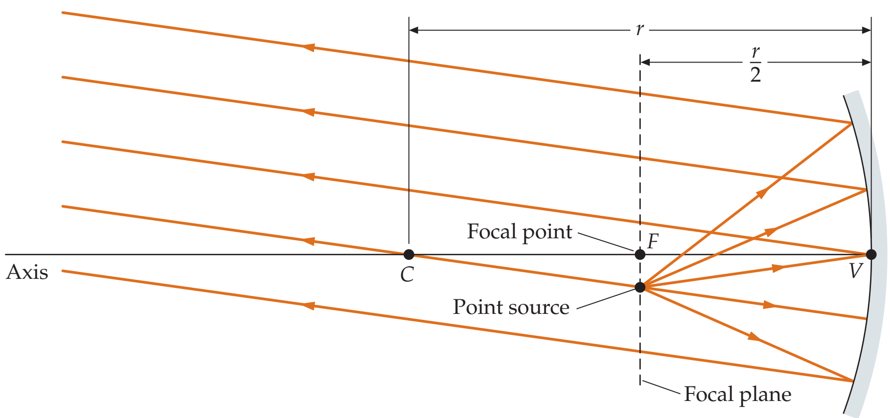

FIGURE 32-14 Reversibility. Rays diverging from a point source on the focal plane of a concave mirror are reflected from the mirror as parallel rays. The rays follow the same paths as in Figure 32-12*a* but in the reverse direction.

Example 32-1 Image in a Concave Mirror

A point source is 12 cm from a concave mirror and 3.0 cm above the axis of the mirror. The radius of curvature of the mirror is 6.0 cm. Find (*a*) the focal length of the mirror and (*b*) the image distance. (*c*) Find the position of the image relative to the axis.

PICTURE The focal length of a spherical mirror is half the radius of curvature. Once the focal length is known, the image distance can be found using the mirror equation (Equation 32-4), and the distance of the image from the axis can be found using Equation 32-2. The image distance from the mirror is the distance from the plane tangent to the mirror at its vertex.

SOLVE

(*a*) The focal length is half the radius of curvature:

$$f = \tfrac{1}{2}r = \tfrac{1}{2}(6.0\text{ cm}) = \boxed{3.0\text{ cm}}$$

(*b*) 1. Use the mirror equation to find a relation for the image distance s':

$$\frac{1}{s} + \frac{1}{s'} = \frac{1}{f}$$

or

$$\frac{1}{12\text{ cm}} + \frac{1}{s'} = \frac{1}{3.0\text{ cm}}$$

2. Solve for s':

$$\frac{1}{s'} = \frac{4}{12\text{ cm}} - \frac{1}{12\text{ cm}} = \frac{3}{12\text{ cm}}$$

$$s' = \boxed{4.0\text{ cm}}$$

(*c*) 1. Use Equation 32-2 to find the distance y' of image from the axis:

$$\frac{y'}{y} = -\frac{s'}{s}$$

2. Solve for y':

$$y' = -\frac{s'}{s}y = -\frac{4.0\text{ cm}}{12\text{ cm}}(3.0\text{ cm}) = \boxed{-1.0\text{ cm}}$$

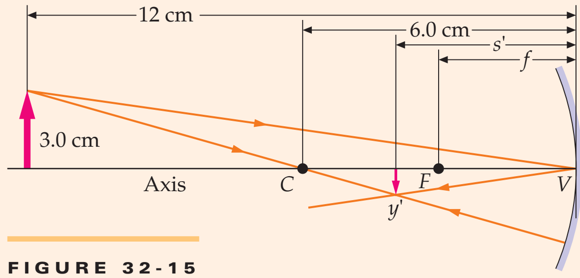

FIGURE 32-15

CHECK In Figure 32-15, two rays from the tip of the arrow have been drawn to locate the corresponding point on the image. By choosing to draw the ray that passes through C and the ray that reflects off the mirror at V, we have chosen to draw two rays that are easy to trace. From this figure, we can see that the results of the solution are very plausible.

PRACTICE PROBLEM 32-3 A concave mirror has a focal length of 4.0 cm. (*a*) What is the mirror's radius of curvature? (*b*) Find the image distance for an object 2.0 cm from the mirror.

CONCEPT CHECK 32-3

What is the radius of curvature of a plane mirror?

RAY DIAGRAMS FOR MIRRORS

A useful method to locate images is by geometric construction of a **ray diagram,** as illustrated in Figure 32-16, where the object is a human figure perpendicular to the axis a distance s from the mirror. By the judicious choice of rays from the head of the figure, we can quickly locate the image. Of the infinitely many rays, there are three rays, **principal rays,** that are particularly convenient to use:

1. The **parallel ray,** drawn parallel to the axis. This ray is reflected through the focal point.
2. The **focal ray,** drawn through the focal point. This ray is reflected parallel to the axis.
3. The **radial ray,** drawn through the center of curvature. This ray strikes the mirror perpendicular to its surface and is thus reflected back on itself.

PRINCIPAL RAYS FOR A MIRROR

These rays are shown in Figure 32-16. The intersection of any two paraxial rays locates the image point of the head. The three principal rays are easier to draw than any of the other rays. Typically, you draw two of the principal rays to locate the image, and then draw the third principal ray as a check to verify the result. Ray diagrams are best drawn with the mirror replaced by a straight line that extends as far as necessary to intercept the rays, as shown in Figure 32-17. (Note that the image in this case is real, inverted, and smaller than the object.)

When the object is between the mirror and its focal point, the rays from an object point reflected from the mirror do not converge but appear to diverge from a point behind the mirror,

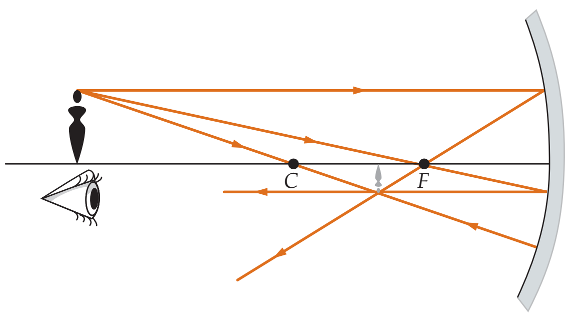

FIGURE 32-16 Ray diagram for the location of the image by geometric construction.

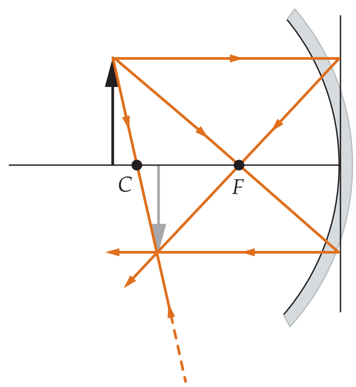

FIGURE 32-17 Ray diagrams are easier to construct if the curved surface is replaced by a plane tangent to the surface at the vertex.

as illustrated in Figure 32-18. In this case, the image is virtual and upright (*upright* meaning not inverted relative to the object). For an object between the mirror and the focal point, s is less than $r/2$, so the image distance s' calculated from Equation 32-1 turns out to be negative. We can apply Equations 32-1, 32-2, 32-3, and 32-4 to this case and to convex mirrors if we adopt a convenient sign convention. Whether the mirror is convex or concave, real images can be formed only in front of the mirror, that is, on the same side of the mirror as the reflected light (and the object). Virtual images are formed behind the mirror where there is no actual light from the object. Our sign convention is as follows:

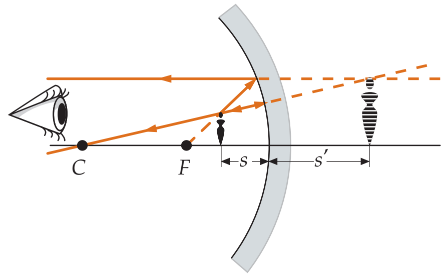

FIGURE 32-18 A virtual image is formed by a concave mirror when the object is inside the focal point. Here the image is located by the radial ray, which is reflected back on itself, and the focal ray, which is reflected parallel to the axis. The two reflected rays appear to diverge from an image point behind the mirror. This image point is found by constructing extensions to the reflected rays.

1. s is positive if the object is on the incident-light side of the mirror.
2. s' is positive if the image is on the reflected-light side of the mirror.
3. r (and thus f) is positive if the mirror is concave so the center of curvature is on the reflected-light side of the mirror.

SIGN CONVENTIONS FOR REFLECTION

The incident-light side and the reflected-light side are, of course, the same side of the mirror. The parameters s, s', r, and f are all positive if a real object* is in front of a concave mirror that forms a real image. A parameter is negative if it does not meet the stated condition for being positive.

The ratio of the image height to the object height is defined as the **lateral magnification** m of the image. From Figure 32-19 and Equation 32-2, we see that the lateral magnification is

$$m = \frac{y'}{y} = -\frac{s'}{s} \qquad 32\text{-}5$$

LATERAL MAGNIFICATION

A negative magnification, which occurs when both s and s' are positive, indicates that the image is inverted.

For plane mirrors, the radius of curvature is infinite. The focal length given by Equation 32-3 is then also infinite. Equation 32-4 then gives $s' = -s$, indicating that the image is behind the mirror at a distance equal to the object distance. The magnification given by Equation 32-5 is then $+1$, indicating that the image is upright and the same size as the object.

Although the preceding equations, coupled with our sign conventions, are relatively easy to use, we often need to know only the approximate location and magnification of the image and whether it is real or virtual and upright or inverted. This knowledge is usually easiest to obtain by constructing a ray diagram. It is always a good idea to use both this graphical method and the algebraic method to locate an image, so that one method serves as a check on the results of the other.

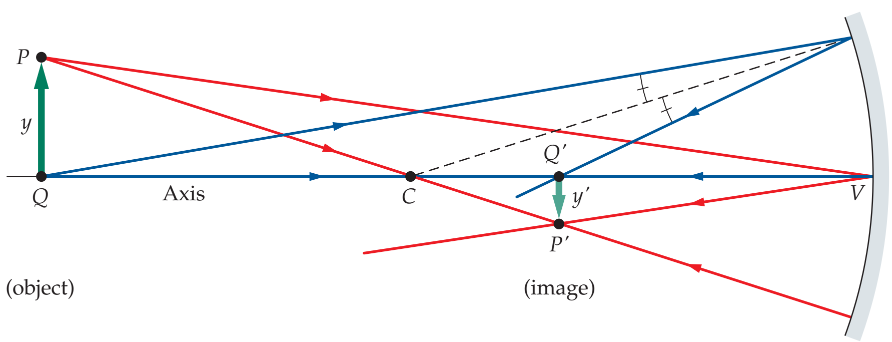

FIGURE 32-19 Geometry for showing the lateral magnification. Rays from the top of the object at P, upon reflection, intersect at P'; and rays from the bottom of the object at Q intersect at Q', where points P and P' have vertical positions y and y', respectively. The lateral magnification m is given by the ratio y'/y. In accord with Equation 32-2, $y'/y = -s'/s$. The minus sign results from the fact that y'/y is negative when s and s' are both positive. A negative m means the image is inverted.

* An object is real if it is on the same side of the mirror as the incident light.

Convex mirrors Figure 32-20 shows a ray diagram for an object in front of a convex mirror. The central ray heading toward the center of curvature C is perpendicular to the mirror and is reflected back on itself. The parallel ray is reflected as if it came from the focal point F behind the mirror. The focal ray (not shown) would be drawn toward the focal point and would be reflected parallel to the axis. We can see from the figure that the image is behind the mirror and is therefore virtual. The image is also upright and smaller than the object.

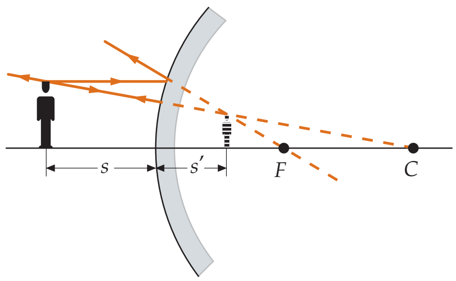

FIGURE 32-20 Ray diagram for an object in front of a convex mirror.

Example 32-2 Image in a Convex Mirror

An object that is 2.0 cm high is 10 cm from a convex mirror that has a radius of curvature equal to 10 cm. (*a*) Locate the image and (*b*) find the height of the image.

PICTURE The ray diagram for this problem is the same as shown in Figure 32-20. From the figure, we see that the image is upright, virtual, and smaller than the object. To find the exact location and height of the image, we use the mirror equation, with $s = 10$ cm and $r = -10$ cm.

SOLVE

(*a*) 1. The image distance s' is related to the object distance s and the focal length f by the mirror equation:

$$\frac{1}{s} + \frac{1}{s'} = \frac{1}{f}$$

2. Calculate the focal length of the mirror:

$$f = \tfrac{1}{2}r = \tfrac{1}{2}(-10\text{ cm}) = -5.0\text{ cm}$$

3. Substitute $s = 10$ cm and $f = -5.0$ cm into the mirror equation to find the image distance:

$$\frac{1}{10\text{ cm}} + \frac{1}{s'} = \frac{1}{-5.0\text{ cm}}$$

4. Solve for s':

$$s' = \boxed{-3.3\text{ cm}}$$

(*b*) 1. The height of the image is m multiplied by the height of the object:

$$y' = my$$

2. Calculate the magnification m:

$$m = -\frac{s'}{s} = -\frac{-3.3\text{ cm}}{10\text{ cm}} = +0.33$$

3. Use m to find the height of the image:

$$y' = my = (0.33)(2.0\text{ cm}) = \boxed{0.67\text{ cm}}$$

CHECK The image distance is negative, indicating a virtual image behind the mirror. The magnification is positive and less than one, indicating that the image is upright and smaller than the object. The results are in agreement with the information obtained from the ray diagram (Figure 32-21).

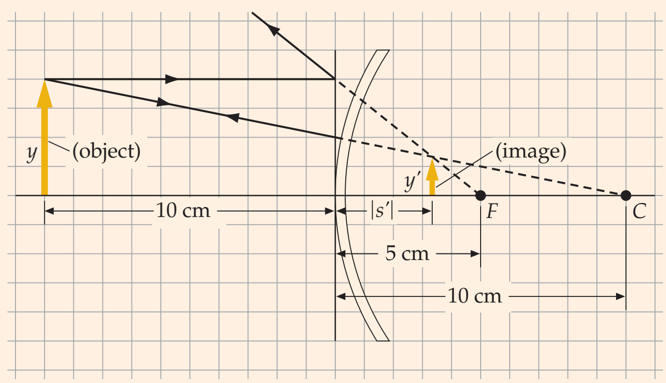

FIGURE 32-21

PRACTICE PROBLEM 32-4 Find the image distance and lateral magnification for an object 5.0 cm away from the mirror in Example 32-2.

Example 32-3 Determining the Range *Context-Rich*

You have a part-time job at Pleasant Hills Golf Course. The fairway of the 16th hole is horizontal for the first 50 yd and then goes down a not-too-steep hill (Figure 32-22), so the people on the tee cannot see the party in front. To prevent people from driving off the tee into the party in front, a convex mirror is mounted on a pole, enabling golfers on the tee to see whether or not the party in front is out of range.* Your boss says that a range finder that works by triangulation could be placed facing the mirror, so the golfers could measure how far the image of the party in front is behind the mirror. Then the golfers could be given a chart telling them how far the next party is from the tee. Your boss knows you are taking a physics course, so he asks you to calculate the distance of the image behind the mirror if the next party is 250 yd from the tee. The radius of curvature of the mirror has a magnitude of 20.0 yd.

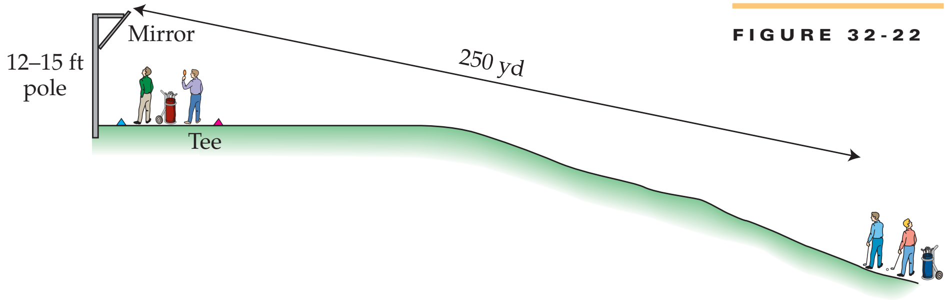

FIGURE 32-22

PICTURE The image distance is related to the object distance by the mirror formula, and the focal length of the lens is half the radius of curvature.

SOLVE

1. Use the mirror equation. For a convex mirror, the radius of curvature is negative:

$$\frac{1}{s} + \frac{1}{s'} = \frac{1}{f}$$

and

$$f = \frac{2}{r}$$

so

$$\frac{1}{250\text{ yd}} + \frac{1}{s'} = \frac{2}{-20.0\text{ yd}}$$

2. The image is 9.62 yd behind the mirror:

$$s' = \boxed{-9.62\text{ yd}}$$

CHECK That the step-2 result is negative is as expected. That is, it was expected that the image would be behind the mirror.

PRACTICE PROBLEM 32-5 What is the distance to the party in front if the image is 9.75 yd behind the mirror?

(*a*)

(*b*)

(*a*) A convex mirror resting on paper that has equally spaced parallel stripes. Note the large number of lines imaged in a small space and the reduction in size and distortion in shape of the image. (*b*) A convex mirror is used for security in a store. *(Richard Megna/Fundamental Photographs.)*

* The mirror was not replaced after it was knocked down during a storm a couple of years ago.

32-2 LENSES

IMAGES FORMED BY REFRACTION

One end of a long transparent cylinder is machined and polished to form a convex spherical surface. Figure 32-23 illustrates the formation of an image by refraction at such a surface. Suppose the cylinder is submerged in a transparent liquid that has an index of refraction n_1, and suppose the cylinder is made of a plastic material that has an index of refraction n_2, where n_2 is greater than n_1. Again, only in the paraxial limit do rays from an object point converge to one point. An equation relating the image distance to the object distance, the radius of curvature, and the indices of refraction can be derived by applying Snell's law of refraction to the rays and using small-angle approximations. The geometry is shown in Figure 32-24. The angles θ_1 and θ_2 are related by Snell's law of refraction: $n_1 \sin\theta_1 = n_2 \sin\theta_2$. Using the small-angle approximation ($\sin\theta = \theta$), Snell's law becomes $n_1\theta_1 = n_2\theta_2$. From triangle ACP', we have $\beta = \theta_2 + \gamma = (n_1/n_2)\theta_1 + \gamma$; and from triangle PAC, we have $\theta_1 = \alpha + \beta$. Eliminating θ_1 from these two equations gives $n_1\alpha + n_2\gamma = (n_2 - n_1)\beta$. Substituting for α, β and γ and using the small-angle approximations $\alpha \approx \ell/s$, $\beta \approx \ell/r$, and $\gamma = \ell/s'$ gives

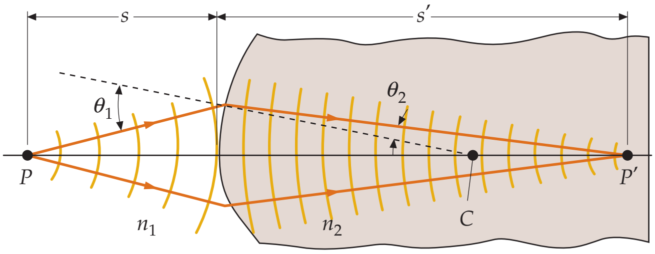

FIGURE 32-23 Image formed by refraction at a spherical surface between two media where the waves move slower in the second medium.

$$\frac{n_1}{s} + \frac{n_2}{s'} = \frac{n_2 - n_1}{r} \tag{32-6}$$

REFRACTION AT A SINGLE SURFACE

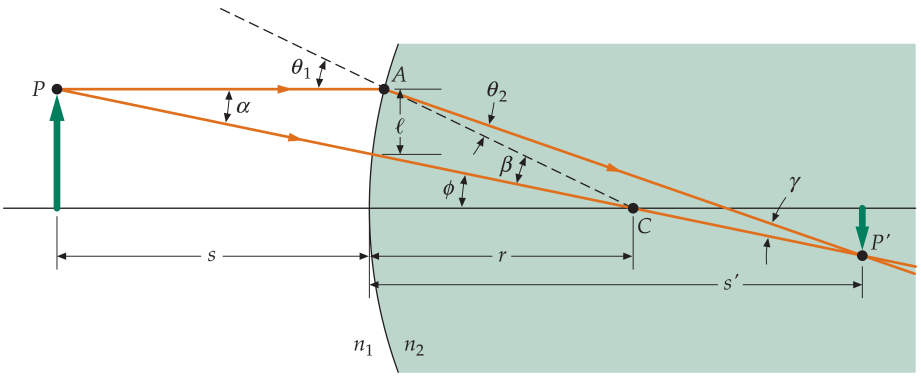

FIGURE 32-24 Geometry for relating the image position to the object position for refraction at a single spherical surface.

In refraction, real images are formed in back of the surface, which we will call the refracted-light side, whereas virtual images occur on the incident-light side, in front of the surface. The sign conventions we use for refraction are similar to those for reflection:

1. s is positive for objects on the incident-light side of the surface.
2. s' is positive for images on the refracted-light side of the surface.
3. r is positive if the center of curvature is on the refracted-light side.

SIGN CONVENTIONS FOR REFRACTION*

* The sign convention of choice for advanced work on optical design is the Cartesian sign convention. It can readily be found on the Internet.

We see that parameters s, s', and r are all positive if a real object is in front of a convex refracting surface that forms a real image. A parameter is negative if it does not meet the stated condition for being positive.

Example 32-4 Magnification by a Refracting Surface — *Try It Yourself*

Derive an expression for the magnification $m = y'/y$ of an image formed by a spherical refracting surface.

PICTURE The magnification is the ratio of y' to y. Using Figure 32-19 and Figure 32-24 as guides, draw a ray diagram suitable for this derivation. The heights are related to the tangents of the angles θ_1 and θ_2, as shown in Figure 32-25. The angles are related by Snell's law. For paraxial rays, you can use the approximations $\tan\theta \approx \sin\theta \approx \theta$, and $\cos\theta \approx 1$.

Cover the column to the right and try these on your own before looking at the answers.

Steps:	Answers
1. Using Figure 32-19 and Figure 32-24 as guides, draw a ray diagram suitable for this derivation. The drawing should include an object, a real image, a refracting surface, and an axis. Then draw an incident ray from the top of the object to the intersection of the axis with the refracting surface, and draw the refracted ray to the corresponding image point (Figure 32-25).	
2. Write expressions for $\tan\theta_1$ and $\tan\theta_2$ in terms of the heights y and $-y'$ and the object and image distances s and s'. (Because y' is negative, use $-y'$, so that $\tan\theta_2$ is positive.)	$\tan\theta_1 = \dfrac{y}{s}$; $\tan\theta_2 = \dfrac{-y'}{s'}$
3. Apply the small-angle approximation $\tan\theta \approx \theta$ to your expressions.	$\theta_1 = \dfrac{y}{s}$; $\theta_2 = \dfrac{-y'}{s'}$
4. Write Snell's law of refraction relating the angles θ_1 and θ_2 using the small-angle approximation $\sin\theta \approx \theta$	$n_1 \sin\theta_1 = n_2 \sin\theta_2$ $n_1\theta_1 = n_2\theta_2$
5. Substitute the expressions for θ_1 and θ_2 found in step 3.	$n_1\left(\dfrac{y}{s}\right) = n_2\left(\dfrac{-y'}{s'}\right)$
6. Solve for the magnification $m = y'/y$.	$\boxed{m = \dfrac{y'}{y} = -\dfrac{n_1 s'}{n_2 s}}$

CHECK The step-6 result for the lateral magnification is dimensionless, as expected.

We see from Example 32-4 that the magnification due to refraction at a spherical surface is

$$m = \frac{y'}{y} = -\frac{n_1 s'}{n_2 s} \tag{32-7}$$

MAGNIFICATION FOR A REFRACTING BOUNDARY

Example 32-5 Image Seen from a Goldfish Bowl

Goldie the goldfish is in a 15.0-cm-radius spherical bowl of water that has an index of refraction of 1.33. Fluffy the cat is sitting on the table with her nose 10.0 cm from the surface of the bowl (Figure 32-26). The light from Fluffy's nose is refracted by the air–water boundary to form an image. Find (*a*) the image distance and (*b*) the magnification of the image of Fluffy's nose. Neglect any effect of the bowl's thin glass wall.

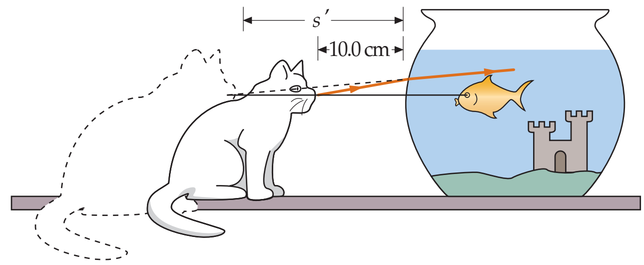

FIGURE 32-26 Goldie sees Fluffy's image farther from the bowl than Fluffy actually is.

PICTURE We find the image distance s' using Equation 32-6 and the magnification using Equation 32-7. Because we are interested in light that goes from Fluffy's nose to the bowl, it follows that the air–water boundary is convex, and that air is the incident-light side of boundary and water is the refracted-light side of boundary. With these identifications, we have $n_1 = 1.00$, $n_2 = 1.33$, $s = +10.0$ cm, and $r = +15.0$ cm.

SOLVE

(*a*) 1. The equation relating the object distance to the image distance is Equation 32-6:

$$\frac{n_1}{s} + \frac{n_2}{s'} = \frac{n_2 - n_1}{r}$$

2. Identify and assign signs to the parameters in the previous step:

$n_1 = 1.00$, $n_2 = 1.33$, $s = +10.0$ cm, and $r = +15.0$ cm

3. Substitute numerical values and solve for s':

$$\frac{1.00}{10.0\text{ cm}} + \frac{1.33}{s'} = \frac{1.33 - 1.00}{15.0\text{ cm}}$$

so

$$s' = \boxed{-17.1\text{ cm}}$$

(*b*) Substitute numerical values into Equation 32-7 to find the magnification m:

$$m = -\frac{n_1 s'}{n_2 s} = -\frac{(1.00)(-17.1\text{ cm})}{(1.33)(10.0\text{ cm})} = \boxed{1.29}$$

CHECK Because s' is negative, the image is virtual; that is, the image is on the side of the refracting surface opposite the refracted light, as shown in Figure 32-26. The fish, Goldie, would see Fluffy to be slightly farther away ($|s'| > s$) than she actually is, and larger ($|m| > 1$) than she actually is. That m is positive indicates the image is upright.

PRACTICE PROBLEM 32-6 If Goldie is 7.5 cm from the side of the bowl nearest Fluffy, find (*a*) the location and (*b*) the magnification of Goldie's image, as seen by Fluffy.

PRACTICE PROBLEM 32-7 The bowl is replaced by an aquarium that has flat sides and Goldie is 7.5 cm from the side where Fluffy is. Use Equation 32-6 to find the location of the image of Goldie that Fluffy sees.

Example 32-6 Image Seen from an Overhead Branch

During the summer months, Goldie the fish spends much of her time in a small pond in her owner's backyard. While enjoying a rest at the bottom of the 1.00-m-deep pond, Goldie is being watched by Fluffy the cat, who is perched on a tree limb 3.00 m above the surface of the pond. How far below the surface is the image of the fish that Fluffy sees? (The index of refraction of water is 1.33.)

PICTURE The surface of the pond is a spherical refracting surface that has a radius of curvature equal to the radius of Earth. (Neglecting the curvature of the surface of Earth, we use $r \approx \infty$.) Thus, Equation 32-6 applies. Because the light reaching Fluffy originates in the water, use $n_1 = 1.33$ and $n_2 = 1.00$.

SOLVE

1. Draw a picture of the situation. Label the object distance and the indices of refraction of the media. Goldie is the object (Figure 32-27):

2. Using Equation 32-6, relate the image position s' to the other relevant parameters:

$$\frac{n_1}{s} + \frac{n_2}{s'} = \frac{n_2 - n_1}{r}$$

3. The refracting surface is virtually flat. Using $r = \infty$, solve for s':

$$s' = -\frac{n_2}{n_1}s$$

4. Using the given values $n_1 = 1.33$, $n_2 = 1.00$ and $s = 1.00$ m, substitute to obtain s':

$$\boxed{s' = -\frac{1}{1.33}(1.00\text{ m}) = -0.752\text{ m}}$$

That the image is negative means that the image is on the side of the surface opposite the refracted light. That is, it is 0.752 m below the surface.

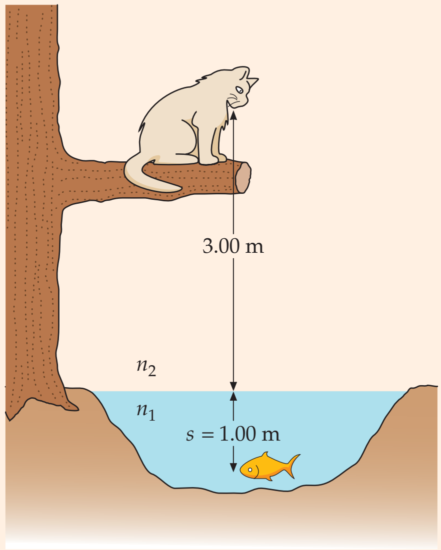

FIGURE 32-27

CHECK The image is between the location of the fish and the surface of the water. This result is expected. Recall that if you dip an oar into the water at an angle, the part of the oar that is underwater appears above where you know it has to be.

TAKING IT FURTHER (1) This image can be seen at the calculated position only when the object is viewed from directly overhead, or nearly so. From that observation point the rays are paraxial, a condition necessary for Equation 32-6 to be valid. If Fluffy is standing on the edge of the pond, the rays will not satisfy the paraxial approximation and Equation 32-6 will not correctly predict the location of the image. (2) The distance (n_2/n_1) multiplied by s is called the apparent depth of the submerged object. If $n_2 = 1$, the apparent depth equals s/n_1.

CONCEPT CHECK 32-4

Draw a ray diagram for the image of Goldie, as described in Example 32-6. That is, draw several rays diverging from an object point P on Goldie, and show that after refracting the rays appear to diverge from an image point P' somewhat above the object point.

THIN LENSES

An important application of Equation 32-6 for refraction at a single surface is finding the position of the image formed by a lens. This determination is done by considering the refraction at each surface of the lens separately to derive an equation relating the image distance to the object distance, the radius of curvature of each surface of the lens, and the index of refraction of the lens material.

We will consider a thin lens that has an index of refraction n and air on both sides. Let the radii of curvature of the surfaces of the lens be r_1 and r_2. If an object is at a distance s from the first surface (and therefore from the lens), the distance s'_1 of the image due to refraction at the first surface can be found using Equation 32-6:

$$\frac{n_{\text{air}}}{s} + \frac{n}{s'_1} = \frac{n - n_{\text{air}}}{r_1} \qquad 32\text{-}8$$

The light refracted at the first surface is again refracted at the second surface. Figure 32-28 shows the case when the image distance s'_1 for the first surface is negative, indicating a virtual image to the left of the surface. Rays in the glass refracted from the first surface diverge as if they came from the image point P'_1. The rays strike the second surface at the same angles as if there were an object at image point P'_1. The image for the first surface therefore becomes

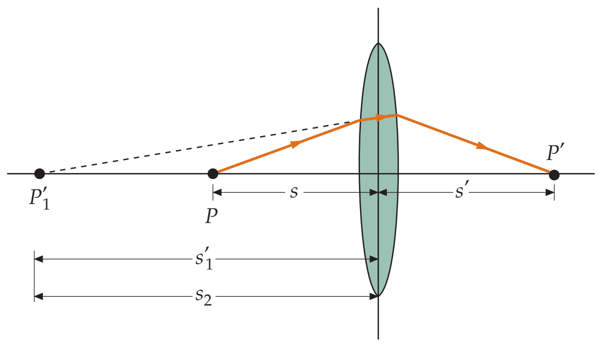

FIGURE 32-28 Refraction occurs at both surfaces of a lens. Here, the refraction at the first surface leads to a virtual image at P'_1. The rays strike the second surface as if they came from P'_1. Image distances are negative when the image is on the incident-light side of the surface, whereas object distances are positive for objects located on that side. Thus, $s_2 (\approx -s'_1)$ is the object distance for the second surface of the lens.

the object for the second surface. Because the lens is of negligible thickness, the object distance s_2 is equal in magnitude to s_1'. Object distances for objects on the incident-light side of a surface are positive, whereas image distances for images located on the incident-light side are negative. Thus, the object distance for the second surface is $s_2' = -s_1'$.* We now write Equation 32-6 for the second surface, where $n_1 = n$, $n_2 = n_{\text{air}}$, and $s = -s_1'$. The image distance for the second surface is the final image distance s' for the lens:

$$\frac{n}{-s_1'} + \frac{n_{\text{air}}}{s'} = \frac{n_{\text{air}} - n}{r_2} \tag{32-9}$$

We can eliminate the image distance for the first surface $-s_1'$ by adding Equations 32-8 and 32-9. We obtain

$$\frac{1}{s} + \frac{1}{s'} = \left(\frac{n}{n_{\text{air}}} - 1\right)\left(\frac{1}{r_1} - \frac{1}{r_2}\right) \tag{32-10}$$

Equation 32-10 gives the image distance s' in terms of the object distance s and the properties r_1, r_2, and n of the thin lens. As with mirrors, the focal length f of a thin lens is defined as the image distance when the object distance is infinite. Setting s equal to infinity and writing f for the image distance s', we obtain

$$\frac{1}{f} = \left(\frac{n}{n_{\text{air}}} - 1\right)\left(\frac{1}{r_1} - \frac{1}{r_2}\right) \tag{32-11}$$

LENS-MAKER'S EQUATION

Equation 32-12 is called the **lens-maker's** equation. Substituting $1/f$ for the right side of Equation 32-10, we obtain

$$\frac{1}{s} + \frac{1}{s'} = \frac{1}{f} \tag{32-12}$$

THIN-LENS EQUATION

This **thin-lens equation** is the same as the mirror equation (Equation 32-4). Recall, however, that the sign conventions for refraction are somewhat different from the sign conventions for reflection. For refraction, the image distance s' is positive when the image is on the refracted-light side of the refracting surface(s), that is, when it is on the side opposite the incident-light side. The sign of the focal length of a lens (see Equation 32-11) is determined by the sign convention for a single refracting boundary. That is, r is positive if the center of curvature is on the same side of the surface as the refracted light. For a lens like that shown in Figure 32-28, r_1 is positive and r_2 is negative, so f is positive.

Figure 32-29*a* shows the wavefronts of plane waves incident on a double convex lens. The central part of the wavefront strikes the lens first. Because the wave speed in the lens is less than that in air (assuming $n > 1$), the central part of the wavefront lags behind the outer parts, resulting in a spherical wavefront that converges at the focal point F'. The rays for this situation are shown in Figure 32-29*b*. Such a lens is called a **converging lens.** Because its focal length as calculated from Equation 32-2 is positive, it is also called a **positive lens.**

* If s_1' were positive, the rays would be converging as they strike the second surface. The object for the second surface would then be a virtual object located to the right of the second surface. This object would be a virtual object. Again, $s_2 = -s_1'$.

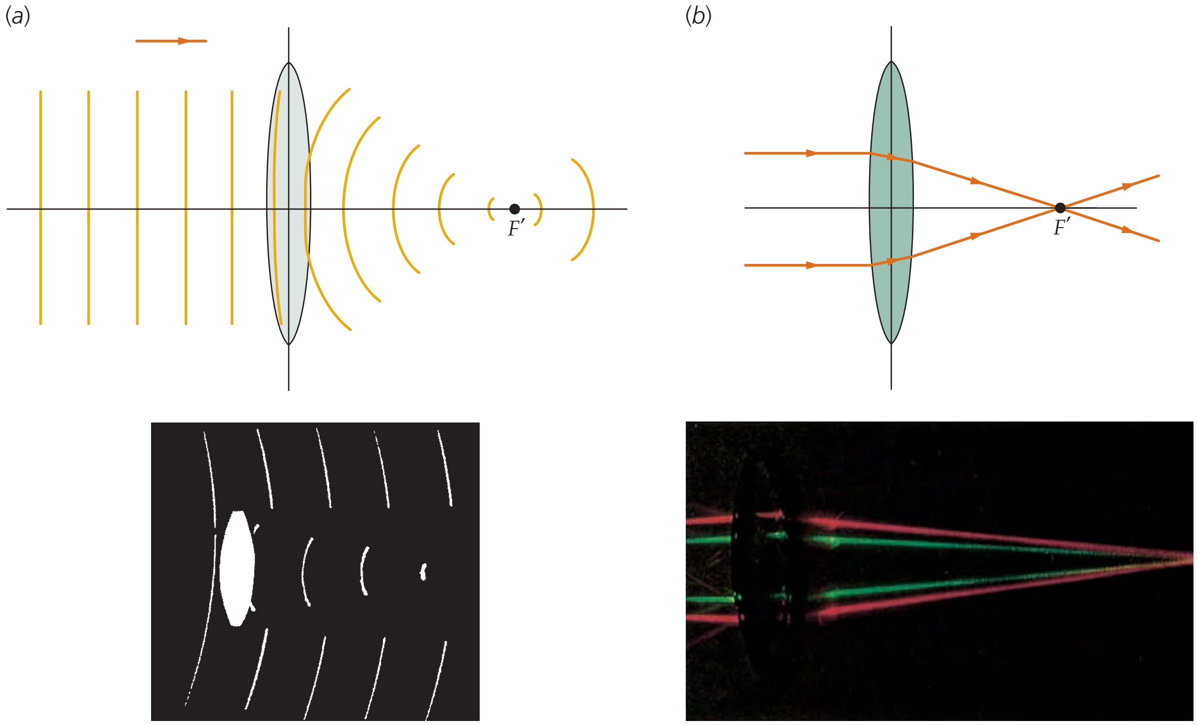

FIGURE 32-29 (*a*) *Top:* Wavefronts for plane waves striking a converging lens. The central part of the wavefront is retarded more by the lens than the outer part, resulting in a spherical wave that converges at the focal point F'. *Bottom:* Wavefronts passing through a lens, shown by a photographic technique called *light-in-flight recording* that uses a pulsed laser to make a hologram of the wavefronts of light. (*b*) *Top:* Rays for plane waves striking a converging lens. The rays are bent at each surface and converge at the focal point. *Bottom:* A photograph of rays focused by a converging lens. *((a) Nils Abramson, (b) Fundamental Photographs.)*

Any lens that is thicker in the middle than at the edges is a converging lens (providing that the index of refraction of the lens is greater than that of the surrounding medium). Figure 32-30 shows the wavefronts and rays for plane waves incident on a double concave lens. In this case, the outer part of the wavefronts lag behind the central parts, resulting in outgoing spherical waves that diverge from a focal point on the incident-light side of the lens. The focal length of this lens is negative. Any lens that is thinner in the middle than at the edges is a **diverging,** or **negative,** lens.

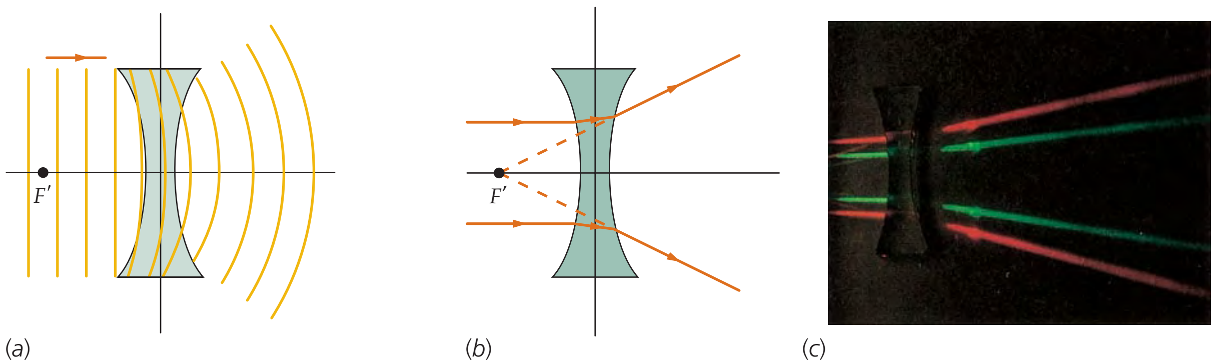

FIGURE 32-30 (*a*) Wavefronts for plane waves striking a diverging lens. Here, the outer part of the wavefront is retarded more than the central part, resulting in a spherical wave that diverges as it moves out, as if it came from the focal point F' to the left of the lens. (*b*) Rays for plane waves striking the same diverging lens. The rays are bent outward and diverge, as if they came from the focal point F'. (*c*) A photograph of rays passing through a diverging lens. *(Fundamental Photographs.)*

Example 32-7 The Lens-Maker's Formula

A double convex, thin glass lens that has an index of refraction $n = 1.50$ has radii of curvature whose magnitudes are 10 cm and 15 cm, as shown in Figure 32-31. Find its focal length in air.

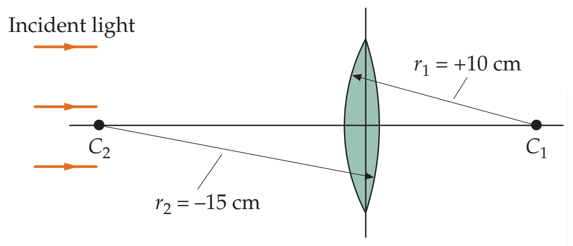

FIGURE 32-31

PICTURE We can find the focal length using the lens-maker's equation (Equation 32-11). Here, light is incident on the surface that has the smaller radius of curvature. The center of curvature C_1 of this surface is on the refracted-light side of the lens; thus, $r_1 = +10$ cm. For the second surface, the center of curvature C_2 is on the incident-light side; therefore, $r_2 = -15$ cm.

SOLVE

Numerical substitution in Equation 32-11 yields the focal length f:

$$\frac{1}{f} = \left(\frac{n}{n_{\text{air}}} - 1\right)\left(\frac{1}{r_1} - \frac{1}{r_2}\right)$$

$$= \left(\frac{1.50}{1.00} - 1\right)\left(\frac{1}{10\text{ cm}} - \frac{1}{-15\text{ cm}}\right) = 0.50\left(\frac{5.0}{30\text{ cm}}\right)$$

$$\therefore f = \boxed{12\text{ cm}}$$

CHECK The calculated focal length is positive, as expected. The lens is thicker in the middle than at the edges, so the focal length is expected to be positive.

PRACTICE PROBLEM 32-8 A double convex thin lens has an index of refraction $n = 1.6$ and its surfaces have radii of curvature of equal magnitude. If the focal length of the lens is 15 cm, what is the magnitude of the radii of curvature of the surfaces?

PRACTICE PROBLEM 32-9 Show that if you reverse the direction of the incoming light for the lens shown in Example 32-7, so that the incoming light is incident on the surface that has the greater radius of curvature, you get the same result for the focal length.

If parallel light strikes the lens of Example 32-7 from the left, it is focused at a point 12 cm to the right of the lens; whereas if parallel light strikes the lens from the right, it is focused at 12 cm to the left of the lens. Both of these points are focal points of the lens. Using the reversibility property of light rays, we can see that light diverging from a focal point and striking a lens will leave the lens as a parallel beam, as shown in Figure 32-32. Incident rays parallel to the axis emerge directed either toward or away from the **first focal point** F. Incident rays directed either toward or away from the **second focal point** F' emerge parallel with the axis. For a converging lens, the first focal point is on the incident-light side and the second focal point is on the refracted-light side. (For a diverging lens the opposite is true.) If parallel light is incident on the lens at a small angle with the axis, as in Figure 32-33, it is focused at a point in the **focal plane** a distance f from the lens.

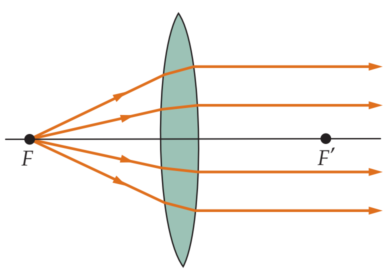

FIGURE 32-32 Light rays diverging from the focal point of a positive lens emerge parallel to the axis.

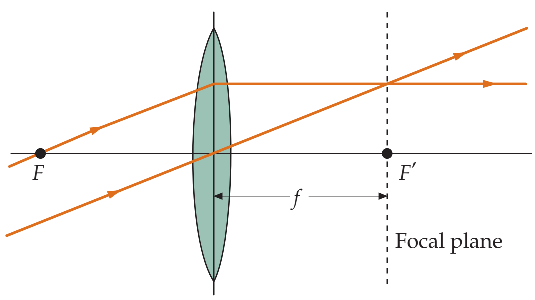

FIGURE 32-33 Parallel rays incident on the lens at an angle to its axis are focused at a point in the focal plane of the lens.

The reciprocal of the focal length is called the **power of a lens.** When the focal length is expressed in meters, the power is given in reciprocal meters, called **diopters** (D):

$$P = \frac{1}{f} \qquad 32\text{-}13$$

The power of a lens measures its ability to focus parallel light at a short distance from the lens. The shorter the focal length, the greater the power. For example, a lens that has a focal length of 25 cm = 0.25 m has a power of 4.0 D. A lens that has a focal length of 10 cm = 0.10 m has a power of 10 D. Because the focal length of a diverging lens is negative, its power is negative.

Example 32-8 Power of a Lens

The lens shown in Figure 32-34 has an index of refraction of 1.50 and radii of curvature whose magnitudes are 10.0 cm and 13.0 cm. Find (*a*) its focal length in air and (*b*) its power.

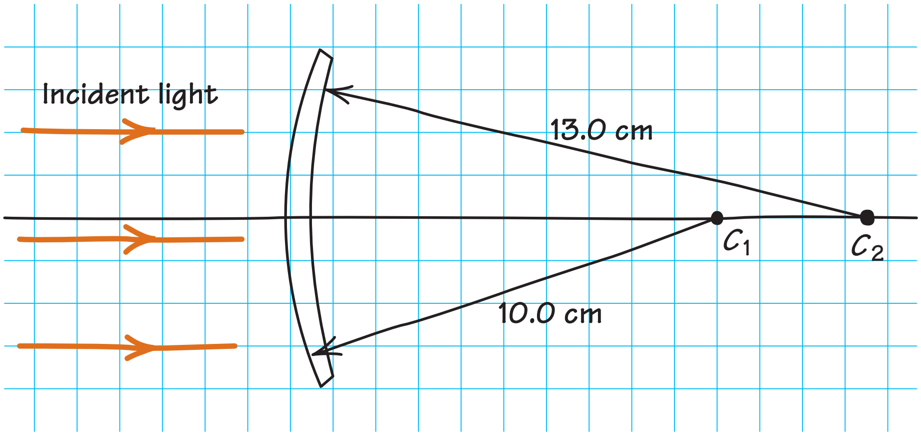

FIGURE 32-34

PICTURE For the orientation of the lens relative to the incident light shown in Figure 32-34, the radius of curvature of the first surface is $r_1 = +10.0$ cm and that of the second surface is $r_2 = +13.0$ cm.

SOLVE

(*a*) Calculate f from the lens-maker's equation using the given value of n and the values of r_1 and r_2 for the orientation shown:

$$\frac{1}{f} = \left(\frac{n}{n_{\text{air}}} - 1\right)\left(\frac{1}{r_1} - \frac{1}{r_2}\right)$$

$$= \left(\frac{1.50}{1.00} - 1\right)\left(\frac{1}{10.0\text{ cm}} - \frac{1}{13.0\text{ cm}}\right)$$

$$\therefore f = \boxed{87\text{ cm}}$$

(*b*) The power is the reciprocal of the focal length expressed in meters:

$$P = \frac{1}{f} = \frac{1}{0.867\text{ m}} = \boxed{1.2\text{ D}}$$

CHECK The values for the focal length and the power are positive. That is what is expected for a lens that is thicker in the middle than at the edges.

TAKING IT FURTHER We obtain the same result no matter which surface the light strikes first.

During laboratory experiments involving lenses, it is usually much easier to measure the focal length than to measure the radii of curvature of the surfaces.

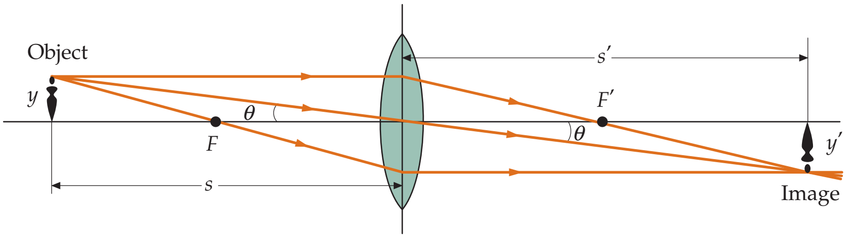

FIGURE 32-35 Ray diagram for a thin converging lens. We draw the rays as if all the bending of light takes place at the central plane. The ray through the center is undeflected because the lens surfaces there are parallel and close together.

RAY DIAGRAMS FOR LENSES

As with images formed by mirrors, it is convenient to locate the images of lenses by graphical methods. Figure 32-35 illustrates the graphical method for a thin converging lens. In the thin lens approximation, we consider the rays to bend at the plane through the center of the lens and perpendicular to the optic axis. The three principal rays are as follows:

1. The **parallel ray,** drawn parallel to the axis. The emerging ray is directed toward the second focal point of the lens.
2. The **central ray,** drawn through the center (the vertex) of the lens. This ray is undeflected. (The faces of the lens are parallel at the center, so the ray emerges in the same direction but displaced slightly. Because the lens is thin, the displacement is negligible.)
3. The **focal ray,** drawn through the first focal point.* This ray emerges parallel to the axis.

PRINCIPAL RAYS FOR A THIN LENS

The weight and bulk of a large-diameter lens can be reduced by constructing the lens from annular segments at different angles so that light from a point is refracted by the segments into a parallel beam. Such an arrangement is called a Fresnel lens. Several Fresnel lenses are used in this lighthouse to produce intense parallel beams of light from a source at the focal point of the lenses. The illuminated surface of an overhead projector is a Fresnel lens. *(Bohdan Hrynewych/Stock Boston.)*

These three rays converge to the image point, as shown in Figure 32-35. In this case, the image is real and inverted. From the figure, we have $\tan\theta = y/s = -y'/s'$. The lateral magnification is then

$$m = \frac{y'}{y} = -\frac{s'}{s} \qquad 32\text{-}14$$

This expression is the same as the expression for mirrors. Again, a negative magnification indicates that the image is inverted. The ray diagram for a diverging lens is shown in Figure 32-36.

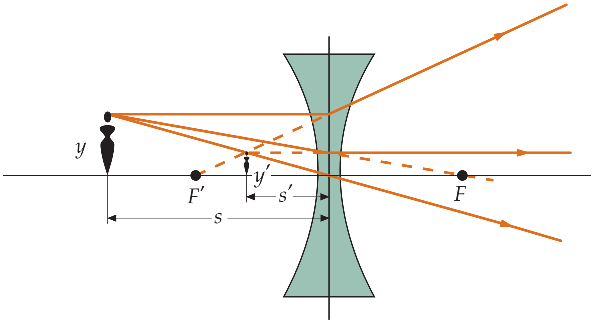

FIGURE 32-36 Ray diagram for a diverging lens. The parallel ray is bent away from the axis, as if it came from the second focal point F'. The ray toward the first focal point F emerges parallel to the axis. For a diverging lens the first focal point F is on the refracted-light side of the lens.

* The focal ray is drawn toward the first focal point F for a diverging lens.

Example 32-9 Image Formed by a Lens

An object that is 1.2 cm high is placed 4.0 cm from a double convex lens that has a focal length of 12 cm. Locate the image both graphically and algebraically, state whether the image is real or virtual, and find its height. Place an eye on the figure positioned and oriented so as to view the image.

PICTURE Locate the image by graphical methods. That means by drawing the three principal rays. The eye is positioned and oriented so the light from the image enters the eye.

SOLVE

1. Draw the parallel ray. This ray leaves the object parallel to the axis, then is bent by the lens to pass through the second focal point, F' (Figure 32-37):

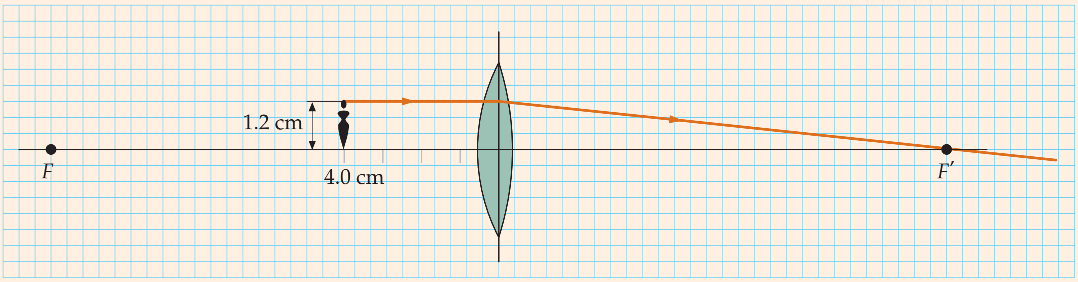

FIGURE 32-37

2. Draw the central ray, which passes undeflected through the center of the lens. Because the two rays are diverging on the refracted-light side, we extend them back to the incident-light side to find the image (Figure 32-38 here):

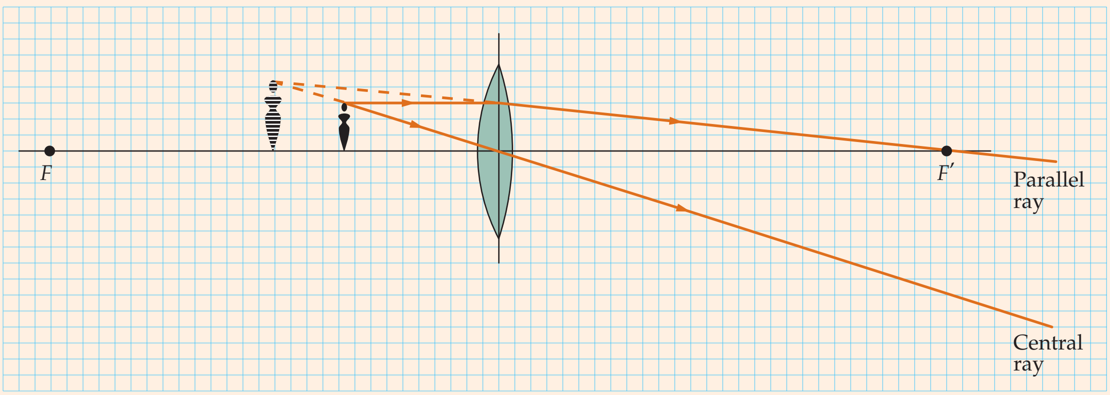

FIGURE 32-38

3. As a check, we also draw the focal ray. This ray leaves the object on a line passing through the first focal point, then emerges parallel to the axis. Note that the image is virtual, upright, and enlarged (Figure 32-39):

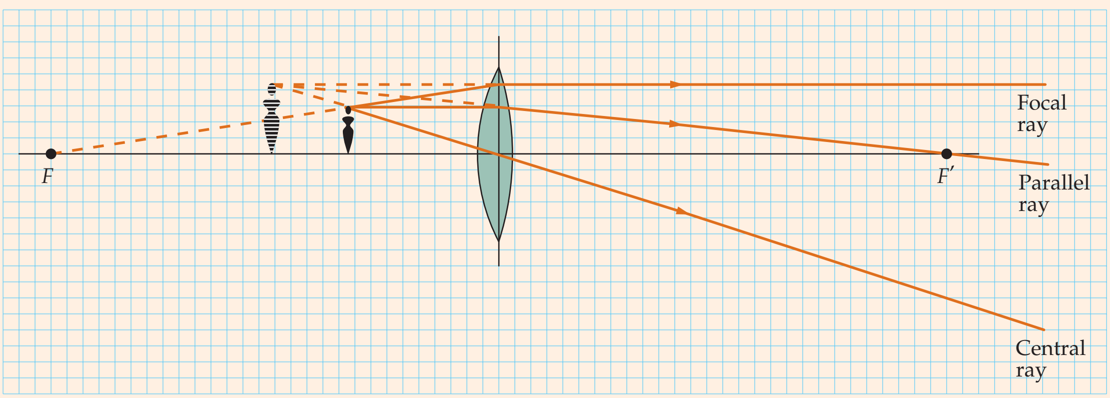

FIGURE 32-39

4. The eye must be positioned so the light from the image enters the eye.

5. We now verify the results of the ray diagram algebraically. First, find the image distance using Equation 32-12:

$$\frac{1}{4.0\text{ cm}} + \frac{1}{s'} = \frac{1}{12\text{ cm}}$$

$$\frac{1}{s'} = \frac{1}{12\text{ cm}} - \frac{1}{4.0\text{ cm}} = -\frac{1}{6.0\text{ cm}}$$

$$s' = -6.0\text{ cm}$$

6. The height of the image is found from the height of the object and the magnification:

$$h' = mh$$

7. The magnification m is given by Equation 32-14:

$$m = -\frac{s'}{s} = -\frac{-6.0\text{ cm}}{4.0\text{ cm}} = \boxed{+1.5}$$

8. Using this result, we find the height of the image, h':

$$h' = mh = (1.5)(1.2\text{ cm}) = \boxed{1.8\text{ cm}}$$

CHECK Note the agreement between the algebraic and ray diagram results. Algebraically, we find that the image is 6.0 cm from the lens on the incident-light side (because $s' < 0$); that is, the image is 2.0 cm to the left of the object. Because $m > 0$, it follows that the image is upright, and because $m > 1$, the image is enlarged. It is good practice to process lens problems both graphically and algebraically and to compare the results.

PRACTICE PROBLEM 32-10 An object is placed 15 cm from a thin lens that has a focal length equal to 10 cm. Find the image distance and the magnification. Is the image real or virtual? Is the image upright or inverted?

PRACTICE PROBLEM 32-11 An object is placed 5.0 cm from a double convex lens that has a focal length equal to 10 cm. Find the image distance and the magnification. Is the image real or virtual? Is the image upright or inverted?

COMBINATIONS OF LENSES

If we have two or more thin lenses, we can find the final image produced by the system by finding the image distance for the first lens and then using it, along with the distance between the lenses, to find the object distance for the second lens. That is, we consider each image, whether it is real or virtual—and whether it is actually formed or not—as the object for the next lens.

Example 32-10 Image Formed by a Second Lens

A second lens that has a focal length equal to +6 cm is placed 12 cm to the right of the lens in Example 32-9. Locate the final image.

PICTURE The principal rays used to locate the image of the first lens will not necessarily be principal rays for the second lens. In this example, however, we have chosen the position of the second lens (Figure 32-40*a*) so that the parallel ray for the first lens turns out to be the central ray for the second lens. Also, the focal ray for the first lens emerges parallel to the axis and is therefore the parallel ray for the second lens. If additional principal rays for the second lens are needed, we simply draw them from the image formed by the first lens. For example, in Figure 32-40*b* we added such a ray, drawn from the first image through the first focal point F_2 of the second lens.

Algebraically we use $s_2 = 18$ cm, because the first image is 6 cm to the left of the first lens and therefore 18 cm to the left of the second lens.

SOLVE

1. Use $s_2 = 18$ cm and $f = 6$ cm to calculate s_2':

$$\frac{1}{s_2} + \frac{1}{s_2'} = \frac{1}{f_2}$$

$$\frac{1}{18\text{ cm}} + \frac{1}{s_2'} = \frac{1}{6\text{ cm}}$$

$$s_2' = 9\text{ cm}$$

$$\boxed{\text{The final image is on the refracted-light side of the second lens and is 9 cm from the second lens.}}$$

2.

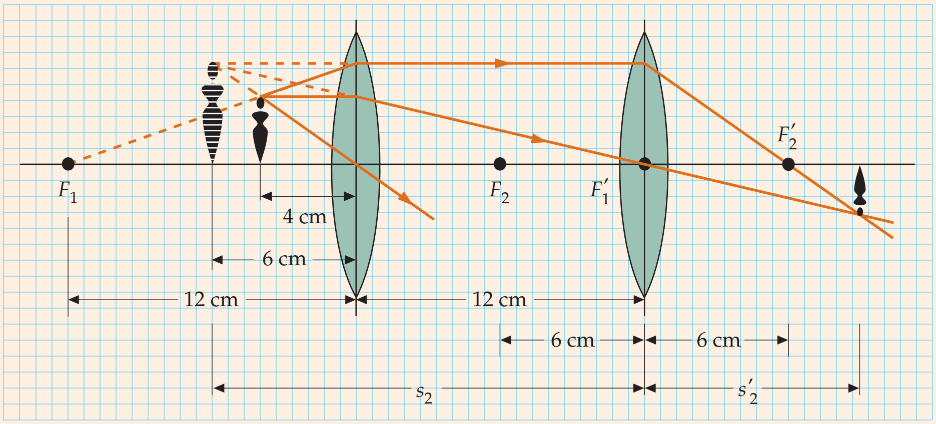

FIGURE 32-40*a*

CHECK The ray diagram in step 2 checks the calculation in step 1. In addition, to check the ray diagram in step 2, we draw the focal ray for the second lens.

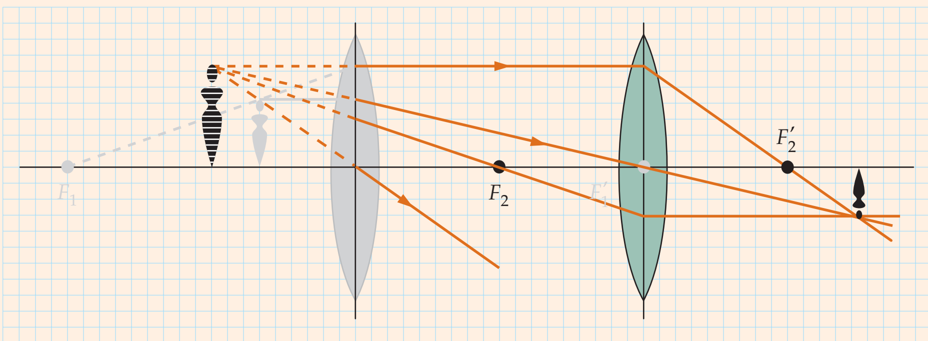

FIGURE 32-40*b*

Example 32-11 A Combination of Two Lenses

Try It Yourself

Two lenses, each having a focal length equal to 10 cm, are 15 cm apart. Find the final image location for an object 15 cm from one of the lenses and 30 cm from the other.

PICTURE Use a ray diagram to find the location of the image formed by lens 1. When these rays strike lens 2 they are further refracted, leading to the final image. More accurate results are obtained algebraically using the thin-lens equation for both lens 1 and lens 2.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps

1. Draw the (*a*) parallel, (*b*) central, and (*c*) focal rays for lens 1 (Figure 32-41). If lens 2 did not alter these rays, they would form the image I_1.

Answers

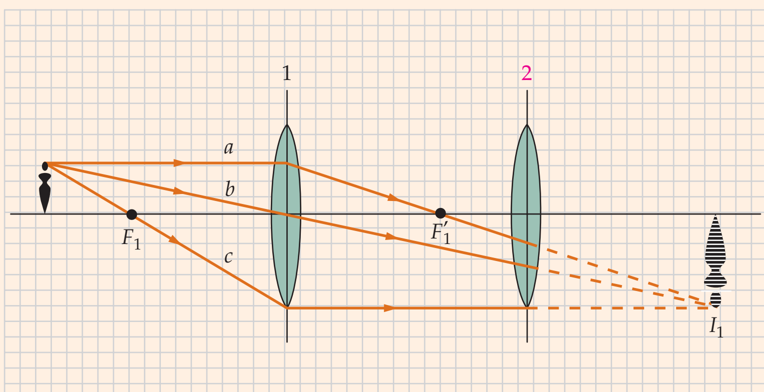

FIGURE 32-41

2. To locate the final image, add three principal rays (d, e, and f) for lens 2. The intersection of these rays gives the location of image I_2 (Figure 32-42).

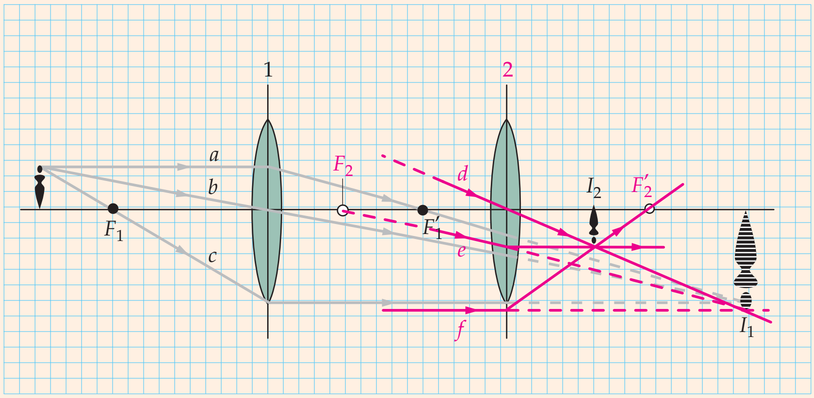

FIGURE 32-42

3. To proceed algebraically, use the thin-lens equation to find the image distance s_1' produced by lens 1. — $s_1' = 30$ cm

4. For lens 2, the image, I_1 is 15 cm from the lens on the refracted-light side; hence, $s_2 = -15$ cm. Use this to find the final image distance s_2'. — $s_2' = \boxed{6 \text{ cm}}$

CHECK From the step-2 ray diagram we see that the final image is about six tenths of the focal length of lens 2. The focal length of lens 2 is 10 cm, so step-2 result and the step-4 result are in agreement.

COMPOUND LENSES

When two thin lenses of focal lengths f_1 and f_2 are placed together, the effective focal length of the combination f_{eff} is given by

$$\frac{1}{f_{\text{eff}}} = \frac{1}{f_1} + \frac{1}{f_2} \qquad \text{32-15}$$

as is shown in the following example (Example 32-12). The power of two lenses in contact is given by

$$P_{\text{eff}} = P_1 + P_2 \qquad \text{32-16}$$

Example 32-12 Two Lenses in Contact — *Try It Yourself*

For two lenses very close together, derive the relation $\dfrac{1}{f_{\text{eff}}} = \dfrac{1}{f_1} + \dfrac{1}{f_2}$.

PICTURE Apply the thin-lens equation to each lens using the fact that the distance between the lenses is negligible, so the object distance for the second lens is the negative of the image distance for the first lens.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. Write the thin-lens equation for lens 1.	$\dfrac{1}{s_1} + \dfrac{1}{s_1'} = \dfrac{1}{f_1}$
2. Using $s_2 = -s_1'$, write the thin-lens equation for lens 2.	$\dfrac{1}{-s_1'} + \dfrac{1}{s_2'} = \dfrac{1}{f_2}$
3. Add your two resulting equations to eliminate s_1'.	$\boxed{\dfrac{1}{s_1} + \dfrac{1}{s_2'} = \dfrac{1}{f_1} + \dfrac{1}{f_2} = \dfrac{1}{f_{\text{eff}}}}$

* 32-3 ABERRATIONS

When all the rays from a point object are not focused at a single image point, the resultant blurring of the image is called **aberration.** Figure 32-43 shows rays from a point source on the axis traversing a thin lens with spherical surfaces. Rays that strike the lens far from the axis are bent much more than are the rays near the axis, with the result that not all the rays are focused at a single point. Instead, the image appears as a circular disk at point *C*, where the diameter is minimum. This type of aberration in a lens is called **spherical aberration;** it is the same as the spherical aberration of mirrors discussed in Section 32-1. Similar but more complicated aberrations called *coma* and *astigmatism* occur when objects are off axis. The aberration in the shape of the image of an extended object that occurs, because the magnification depends on the distance of the object point from the axis, is called **distortion.** We will not discuss these aberrations further, except to point out that they do not arise from any defect in the lens or mirror but instead result from the application of the laws of refraction and reflection to spherical surfaces. These aberrations are not evident in our simple equations, because we used small-angle approximations in the derivation of the equations.

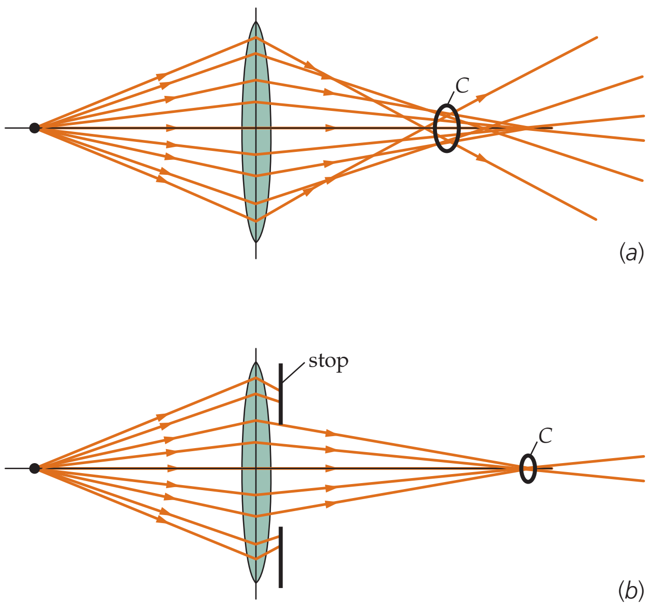

FIGURE 32-43 Spherical aberration in a lens. (*a*) Rays from a point object on the axis are not focused at a point. (*b*) Spherical aberration can be reduced by using a stop to block off the outer parts of the lens, but this also reduces the amount of light reaching the image.

Some aberrations can be eliminated or partially corrected by using nonspherical surfaces for mirrors or lenses, but nonspherical surfaces are usually much more difficult and costly to produce than spherical surfaces. One example of a nonspherical reflecting surface is the parabolic mirror illustrated in Figure 32-44. Rays that are parallel to the axis of a parabolic surface are reflected and focused at a common point, no matter how far the rays are from the axis. Parabolic reflecting surfaces are sometimes used in large astronomical telescopes, which need a large reflecting surface to gather as much light as possible to make the image as intense as possible (reflecting telescopes are described in the upcoming optional Section 32-4). Satellite dishes use parabolic surfaces to focus microwaves from communications satellites. A parabolic surface can also be used in a searchlight to produce a parallel beam of light from a small source placed at the focal point of the surface.

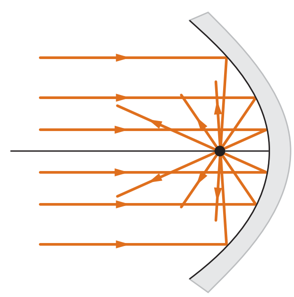

FIGURE 32-44 A parabolic mirror focuses all rays parallel to the axis to a single point with no spherical aberration.

An important aberration found with lenses but not found with mirrors is **chromatic aberration,** which is due to variations in the index of refraction with wavelength. From Equation 32-11, we can see that the focal length of a lens depends on its index of refraction and is therefore different for different wavelengths. Because n is slightly greater for blue light than for red light, the focal length for blue light will be shorter than the focal length for red light.

Chromatic aberration and other aberrations can be partially corrected by using combinations of lenses instead of a single lens. For example, a positive lens and a negative lens of greater focal length can be used together to produce a converging lens system that has much less chromatic aberration than a single lens of the same focal length. A high quality camera lens typically contains six elements to correct the various aberrations that are present.

* 32-4 OPTICAL INSTRUMENTS

*THE EYE

The optical system of prime importance is the eye, which is shown in Figure 32-45. Light enters the eye through a variable aperture, the pupil. The light is converged by the cornea, with assistance from the lens, to form an image on the retina, which has a film of nerve fibers covering the back surface of the eye. The retina contains tiny sensing structures called *rods* and *cones*, which detect the light and transmit the information along the optic nerve to the brain. The shape of the crystalline lens can be altered slightly by the action of the ciliary muscle. When the eye is focused on an object far away, the muscle is relaxed and the cornea-lens system has its maximum focal length, about 2.5 cm, which is the distance from the cornea to the retina. When the object is brought closer to the eye, the ciliary muscle increases the curvature of the lens slightly, thereby decreasing its focal length, so that the image is again focused on the retina. This process is called *accommodation*. If the object is too close to the eye, the lens cannot focus the light on the retina and the image is blurred. The closest point for which the lens can focus the image on the retina is called the **near point.** The distance from the eye to the near point varies greatly from one person to another and changes with age. At 10 years, the near point may be as close as 7 cm, whereas at 60 years it may recede to 200 cm because of the loss of flexibility of the lens. The standard value taken for the near point is 25 cm.

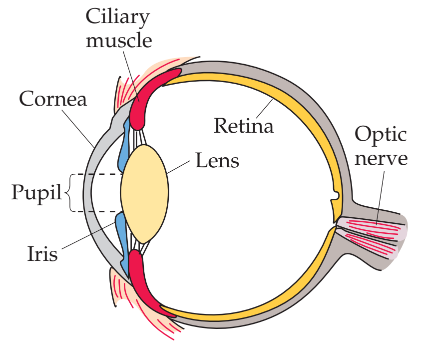

FIGURE 32-45 The human eye. The amount of light entering the eye is controlled by the iris, which regulates the size of the pupil. The lens thickness is controlled by the ciliary muscle. The cornea and lens together converge the light to focus the image on the retina, which contains approximately 125 million receptors, called rods and cones, and approximately 1 million optic-nerve fibers.

If the eye underconverges, resulting in the images being focused behind the retina, the person is said to be farsighted. A farsighted person can see distant objects clearly where little convergence is required, but has trouble seeing close objects clearly. Farsightedness is corrected with a converging (positive) lens (Figure 32-46).

On the other hand, the eye of a nearsighted person overconverges and focuses light from distant objects in front of the retina. A nearsighted person can see nearby objects clearly (objects for which the widely diverging incident rays can be focused on the retina), but has trouble seeing distant objects clearly. Nearsightedness is corrected with a diverging (negative) lens (Figure 32-47).

Another common defect of vision is astigmatism, which is caused by the cornea being not quite spherical but having a different curvature in one plane than in another. This results in a blurring of the image of a point object into a short line. Astigmatism is corrected by glasses using lenses of cylindrical rather than spherical shape.

The *apparent size* of an object is determined by the actual size of the image on the retina. The larger the image on the retina, the larger the apparent size and the greater the number of rods and cones that are illuminated by the light from the object. From Figure 32-48, we see that the size of the image on the retina is greater

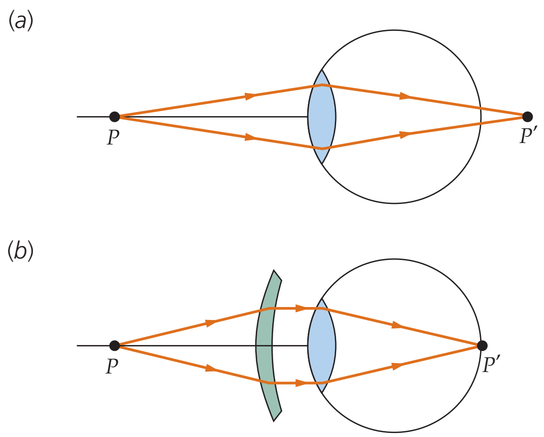

FIGURE 32-46 (*a*) A farsighted eye focuses rays from a nearby object to a point behind the retina. (*b*) A converging lens corrects this defect by bringing the image onto the retina. These diagrams, and those following, are drawn as if all the focusing of the eye is done at the cornea; in fact, the lens and cornea system act more like a spherical refracting surface than a thin lens.

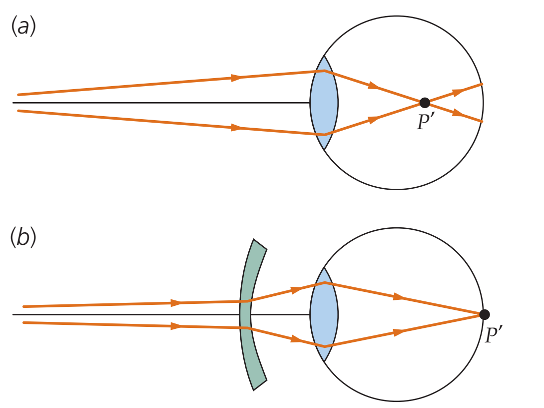

FIGURE 32-47 (*a*) A nearsighted eye focuses rays from a distant object to a point in front of the retina. (*b*) A diverging lens corrects this defect.

when the object is close than it is when the object is far away. The apparent size of an object is thus greater when the object is closer to the eye. The image size is proportional to the angle θ subtended by the object at the eye. For Figure 32-48,

$$\phi = \frac{y'}{2.5\text{ cm}} \quad \text{and} \quad \theta \approx \frac{y}{s} \qquad 32\text{-}17$$

for small angles. Applying the law of refraction gives $n_{air} \sin\theta = n \sin\phi$, where $n_{air} = 1.00$ and n is the refractive index inside the eye. For small angles this becomes

$$\theta \approx n\phi \qquad 32\text{-}18$$

Combining Equations 32-17 and 32-18 gives

$$\frac{y}{s} \approx n\frac{y'}{2.5\text{ cm}} \quad \text{or} \quad y' \approx \frac{2.5\text{ cm}}{n}\frac{y}{s} \qquad 32\text{-}19$$

The size of the image on the retina is proportional to the size of the object and inversely proportional to the distance from the cornea to the object. Because the near point is the closest point to the eye for which a sharp image can be formed on the retina, the distance from the cornea to the near point is called the *distance of most distinct vision*.

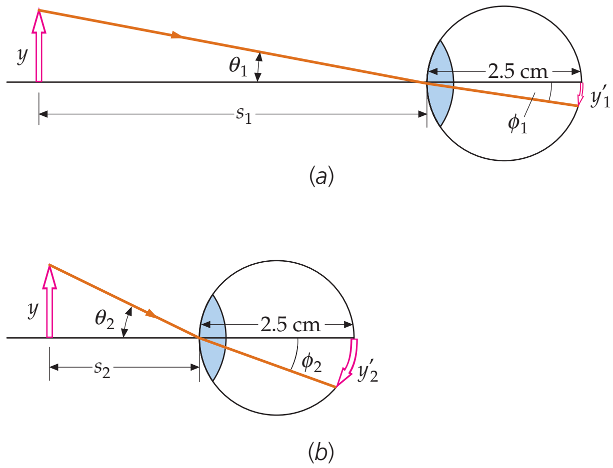

FIGURE 32-48 (*a*) A distant object of height *y* looks small because the image on the retina is small. (*b*) When the same object is closer, it looks larger because the image on the retina is larger.

Example 32-13 Reading Glasses

The near-point distance of a person's eye is 75 cm. Using a reading glasses lens placed a negligible distance from the eye, the near-point distance of the lens-eye system is 25 cm. That is, the image on the retina is blurry if an object is placed less than 25 cm in front of the lens. (*a*) What power is the reading glasses lens and (*b*) what is the lateral magnification of the image formed by the lens? (*c*) Which produces the bigger image on the retina, (1) the object at the near point of, and viewed by, the unaided eye or (2) the object at the near point of the lens-eye system and viewed through the lens that is immediately in front of the eye?

PICTURE A near-point distance of the lens-eye system of 25 cm means the lens forms a virtual image 75 cm in front of the lens if an object is placed 25 cm in front of the lens. Figure 32-49*a* shows a diagram of an object 25 cm from a converging lens that produces a virtual, upright image at $s' = -75$ cm. Figure 32-49*b* shows the image on the retina formed by the focusing power of the eye.

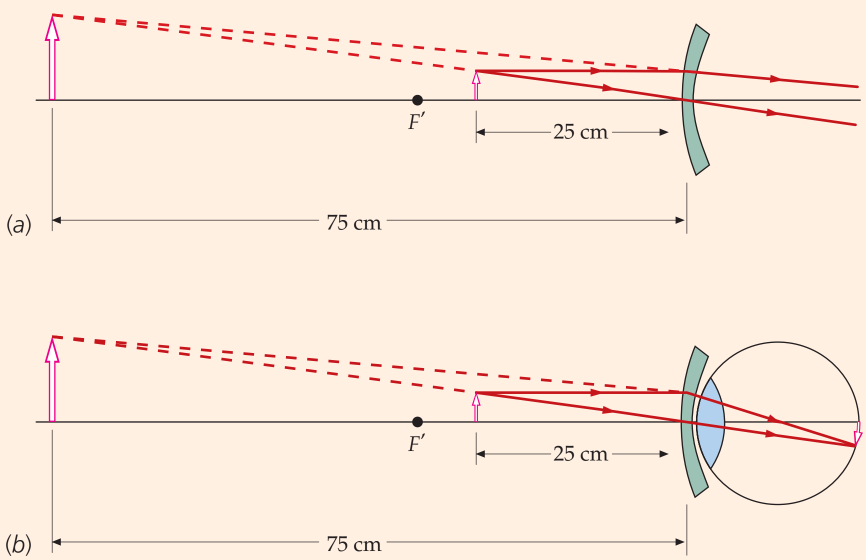

FIGURE 32-49

SOLVE

(*a*) Use the thin-lens equation, $s = 25$ cm, and $s' = -75$ cm to calculate the power, $1/f$:

$$\frac{1}{f} = \frac{1}{s} + \frac{1}{s'} = \frac{1}{25\text{ cm}} + \frac{1}{-75\text{ cm}}$$

$$= \frac{2}{75\text{ cm}} = \frac{2}{0.75\text{ m}} = \boxed{2.7\text{ D}}$$

(*b*) Using $m = -s'/s$, find m:

$$m = -\frac{s'}{s} = -\frac{-75\text{ cm}}{25\text{ cm}} = \boxed{3.0}$$

(*c*) In both cases, the rays entering the eye appear to diverge from points on an image 75 cm in front of the eye. However, with the lens in place, the image 75 cm in front of the eye is larger than the object by a factor of 3:

$\boxed{\text{Option 2}}$

TAKING IT FURTHER (1) If your near point is 75 cm, you are farsighted. To read a book you must hold it at least 75 cm from your eye to be able to focus on the print. The image of the print on your retina is then very small. The reading glasses lens produces an image also 75 cm from your eye, and this image is three times larger than the actual print. Thus, looking through the lens, the image of the print on the retina is larger by a factor of 3. (2) In this example, the distance from the lens to the eye was negligible. The results are slightly different if this distance is not negligible, which is factored into the calculations.

PRACTICE PROBLEM 32-12 Calculate the power of the eye for which the near point is 75 cm and the cornea-retina distance is 2.5 cm, and calculate the combined power of the lens and eye when they are in contact. Compare this result with the power of a lens for which $s' = 2.5$ cm, when $s = 25$ cm.

*THE SIMPLE MAGNIFIER

We saw in Example 32-13 that the *apparent* size of an object can be increased by using a converging lens placed next to the eye. A converging lens is called a **simple magnifier** if it is placed next to the eye and if the object is placed closer to the lens than its focal length, as was the case for the lens in Example 32-13. In that example, the lens formed a virtual image at the near point of the eye, the same location that the object must be placed for best viewing by the unaided eye. So, with the lens in place, the magnitude of the image distance $|s'|$ was greater than the object distance s, so the image seen by the eye is magnified by $m = |s'|/s$. If the actual height of the object is y, then the height y' of the image formed by the lens is my. To the eye, this image subtends an angle θ (Figure 32-50) given approximately by

$$\theta = \frac{my}{|s'|} = m\frac{y}{|s'|} = \frac{|s'|}{s}\frac{y}{|s'|} = \frac{y}{s}$$

which is the *very same angle* the object would subtend if the lens were removed while the object and the eye are left in place. That is, the apparent size of the image seen by the eye through the lens is the same as the apparent size of the object that would be seen by the eye were the lens removed (assuming the eye could focus at that distance). Thus, the apparent size of the object seen through the lens is inversely proportional to the distance from the object to the eye with the lens in place. The smaller s is, the larger the subtended angle θ and the larger the apparent size of the object.

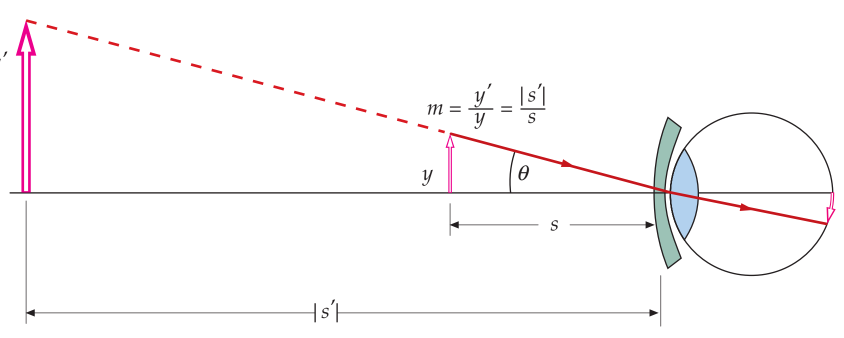

FIGURE 32-50

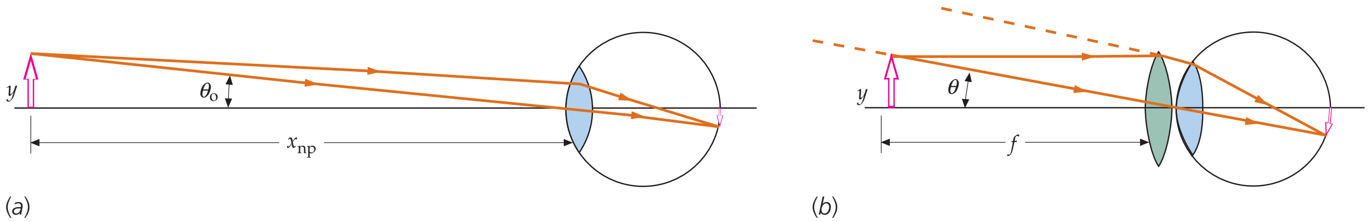

FIGURE 32-51 (*a*) An object at the near point subtends an angle θ_o at the naked eye. (*b*) When the object is at the focal point of the converging lens, the rays emerge from the lens parallel and enter the eye as if they came from an object a very large distance away. The image can thus be viewed at infinity by the relaxed eye. When f is less than the near-point distance, the converging lens allows the object to be brought closer to the eye. This increases the angle subtended by the object to θ, thereby increasing the size of the image on the retina.

In Figure 32-51*a*, a small object of height y is at the near point of the eye at a distance x_{np}. The angle subtended, θ_o, is given approximately by

$$\theta_o = \frac{y}{x_{np}}$$

In Figure 32-51*b*, a converging lens of focal length f that is smaller than x_{np} is placed a negligible distance in front of the eye, and the object is placed in the focal plane of the lens. The rays emerge from the lens parallel, indicating that the image is located an infinite distance in front of the lens. The parallel rays are focused by the relaxed eye on the retina. The angle subtended by this image is equal to the angle subtended by the object (assuming that the lens is a negligible distance from the eye). The angle subtended by the object is approximately

$$\theta = \frac{y}{f}$$

The ratio θ/θ_o is called the *angular magnification* or *magnifying power M* of the lens:

$$M = \frac{\theta}{\theta_o} = \frac{x_{np}}{f} \qquad \text{32-20}$$

Simple magnifiers are used as eyepieces (called oculars) in microscopes and telescopes to view a real image formed by another lens or lens system. To correct aberrations, combinations of lenses that result in a short positive focal length may be used in place of a single lens, but the principle of the simple magnifier is the same.

Example 32-14 Angular Magnification of a Simple Magnifier — *Try It Yourself*

A person who has a near point of 25 cm uses a 40-D lens as a simple magnifier. What angular magnification is obtained?

PICTURE The angular magnification is found from the focal length f (Equation 32-20), which is the reciprocal of the power.

SOLVE

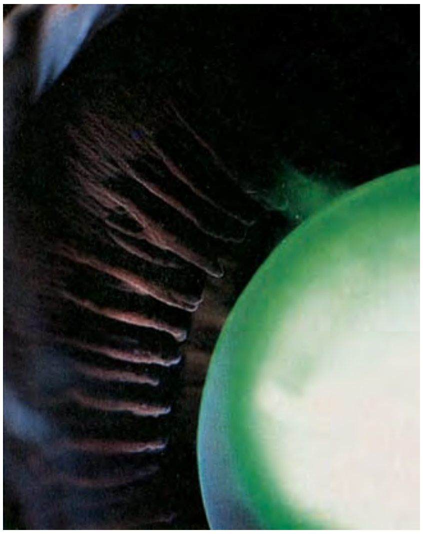
Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. Calculate the focal length of the lens using $P = 1/f$ (Equation 32-13).	$f = 2.5$ cm
2. Use your result from step 1 and incorporate the result into Equation 32-20 to calculate the angular magnification.	$M = \boxed{10}$

TAKING IT FURTHER Looking through the lens, the object appears 10 times larger because it can be placed at 2.5 cm rather than at 25 cm from the eye, thus increasing the size of the image on the retina tenfold.

PRACTICE PROBLEM 32-13 What is the angular magnification in this example if the near point of the person is 30 cm rather than 25 cm?

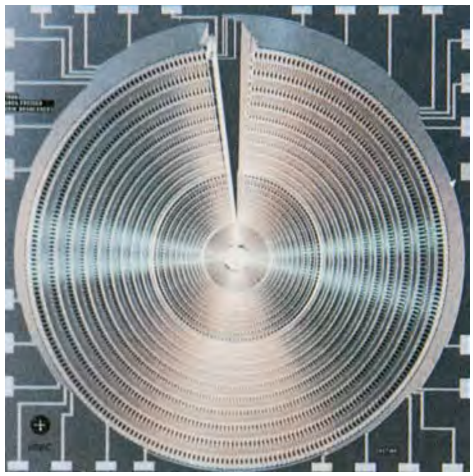
(*a*)



(*b*)

(*a*) The human eye in profile. (*b*) The lens of the eye is kept in place by the ciliary muscle (shown here in the upper left), which rings the lens. When the ciliary muscle contracts, the lens tends to bulge. The greater lens curvature enables the eye to focus on nearby objects. (*c*) Some of the 120 million rods and 7 million cones in the eye, magnified approximately 5000 times. The rods (the more slender of the two) are more sensitive in dim light, whereas the cones are more sensitive to color. The rods and cones form the bottom layer of the retina and are covered by nerve cells, blood vessels, and supporting cells. Most of the light entering the eye is reflected or absorbed before reaching the rods and cones. The light that does reach them triggers electrical impulses along nerve fibers that ultimately reach the brain. (*d*) A neural net used in the vision system of certain robots. Loosely modeled on the human eye, it contains 1920 sensors. *((a), (b) and (c) Lennart Nilsson, (d) Courtesy IMEC and University of Pennsylvania Department of Electrical Engineering.)*

(*c*)



(*d*)

*THE COMPOUND MICROSCOPE

The compound microscope (Figure 32-52) is used to look at very small objects at short distances. In its simplest form, it consists of two converging lenses. The lens nearest the object, called the **objective,** forms a real image of the object. This image is enlarged and inverted. The lens nearest the eye, called the **eyepiece** or **ocular,** is used as a simple magnifier to view the image formed by the objective. The eyepiece is placed so that the image formed by the objective falls at the first focal point of the eyepiece. The light from each point on the object thus emerges from the eyepiece as a parallel beam, as if it were coming from a point a great distance in front of the eye. (This is commonly called *viewing the image at infinity*.)

The distance between the second focal point of the objective and the first focal point of the eyepiece is called the **tube length** L. The tube length is fixed at 16 cm. The object is placed just outside the first focal point of the objective so that an enlarged image is formed at the first focal point of the eyepiece a distance $L + f_o$ from the objective, where f_o is the focal length of the objective. From Figure 32-52, $\tan\beta = y/f_o = -y'/L$. The lateral magnification of the objective is therefore

$$m_o = \frac{y'}{y} = -\frac{L}{f_o} \tag{32-21}$$

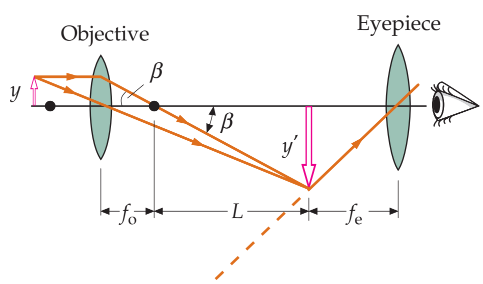


FIGURE 32-52 Schematic diagram of a compound microscope consisting of two positive lenses, the objective of focal length f_o and the eyepiece of focal length f_e. The real image of the object formed by the objective is viewed by the eyepiece, which acts as a simple magnifier. The final image is at infinity.

The angular magnification of the eyepiece (from Equation 32-20) is

$$M_e = \frac{x_{np}}{f_e}$$

where x_{np} is the near-point distance of the viewer and f_e is the focal length of the eyepiece. The magnifying power of the compound microscope is the product of the lateral magnification of the objective and the angular magnification of the eyepiece:

$$M = m_o M_e = -\frac{L}{f_o}\frac{x_{np}}{f_e} \qquad 32\text{-}22$$

MAGNIFYING POWER OF A MICROSCOPE

Example 32-15 The Compound Microscope

A microscope has an objective lens that has a focal length equal to 1.2 cm and an eyepiece that has a focal length equal to 2.0 cm. These lenses are separated by 20.0 cm. (*a*) Find the magnifying power if the near point of the viewer is 25.0 cm. (*b*) Where should the object be placed if the final image is to be viewed at infinity?

PICTURE To calculate the magnifying power, we use Equation 32-22. To calculate the object distance for the objective, we use the lens equation.

SOLVE

(*a*) 1. The magnifying power is given by Equation 32-22:

$$M = -\frac{L}{f_o}\frac{x_{np}}{f_e}$$

2. The tube length L is the distance between the lenses minus the focal distances:

$$L = 20.0\text{ cm} - 2.0\text{ cm} - 1.2\text{ cm} = 16.8\text{ cm}$$

3. Substitute this value for L and the given values of x_{np}, f_o, and f_e to calculate M:

$$M = -\frac{L}{f_o}\frac{x_{np}}{f_e} = -\frac{16.8\text{ cm}}{1.2\text{ cm}}\frac{25.0\text{ cm}}{2.0\text{ cm}} = \boxed{-180}$$

(*b*) 1. Calculate the object distance s in terms of the image distance for the objective s' and the focal length f_o:

$$\frac{1}{s} + \frac{1}{s'} = \frac{1}{f_o}$$

2. From Figure 32-52, the image distance for the image of the objective is $f_o + L$:

$$s' = f_o + L = 1.2\text{ cm} + 16.8\text{ cm} = 18.0\text{ cm}$$

3. Substitute to calculate s:

$$\frac{1}{s} + \frac{1}{18.0\text{ cm}} = \frac{1}{1.2\text{ cm}}$$

$$s = \boxed{1.3\text{ cm}}$$

CHECK The magnifying power is very large, which is the purpose of a compound microscope.

TAKING IT FURTHER The object should thus be placed at 1.3 cm from the objective or 0.1 cm outside its first focal point.

*THE TELESCOPE

A telescope is used to view objects that are far away and are often large. The telescope works by creating a real image of the object that is much closer than the object. The astronomical telescope, illustrated schematically in Figure 32-53, consists of two converging lenses—an objective lens that forms a real, inverted image and an eyepiece that is used as a simple magnifier to view that image. Because the object is very far away, the image of the objective lies in the focal plane of the objective, and the image distance equals the focal length f_o. The image formed by the objective is much smaller than the object (because the object distance is

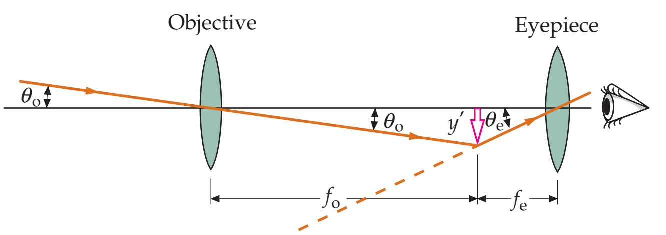

FIGURE 32-53 Schematic diagram of an astronomical telescope. The objective lens forms a real, inverted image of a distant object near its second focal point, which coincides with the first focal point of the eyepiece. The eyepiece serves as a simple magnifier to view the image.

much larger than the focal length of the objective). For example, if we are looking at the moon, the image of the moon formed by the objective is much smaller than the moon itself. The function of the objective is not to magnify the object, but to produce an image that is close enough to us so it can be magnified by the eyepiece acting as a simple magnifier. The eyepiece is placed a distance f_e from the image, where f_e is the focal length of the eyepiece, so the final image can be viewed at infinity. Because this image is at the second focal plane of the objective and at the first focal plane of the eyepiece, the objective lens and the eyepiece must be separated by the sum of the focal lengths of the objective lens and eyepiece, $f_o + f_e$.

The magnifying power of the telescope is the angular magnification θ_e/θ_o, where θ_e is the angle subtended by the virtual image produced by the eyepiece as viewed through the eyepiece, and θ_o is the angle subtended by the object when it is viewed directly by the unaided eye. The angle θ_o is the same as that subtended by the object at the objective shown in Figure 32-53. (The distance from a distant object, such as the moon, to the objective is essentially the same as the distance to the eye.) From this figure, we can see that

$$\tan\theta_o = \frac{y}{s} = -\frac{y'}{f_o} \approx \theta_o$$

where we have used the small-angle approximation $\tan\theta \approx \theta$. The angle θ_e in the figure is that subtended by the image at infinity formed by the eyepiece:

$$\tan\theta_e = \frac{y'}{f_e} \approx \theta_e$$

Because y' is negative, θ_e is negative, indicating that the image is inverted. The magnifying power of the telescope is then

$$M = \frac{\theta_e}{\theta_o} = -\frac{f_o}{f_e} \qquad 32\text{-}23$$

MAGNIFYING POWER OF A TELESCOPE

From Equation 32-23, we can see that a large magnifying power is obtained with an objective of large focal length and an eyepiece of short focal length.

PRACTICE PROBLEM 32-14

The world's largest refracting telescope is at the Yerkes Observatory of the University of Chicago at Williams Bay, Wisconsin. The telescope's objective has a diameter of 1.02 m and a focal length of 19.5 m. The focal length of the eyepiece is 10.0 cm. What is its magnifying power?

The main consideration with an astronomical telescope is not its magnifying power but its light-gathering power, which depends on the size of the objective. The larger the objective, the brighter the image. Very large lenses without aberrations are difficult to produce. In addition, there are mechanical problems in supporting very large, heavy lenses by their edges. A reflecting telescope (Figure 32-54 and Figure 32-55) uses a concave mirror instead of a lens for its objective. The mirror offers several advantages. For example, a mirror does not produce chromatic aberration.

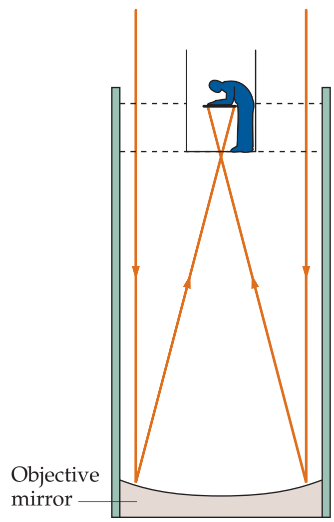

FIGURE 32-54 A reflecting telescope uses a concave mirror instead of a lens for its objective. Because the viewer compartment blocks off some of the incoming light, the arrangement shown here is used only in telescopes with very large objective mirrors.

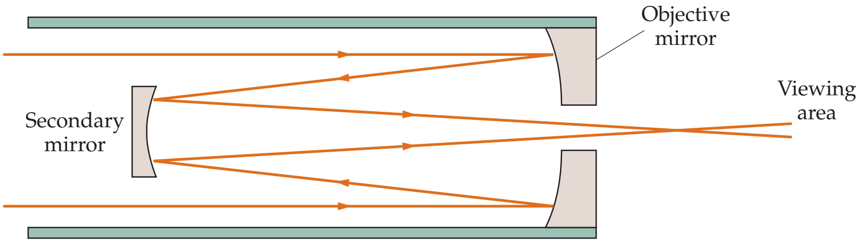

FIGURE 32-55 This reflecting telescope has a secondary mirror to redirect the light through a small hole in the objective mirror, thus providing more room for auxiliary instruments in the viewing area.

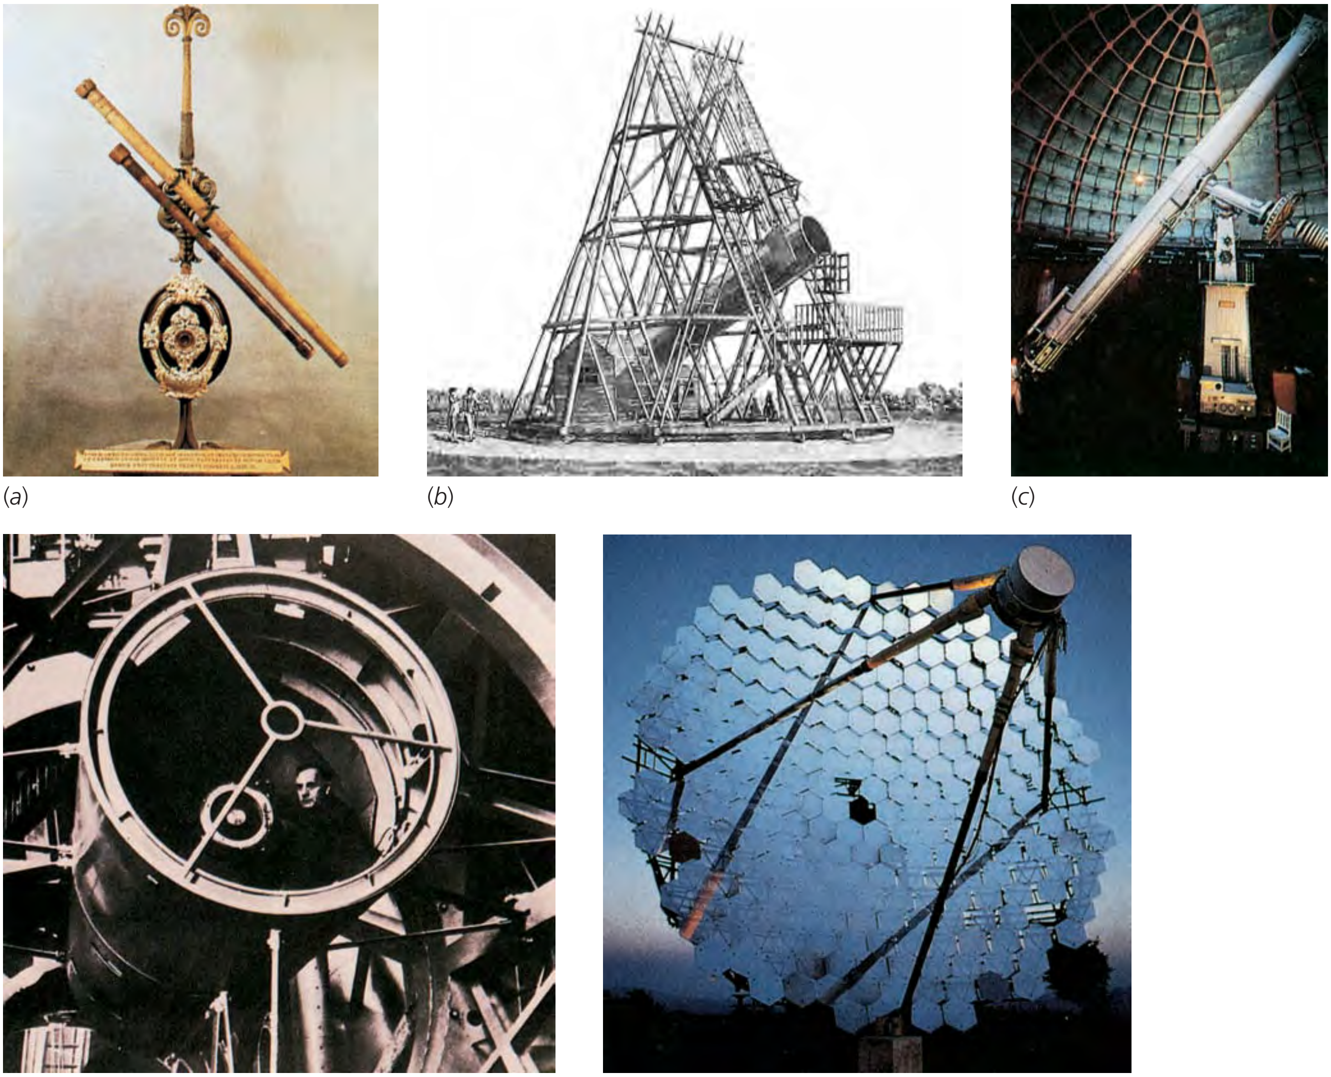
In addition, mechanical support is much simpler, because the mirror weighs far less than a lens of equivalent optical quality, and the mirror can be supported over its entire back surface. In modern Earth-based telescopes, the objective mirror consists of several dozen adaptive mirror segments that can be adjusted individually to correct for minute variations in gravitational stress when the telescope is tilted, and to compensate for thermal expansions and contractions and other changes caused by climatic conditions. In addition, they can adjust to nullify the distortions produced by atmospheric fluctuations.



(*a*) (*b*) (*c*) (*d*) (*e*)

Astronomy at optical wavelengths began with Galileo approximately 400 years ago. In the twentieth century, astronomers began to explore the electromagnetic spectrum at other wavelengths; beginning with radio astronomy in the 1940s, satellite-based X-ray astronomy in the early 1960s, and more recently, ultraviolet, infrared, and gamma-ray astronomy. (*a*) Galileo's seventeenth-century telescope, with which he discovered mountains on the moon, sunspots, Saturn's rings, and the bands and moons of Jupiter. (*b*) An engraving of the reflector telescope built in the 1780s and used by the great astronomer Friedrich Wilhelm Herschel, who was the first to observe galaxies outside our own. (*c*) Because it is difficult to make large, flaw-free lenses, refractor telescopes like this 91.4-cm telescope at Lick Observatory have been superseded in light-gathering power by reflector telescopes. (*d*) The great astronomer Edwin Powell Hubble, who discovered the apparent expansion of the universe, is shown seated in the observer's cage of the 5.08-m Hale reflecting telescope, which is large enough for the observer to sit at the prime focus itself. (*e*) This 10-m optical reflector at the Whipple Observatory in southern Arizona is the largest instrument designed exclusively for use in gamma-ray astronomy. High-energy gamma rays of unknown origin strike the upper atmosphere and create cascades of particles. Among these particles are high-energy electrons that emit Cerenkov radiation observable from the ground. According to one hypothesis, high-energy gamma rays are emitted as matter is accelerated toward ultradense rotating stars called pulsars. *((a) Scala/Art Resource, (b) Royal Astronomical Society Library, (c) Lick Observatory, courtesy of the University of California Regents, (d) California Institute of Technology, (e) Gary Ladd.)*

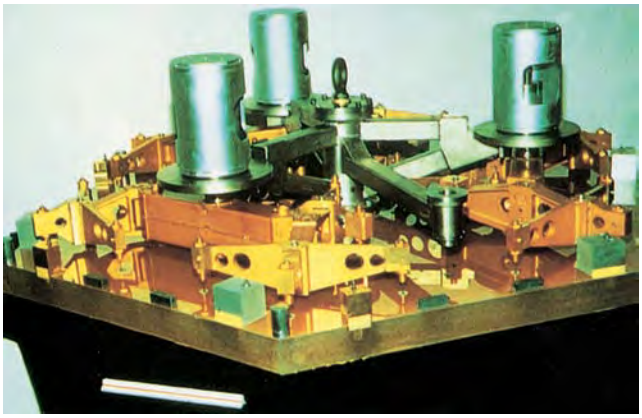
(*b*)



(*c*)

(*a*) The Keck Observatory, atop the inactive volcano of Mauna Kea, Hawaii, houses the world's largest optical telescope. The clear, dry air and lack of light pollution make the remote heights of Mauna Kea an ideal site for astronomical observations. (*b*) The Keck telescope is composed of 36 hexagonal mirror segments performing together as if they were a single mirror 10 m wide—roughly twice as large as the largest single-mirror telescope presently in operation. (*c*) Beneath each Keck mirror is a system of computer-controlled sensors and motor-driven actuators that can continuously vary the mirror's shape. These variations, which are sensitive to within 100 nm, enable the system to correct for variations in the alignments of the segments due to minute variations in gravitational stress when the telescope is tilted and to compensate for thermal expansions and contractions and fluctuations caused by gusts of wind on the mountaintop. *(California Association for Research in Astronomy.)*

The Hubble Space Telescope is high above the atmospheric turbulence that limits the ability of ground-based telescopes to resolve images at optical wavelengths. *(NASA.)*

Physics Spotlight

Eye Surgery: New Lenses for Old

Unfortunately, this person has a cataract affecting the entire lens of her right eye. The presence of the cataract is associated with the severe eczema that can be seen on her forehead. *(Western Ophthalmic Hospital/Photo Researchers.)*

The first documented eye surgery took place over 2000 years ago and was performed by a surgeon in India known today as Susruta.[*, †] The lens of the human eye is susceptible to clouding with age and exposure to ultraviolet light or with exposure to some diseases or chemicals. This opacity is called a cataract. In the *Susruta Samhita*, the surgeon wrote of diagnosing and removing cataract-clouded lenses.

In 2005, more than two million cataract surgeries were performed in the United States.[‡] Most involved removing the lens and implanting an artificial lens inside the eye. Although permanent *i*ntra*o*cular *l*enses (IOLs) were pioneered in 1951,[#] they did not gain widespread acceptance until the 1980s. Before then, patients had to wear strong external corrective lenses (eyeglasses or contact lenses after the 1960s) after cataract surgery.

Cataract patients who have had IOLs implanted have had to wear external corrective lenses, because the IOLs are fixed focus lenses. However, several different IOLs that have variable focus have been recently introduced.[°, §] These accommodative, multifocal lenses are flexed and focused by the eye muscles. Some patients have had such good results with accommodative IOLs that they do not need supplemental glasses.

Many people without cataracts wear external corrective lenses. In the United States alone, over 150 million people spend at least $15 billion on external corrective lenses each year.[¶] In addition, nearly a million get refractive surgery each year that promises to reduce their need for external corrective lenses.[**] Refractive surgery reshapes the cornea to minimize refractive errors. It was pioneered in the 1930s, but did not become popular until techniques that use lasers were developed in the late 1980s.[††] Refractive surgery can be done by using chemicals or mechanical abrasion, but it is most commonly done by using lasers that vaporize minute pieces of the cornea. Some refractive surgeries involve cutting a thin flap in the outer layers of the cornea, shaping the stroma, the thickest layer of the cornea underneath, and then replacing the flap. Other surgeries just involve shaping the outer surface of the cornea.[‡‡]

Refractive surgeries work best on patients who have medium to low refractive error. In those patients, however, the results are promising. Up to 72% of the patients who have low to moderate nearsightedness ended up with postsurgical uncorrected vision that is considered 20/20, or normal.[##] Recently, customized wavefront-guided laser surgery has been used to minimize refractive errors that are not fixed by earlier techniques of eye surgery.[°°] A light is bounced off of the retina through many locations on the cornea. The returning wavefront is mapped, and very tiny refractive errors are located for elimination. With custom wavefront-guided laser surgery, up to 89% of patients ended up with uncorrected 20/20 vision.

But even with the best surgeons, there can be complications with refractive surgeries.[§§, ¶¶] The most common is dry eyes, but in up to 2% of patients vision can actually be worse after surgery.[***] Complications are more likely in people who have large refractive errors, and refractive surgery is not recommended for them. But those people may also eventually be able to not wear external corrective lenses. Recently, accommodative IOLs have been tested on people who have high refractive errors. Many were able to have near-normal vision after surgery without additional corrective lenses.[†††]

Summary

TOPIC	RELEVANT EQUATIONS AND REMARKS	
1. Virtual and Real Images and Objects		
Images	An image is *real* if actual light rays converge to each image point. This can occur on the reflected-light side of a mirror or on the refracted-light side of a thin lens or refracting surface. An image is *virtual* if only the extensions of the actual light rays converge to each image point. This can occur behind a mirror or on the incident-light side of a lens or refracting surface.	
Objects	A real object is either a physical object or a real image. An object is *real* if actual light rays diverge from each object point. This can occur only on the incident-light side of a mirror, lens, or refracting surface. An object is *virtual* if only extensions of actual light rays diverge from each object point. This can occur only behind a mirror or on the refracted-light side of a lens or refracting surface.	
2. Spherical Mirrors		
Focal length	The focal length is the image distance when the object is at infinity, so the incident light is parallel to the axis.	
Mirror equation (for locating an image)	$$\frac{1}{s}+\frac{1}{s'}=\frac{1}{f}$$	32-4
	where	
	$$f=\frac{r}{2}$$	32-3
Lateral magnification	$$m=\frac{y'}{y}=-\frac{s'}{s}$$	32-5
Ray diagrams	Images can be located by a ray diagram using any two paraxial rays. The parallel, focal, and radial rays are the easiest to draw: 1. The parallel ray, drawn parallel to the axis, is reflected through the focal point. 2. The focal ray, drawn through the focal point, is reflected parallel to the axis. 3. The radial ray, drawn through the center of curvature, is reflected back on itself.	
Sign conventions for reflection	1. s is positive if the object is on the incident-light side of the mirror. 2. s' is positive if the image is on the reflected-light side of the mirror. 3. r and f are positive if the mirror is concave so the center of curvature is on the reflected-light side of the mirror.	
3. Images Formed by Refraction		
Refraction at a single surface	$$\frac{n_1}{s}+\frac{n_2}{s'}=\frac{n_2-n_1}{r}$$	32-6
	where n_1 is the index of refraction of the medium on the incident-light side of the surface.	
Magnification	$$m=\frac{y'}{y}=-\frac{n_1 s'}{n_2 s}$$	32-7
Sign conventions for refraction	1. s is positive for objects on the incident-light side of the surface.	
	2. s' is positive for images on the refracted-light side of the surface.	
	3. r is positive if the center of curvature is on the refracted-light side of the surface.	

TOPIC	RELEVANT EQUATIONS AND REMARKS	
4. Thin Lenses		
Focal length (lens-maker's equation)	$\frac{1}{f} = \left(\frac{n}{n_{\text{air}}} - 1\right)\left(\frac{1}{r_1} - \frac{1}{r_2}\right)$ A positive lens ($f > 0$) is a converging lens. A negative lens ($f < 0$) is a diverging lens.	32-11
First and second focal points	Incident rays parallel to the axis emerge directed either toward or away from the *first focal point F′*. Incident rays directed either toward or away from the *second focal point F* emerge parallel with the axis.	
Power	$P = \frac{1}{f}$	32-13
Thin-lens equation (for locating image)	$\frac{1}{s} + \frac{1}{s'} = \frac{1}{f}$	32-12
Magnification	$m = \frac{y'}{y} = -\frac{s'}{s}$	32-14
Ray diagrams	Images can be located by a ray diagram using any two paraxial rays. The parallel, central, and focal rays are the easiest to draw: 1. The parallel ray, drawn parallel to the axis, emerges directed toward (or away from) the second focal point. 2. The central ray, drawn through the center of the lens, is not deflected. 3. The focal ray, drawn through (or toward) the first focal point, emerges parallel to the axis.	
Sign conventions for lenses	The sign conventions are the same as for refraction at a spherical surface.	
5. *Aberrations	Blurring of the image of a single object point is called aberration. Spherical aberration results from the fact that a spherical surface focuses only paraxial rays (those that travel close to the axis) to a single point. Nonparaxial rays are focused at nearby points depending on the angle made with and distance from the axis. Spherical aberration can be reduced by blocking the rays farthest from the axis. This, of course, reduces the amount of light reaching the image. Chromatic aberration, which occurs with lenses but not mirrors, results from the variation in the index of refraction with wavelength. Lens aberrations are most commonly reduced by using a series of lens elements.	
6. *The Eye	The cornea–lens system of the eye focuses light on the retina, where it is sensed by the rods and cones that send information along the optic nerve to the brain. When the eye is relaxed, the focal length of the cornea-lens system is about 2.5 cm, which is the distance to the retina. When objects are brought near the eye, the lens changes shape to decrease the overall focal length so that the image remains focused on the retina. The closest distance for which the image can be focused on the retina is called the near point, typically about 25 cm. The apparent size of an object depends on the size of the image on the retina. The closer the object, the larger the image on the retina and therefore the larger the apparent size of the object.	
7. *The Simple Magnifier	A simple magnifier consists of a lens with a positive focal length that is smaller than the near point.	
Magnifying power (angular magnification)	$M = \frac{\theta}{\theta_o} = \frac{x_{\text{np}}}{f}$	32-20
8. *The Compound Microscope	The compound microscope is used to look at very small objects that are nearby. It consists of two converging lenses (or lens systems), an objective and an eyepiece. The object to be viewed is placed just outside the focal point of the objective, which forms an enlarged image of the object at the focal plane of the eyepiece. The eyepiece acts as a simple magnifier to view the final image.	

TOPIC	RELEVANT EQUATIONS AND REMARKS
Magnifying power (angular magnification)	$$M = m_o M_e = -\frac{L}{f_o}\frac{x_{np}}{f_e} \qquad \text{32-22}$$ where L is the tube length, the distance between the second focal point of the objective and the first focal point of the eyepiece.
9. *The Telescope	The telescope is used to view objects that are far away. The objective of the telescope forms a real image of the object that is much smaller than the object but much closer. The eyepiece is then used as a simple magnifier to view the image. A reflecting telescope uses a mirror for its objective.
Magnifying power (angular magnification)	$$M = \frac{\theta_e}{\theta_o} = -\frac{f_o}{f_e} \qquad \text{32-23}$$

Answers to Concept Checks

32-2 Ben can see only the image at P_1'.

32-3 Infinity

32-4

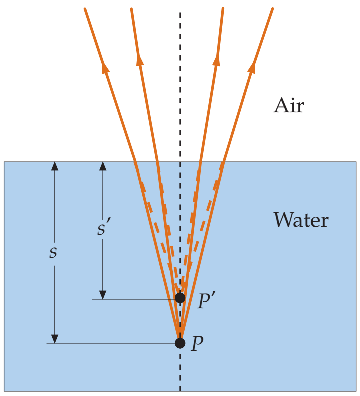

FIGURE 32-56 Ray diagram for the image of an object in water as viewed from directly overhead. The depth of the image is less than the depth of the object.

Answers to Practice Problems

32-3 (*a*) 8.0 cm (*b*) $s' = -4.0$ cm

32-4 $s' = -2.5$ cm, $m = +0.50$; the image is upright, virtual, and reduced in size.

32-5 390 yd

32-6 (*a*) $s' = -6.44$ cm and (*b*) $m = 1.14$. Fluffy sees Goldie to be 1.1 cm closer and 14 percent larger than she actually is.

32-7 The image is 5.6 cm from the near side of the aquarium.

32-8 18 cm

32-10 $s' = 30$ cm, $m = -2.0$; real, inverted

32-11 $s' = -10$ cm, $m = 2.0$; virtual, upright

32-12 $P_{eye} = 41.33$ D; $P_c = 41.33$ D $+ 2.67$ D $= 44$ D; the two powers are equal

32-13 $M = 12$

32-14 $M = -195$

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • Can a virtual image be photographed? If so, give an example. If not, explain why.

2 • Suppose the x, y, and z axes of a 3-D coordinate system are painted different colors. One photograph is taken of the coordinate system and another is taken of its image in a plane mirror. Is it possible to tell that one of the photographs is of a mirror image? Or could both photographs be of the real coordinate system from different angles?

3 • True or False

(*a*) The virtual image formed by a concave mirror is always smaller than the object.
(*b*) A concave mirror always forms a virtual image.
(*c*) A convex mirror never forms a real image of a real object.
(*d*) A concave mirror never forms an enlarged real image of an object. SSM

4 • An ant is crawling along the axis of a concave mirror that has radius of curvature R. At what object distances, if any, will the mirror produce (*a*) an upright image, (*b*) a virtual image, (*c*) an image smaller than the object, and (*d*) an image larger than the object?

5 • An ant is crawling along the axis of a convex mirror that has radius of curvature R. At what object distances, if any, will the mirror produce (*a*) an upright image, (*b*) a virtual image, (*c*) an image smaller than the object, and (*d*) an image larger than the object? SSM

6 •• Convex mirrors are often used for rearview mirrors on cars and trucks to give a wide-angle view. "Warning, objects are closer than they appear" is written below the mirrors. Yet, according to a ray diagram, the image distance for distant objects is much shorter than the object distance. Why then do they appear more distant?

7 • As an ant on the axis of a concave mirror crawls from a great distance to the focal point of a concave mirror, the image of the ant moves (*a*) from a great distance toward the focal point and is always real, (*b*) from the focal point to a great distance from the mirror and is always real, (*c*) from the focal point to the center of curvature of the mirror and is always real, (*d*) from the focal point to a great distance from the mirror and changes from a real image to a virtual image.

8 • A kingfisher bird that is perched on a branch a few feet above the water is viewed by a scuba diver submerged beneath the surface of the water directly below the bird. Does the bird appear to the diver to be closer to or farther from the surface than the actual bird? Explain your answer using a ray diagram.

9 • An object is placed on the axis of a diverging lens whose focal length has a magnitude of 10 cm. The distance from the object to the lens is 40 cm. The image is (*a*) real, inverted, and diminished, (*b*) real, inverted, and enlarged, (*c*) virtual, inverted, and diminished, (*d*) virtual, upright, and diminished, (*e*) virtual, upright, and enlarged.

10 • If an object is placed between the focal point of a converging lens and the optical center of the lens, the image is (*a*) real, inverted, and enlarged, (*b*) virtual, upright, and diminished, (*c*) virtual, upright, and enlarged, (*d*) real, inverted, and diminished.

11 • A converging lens is made of glass that has an index of refraction of 1.6. When the lens is in air, its focal length is 30 cm. When the lens is immersed in water, its focal length (*a*) is greater than 30 cm, (*b*) is between zero and 30 cm, (*c*) is equal to 30 cm, (*d*) has a negative value.

12 • True or false:
(*a*) A virtual image cannot be displayed on a screen.
(*b*) A negative image distance implies that the image is virtual.
(*c*) All rays parallel to the axis of a spherical mirror are reflected through a single point.
(*d*) A diverging lens cannot form a real image from a real object.
(*e*) The image distance for a converging lens is always positive.

13 • **Biological Application** Both the human eye and the digital camera work by forming real images on light-sensitive surfaces. The eye forms a real image on the retina and the camera forms a real image on a CCD array. Explain the difference between the ways in which these two systems *accommodate*. That is, the difference between how an eye adjusts and how a camera adjusts (or can be adjusted) to form a focused image for objects at both large and short distances from the camera.

14 • **Biological Application** If an object is 25 cm in front of the naked eye of a farsighted person, an image (*a*) would be formed behind the retina if it were not for the fact that that the light is blocked (by the back of the eyeball) and the corrective contact lens should be convex, (*b*) would be formed behind the retina if it were not for the fact that that the light is blocked (by the back of the eyeball) and the corrective contact lens should be concave, (*c*) is formed in front of the retina and the corrective contact lens should be convex, (*d*) is formed in front of the retina and the corrective contact lens should be concave.

15 •• Explain the following statement: A microscope is an object magnifier, but a telescope is an angle magnifier. *Hint: Take a look at the ray diagram for each magnifier and use it to explain the difference in adjectives.*

ESTIMATION AND APPROXIMATION

16 • Estimate the location and size of the image of your face when you hold a shiny new tablespoon a foot in front of your face and with the convex side toward you.

17 • Estimate the focal length of the "mirror" produced by the surface of the water in the reflection pool in front of the Lincoln Memorial on a still night.

18 •• Estimate the maximum value that could be obtained for the magnifying power of a simple magnifier, using Equation 32-20. *Hint: Think about the smallest focal length lens that could be made from glass and still be used as a magnifier.*

PLANE MIRRORS

19 • The image of the object point P in Figure 32-57 is viewed by an eye, as shown. Draw two rays from the object point that reflect from the mirror and enter the eye. If the object point and the mirror are fixed in their locations, indicate the range of locations where the eye can be positioned and still see the image of the object point. SSM

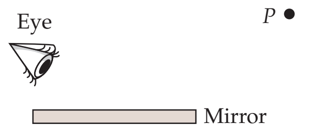

FIGURE 32-57 Problem 19

20 • You are 1.62 m tall and want to be able to see your full image in a vertical plane mirror. (*a*) What is the minimum height of the mirror that will meet your needs? (*b*) How far above the floor should the bottom of mirror in (*a*) be placed, assuming that the top of your head is 14 cm above your eye level? Use a ray diagram to explain your answer.

21 •• (*a*) Two plane mirrors make an angle of 90°. The light from a point object that is arbitrarily positioned in front of the mirrors produces images at three locations. For each image location, draw two rays from the object that, after one or two reflections, appear to come from the image location. (*b*) Two plane mirrors make an angle of 60° with each other. Draw a sketch to show the location of all the images formed of an object on the bisector of the angle between the mirrors. (*c*) Repeat Part (*b*) for an angle of 120°. SSM

22 •• Show that the mirror equation (Equation 32-4 where $f = r/2$) yields the correct image distance and magnification for a plane mirror.

23 •• When two plane mirrors are parallel, such as on opposite walls in a barber shop, multiple images arise because each image in one mirror serves as an object for the other mirror. An object is placed between parallel mirrors separated by 30 cm. The object is 10 cm in front of the left mirror and 20 cm in front of the right mirror. (*a*) Find the distance from the left mirror to the first four images in that mirror. (*b*) Find the distance from the right mirror to the first four images in that mirror. (*c*) Explain why each more distant image becomes fainter and fainter.

SPHERICAL MIRRORS

24 •• A concave mirror has a radius of curvature equal to 24 cm. Use ray diagrams to locate the image, if it exists, for an object near the axis at distances of (*a*) 55 cm, (*b*) 24 cm, (*c*) 12 cm, and (*d*) 8.0 cm from the mirror. For each case, state whether the image is real or virtual; upright or inverted; and enlarged, reduced, or the same size as the object.

25 • (*a*) Use the mirror equation (Equation 32-4 where $f = r/2$) to calculate the image distances for the object distances and mirror of Problem 24. (*b*) Calculate the magnification for each given object distance. SSM

26 • A convex mirror has a radius of curvature that has a magnitude equal to 24 cm. Use ray diagrams to locate the image, if it exists, for an object near the axis at distances of (*a*) 55 cm, (*b*) 24 cm, (*c*) 12 cm, (*d*) 8.0 cm, and (*e*) 1.0 cm from the mirror. For each case, state whether the image is real or virtual; upright or inverted; and enlarged, reduced, or the same size as the object.

27 • (*a*) Use the mirror equation (Equation 32-4 where $f = r/2$) to calculate the image distances for the object distances and mirror of Problem 26. (*b*) Calculate the magnification for each given object distance.

28 •• Use the mirror equation (Equation 32-4 where $f = r/2$) to prove that a convex mirror cannot form a real image of a real object, no matter where the object is placed.

29 • A dentist wants a small mirror that will produce an upright image that has a magnification of 5.5 when the mirror is located 2.1 cm from a tooth. (*a*) Should the mirror be concave or convex? (*b*) What should the radius of curvature of the mirror be? SSM

30 •• **CONTEXT-RICH** Convex mirrors are used in many stores to provide a wide angle of surveillance for a reasonable mirror size. Your summer job is at a local convenience store that uses the mirror shown in Figure 32-58. This setup allows you (or the clerk) to survey the entire store when you are 5.0 m from the mirror. The mirror has a radius of curvature equal to 1.2 m. Assume all rays are paraxial. (*a*) If a customer is 10 m from the mirror, how far from the mirror is his image? (*b*) Is the image in front of or behind the mirror? (*c*) If the customer is 2.0 m tall, how tall is his image?

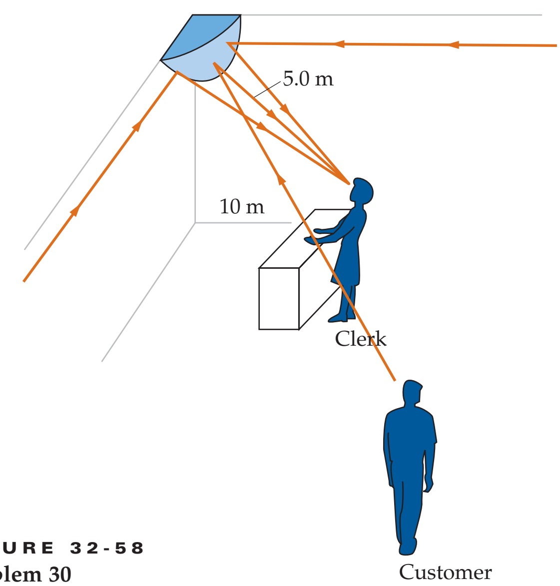

FIGURE 32-58
Problem 30

31 •• A certain telescope uses a concave spherical mirror that has a radius equal to 8.0 m. Find the location and diameter of the image of the moon formed by this mirror. The moon has a diameter of 3.5×10^6 m and is 3.8×10^8 m from Earth.

32 •• A piece of a thin spherical shell that has a radius of curvature of 100 cm is silvered on both sides. The concave side of the piece forms a real image 75 cm from the piece. The piece is then turned around so that its convex side faces the object. The piece is moved so that the image is now 35 cm from the piece on the concave side. (*a*) How far was the piece moved? (*b*) Was it moved toward the object or away from the object?

33 •• Two light rays parallel to the optic axis of a concave mirror strike that mirror as shown in Figure 32-59. The mirror has a radius of curvature equal to 5.0 m. They then strike a small spherical mirror that is 2.0 m from the large mirror. The light rays finally meet at the vertex of the large mirror. Note: The small mirror is shown as planar, so as not to give away the answer, but it is *not* actually planar. (*a*) What is the radius of curvature of the small mirror? (*b*) Is that mirror convex or concave? Explain your answer.

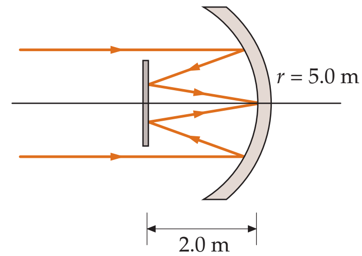

FIGURE 32-59
Problem 33

IMAGES FORMED BY REFRACTION

34 •• A very long 1.75-cm-diameter glass rod has one end ground and polished to a convex spherical surface that has a 7.20-cm radius. The glass material has an index of refraction of 1.68. (*a*) A point object in air is on the axis of the rod and 30.0 cm from the spherical surface. Find the location of the image and state whether the image is real or virtual. (*b*) Repeat Part (*a*) for a point object in air, on the axis, and 5.00 cm from the spherical surface. Draw a ray diagram for each case.

35 • A fish is 10 cm from the front surface of a spherical fish bowl of radius 20 cm. (*a*) How far behind the surface of the bowl does the fish appear to someone viewing the fish from in front of the bowl? (*b*) By what distance does the fish's apparent location change (relative to the front surface of the bowl) when it swims away to 30 cm from the front surface? SSM

36 •• A very long 1.75-cm-diameter glass rod has one end ground and polished to a concave spherical surface that has a 7.20-cm radius. The glass material has an index of refraction of 1.68. A point object in air is on the axis of the rod and 15.0 cm from the spherical surface. Find the location of the image and state whether the image is real or virtual. Draw a ray diagram.

37 •• Repeat Problem 34 for when the glass rod and the object are immersed in water, and (*a*) the object is 6.00 cm from the spherical surface, and (*b*) the object is 12.0 cm from the spherical surface. SSM

38 •• Repeat Problem 36 for when the glass rod and the object are immersed in water and the object is 20 cm from the spherical surface.

39 •• A rod that is 96.0 cm long is made of glass that has an index of refraction equal to 1.60. The rod has its ends ground to convex spherical surfaces that have radii equal to 8.00 cm and 16.0 cm. An object is in air on the long axis of the rod 20.0 cm from the end that has the 8.00-cm radius. (*a*) Find the image distance due to refraction at the 8.00-cm-radius surface. (*b*) Find the position of the final image due to refraction at both surfaces. (*c*) Is the final image real or virtual?

40 •• Repeat Problem 39 for an object in air on the axis of the glass rod 20.0 cm from the end that has the 16.0-cm radius.

THIN LENSES AND THE LENS-MAKER'S EQUATION

41 • A double concave lens that has an index of refraction equal to 1.45 has radii whose magnitudes are equal to 30.0 cm and 25.0 cm. An object is located 80.0 cm to the left of the lens. Find (*a*) the focal length of the lens, (*b*) the location of the image, and (*c*) the magnification of the image. (*d*) Is the image real or virtual? Is the image upright or inverted? SSM

42 • The following thin lenses are made of glass that has an index of refraction equal to 1.60. Make a sketch of each lens and find each focal length in air: (*a*) $r_1 = 20.0$ cm and $r_2 = 10.0$ cm, (*b*) $r_1 = 10.0$ cm and $r_2 = 20.0$ cm, and (*c*) $r_1 = -10.0$ cm and $r_2 = -20.0$ cm.

43 • The following four thin lenses are made of glass that has an index of refraction of 1.5. The radii given are *magnitudes*. Make a sketch of each lens and find each focal length in air: (*a*) double-convex that has radii of curvature equal to 15 cm and 26 cm, (*b*) plano-convex that has a radius of curvature equal to 15 cm, (*c*) double concave that has radii of curvature equal to 15 cm, and (*d*) plano-concave that has a radius of curvature equal to 26 cm.

44 • Find the focal length of a glass lens that has an index of refraction equal to 1.62, a concave surface that has a radius of curvature of magnitude 100 cm, and a convex surface that has a radius of curvature of magnitude 40.0 cm.

45 •• (*a*) An object that is 3.00 cm high is placed 25.0 cm in front of a thin lens that has a power equal to 10.0 D. Draw a ray diagram to find the position and the size of the image and check your results using the thin-lens equation. (*b*) Repeat Part (*a*) if the object is placed 20.0 cm in front of the lens. (*c*) Repeat Part (*a*) for an object placed 20.0 cm in front of a thin lens that has a power equal to −10.0 D. SSM

46 •• The lens-maker's equation has three design parameters. They consist of the index of refraction of the lens and the radii of curvature for its two surfaces. Thus, there are many ways to design a lens that has a particular focal length in air. Use the lens-maker's equation to design three different thin converging lenses, each having a focal length of 27.0 cm and each made from glass that has an index of refraction of 1.60. Sketch each of your designs.

47 •• Repeat Problem 46, but for a diverging lens that has a focal length in air of the same magnitude.

48 •• (*a*) What is meant by a negative object distance? Describe a specific situation in which a negative object distance can occur. (*b*) Find the image distance and the magnification for a thin lens in air when the object distance is −20 cm and the lens is a converging lens that has a focal length of 20 cm. Describe the image—is it virtual or real, upright or inverted? (*c*) Repeat Part (*b*) if the object distance is, instead, −10 cm, and the lens is diverging and has a focal length (magnitude) of 30 cm.

49 •• Two converging lenses, each having a focal length equal to 10 cm, are separated by 35 cm. An object is 20 cm to the left of the first lens. (*a*) Find the position of the final image using both a ray diagram and the thin-lens equation. (*b*) Is the final image real or virtual? Is the final image upright or inverted? (*c*) What is the overall lateral magnification? SSM

50 •• Repeat Problem 49, but with the second lens replaced by a diverging lens that has a focal length equal to −15 cm.

51 •• (*a*) Show that to obtain a magnification of magnitude $|m|$ using a converging thin lens of focal length f, the object distance must be equal to $(1 + |m|^{-1})f$. (*b*) You want to use a digital camera which has a lens whose focal length is 50.0 mm to take a picture of a person 1.75 m tall. How far from the camera lens should you have that person stand so that the image size on the light-receiving sensors of your camera is 24.0 mm?

52 •• **Spreadsheet** A converging lens has a focal length of 12.0 cm. (*a*) Using a spreadsheet program or graphing calculator, plot the image distance as a function of the object distance, for object distances ranging from $1.10f$ to $10.0f$, where f is the focal length. (*b*) On the same graph used in Part (*a*), but using a different y axis, plot the magnification of the lens as a function of the object distance. (*c*) What type of image is produced for this range of object distances—real or virtual, upright or inverted? (*d*) Discuss the significance of any asymptotic limits your graphs have.

53 •• **Spreadsheet** A converging lens has a focal length of 12.0 cm. (*a*) Using a spreadsheet program or graphing calculator, plot the image distance as a function of the object distance, for object distances ranging from $0.010f$ to $0.90f$, where f is the focal length. (*b*) On the same graph used in Part (*a*), but using a different y axis, plot the magnification of the lens as a function of the object distance. (*c*) What type of image is produced for this range of object distances—real or virtual, upright or inverted? (*d*) Discuss the significance of any asymptotic limits your graphs have.

54 •• An object is 15.0 cm in front of a converging lens that has a focal length equal to 15.0 cm. A second converging lens that also has a focal length equal to 15.0 cm is located 20.0 cm in back of the first. (*a*) Find the location of the final image and describe its properties (for example, real and inverted) and (*b*) draw a ray diagram to corroborate your answers to Part (*a*).

55 •• An object is 15.0 cm in front of a converging lens that has a focal length equal to 15.0 cm. A diverging lens that has a focal length whose magnitude is equal to 15.0 cm is located 20.0 cm in back of the first. (*a*) Find the location of the final image and describe its properties (for example, real and inverted) and (*b*) draw a ray diagram to corroborate your answers to Part (*a*). SSM

56 ••• In a convenient form of the thin-lens equation used by Newton, the object and image distances x and x' are measured from the focal points F and F', and not from the center of the lens. (*a*) Indicate x and x' on a sketch of a lens and show that if $x = s - f$ and $x' = s' - f$, the thin-lens equation (Equation 32-12) can be rewritten as $xx' = f^2$. (*b*) Show that the lateral magnification is given by $m = -x'/f = -f/x$.

57 ••• In *Bessel's method* for finding the focal length f of a lens, an object and a screen are separated by distance L, where $L > 4f$. It is then possible to place the lens at either of two locations, both between the object and the screen, so that there is an image of the object on the screen, in one case magnified and in the other case reduced. Show that if the distance between those two lens locations is D, then the focal length is given by $f = \frac{1}{4}(L^2 - D^2)/L$. *Hint: Refer to Figure 32-60.* SSM

58 ••• **Engineering Application, Context-Rich** You are working for an optician during the summer. The optician needs to measure an unknown focal length and you suggest using *Bessel's method* (see Problem 57), which you used during a physics lab. You set the object-to-image distance at 1.70 m. The lens position is adjusted to get a sharp image on the screen. A second sharp image is found when the lens is moved a distance of 72 cm from its first location. (*a*) Sketch the ray diagram for the two locations. (*b*) Find the focal length of the lens using Bessel's method. (*c*) What are the two locations of the lens with respect to the object? (*d*) What are the magnifications of the images when the lens is in the two locations?

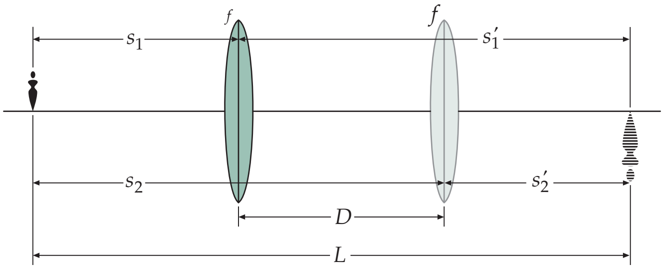

FIGURE 32-60 Problems 57 and 58

59 ••• An object is 17.5 cm to the left of a lens that has a focal length of +8.50 cm. A second lens, which has a focal length of −30.0 cm, is 5.00 cm to the right of the first lens. (*a*) Find the distance between the object and the final image formed by the second lens. (*b*) What is the overall magnification? (*c*) Is the final image real or virtual? Is the final image upright or inverted?

*ABERRATIONS

60 • Chromatic aberration is a common defect of (*a*) concave and convex lenses, (*b*) concave lenses only, (*c*) concave and convex mirrors, (*d*) all lenses and mirrors.

61 • **ENGINEERING APPLICATION** Discuss some of the reasons why most telescopes that are used by astronomers are reflecting rather than refracting telescopes.

62 • A symmetric double-convex lens has radii of curvature equal to 10.0 cm. It is made from glass that has an index of refraction equal to 1.530 for blue light and equal to 1.470 for red light. Find the focal length of this lens for (*a*) red light and (*b*) blue light.

*THE EYE

63 • **BIOLOGICAL APPLICATION** Find the change in the focal length of the eye when an object originally at 3.0 m is brought to 30 cm from the eye.

64 • **BIOLOGICAL APPLICATION** A farsighted person requires lenses that have powers equal to 1.75 D to read comfortably from a book that is 25.0 cm from his eyes. What is that person's near point without the lenses?

65 • **BIOLOGICAL APPLICATION** If two point objects close together are to be seen as two distinct objects, the images must fall on the retina on two different cones that are not adjacent. That is, there must be an unactivated cone between them. The separation of the cones is about 1.00 μm. Model the eye as a uniform 2.50-cm-diameter sphere that has a refractive index of 1.34. (*a*) What is the smallest angle the two points can subtend? (See Figure 32-61.) (*b*) How close together can two points be if they are 20.0 m from the eye? SSM

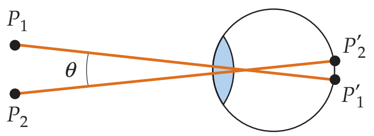

FIGURE 32-61 Problem 65

66 • **BIOLOGICAL APPLICATION** Suppose the eye were designed like a camera that has a lens of fixed focal length equal to 2.50 cm that could move toward or away from the retina, has air on both sides of the lens, and has no cornea. Approximately how far would the lens have to move to focus the image of an object 25.0 cm from the eye onto the retina? *Hint: Find the distance from the retina to the image behind it for an object at* 25.0 cm.

Note: **Problems 67 through 69 refer to the model of the eye shown in Figure 32-62.**

67 •• **BIOLOGICAL APPLICATION** A simple model for the eye is a lens that has a variable power P located a fixed distance d in front of a screen, with the space between the lens and the screen filled by air. This "eye" can focus for all values of object distance s such that $x_{np} \le s \le x_{fp}$ where the subscriptson the variables refer to "near point" and "far point," respectively. This "eye" is said to be normal if it can focus on very distant objects. (*a*) Show that for a normal "eye" of this type, the required minimum value of P is given by $P_{min} = 1/d$. (*b*) Show that the maximum value of P is given by $P_{max} = 1/x_{np} + 1/d$. (*c*) The difference between the maximum and minimum powers, symbolized by A, is defined as $A = P_{max} - P_{min}$ and is called the *accommodation*. Find the minimum power and accommodation for this model eye that has a screen distance of 2.50 cm, a far point distance of infinity, and a near point distance of 25.0 cm. SSM

68 •• **BIOLOGICAL APPLICATION** (This problem refers to the model eye described in Problem 67.) In an eye that exhibits nearsightedness, the eye cannot focus on distant objects. (*a*) Show that for a nearsighted model eye capable of focusing out to a maximum distance x_{fp}, the minimum value of the power P is greater than that of a normal eye (that has a far point at infinity) and is given by $P_{min} = 1/x_{fp} + 1/d$. (*b*) To correct for nearsightedness, a contact lens may be placed directly in front of the lens of the model eye. What power contact lens would be needed to correct the vision of a nearsighted model eye that has a far-point distance of 50.0 cm?

69 •• **BIOLOGICAL APPLICATION** (This problem refers to the model eye described in Problem 67.) In an eye that exhibits farsightedness, the eye may be able to focus on distant objects but cannot focus on close objects. (*a*) Show that for a farsighted model eye capable of focusing only as close as a distance x'_{np}, the maximum value of the power P is given by $P_{max} = 1/x'_{np} + 1/d$. (*b*) Show that, compared to a model eye capable of focusing as close as a distance x_{np} (where $x_{np} < x'_{np}$), the maximum power of the farsighted lens is too small by $1/x_{np} - 1/x'_{np}$. (*c*) What power contact lens would be needed to correct the vision of a farsighted model eye, with $x'_{np} = 150$ cm, so that the eye may focus on objects as close as 15 cm?

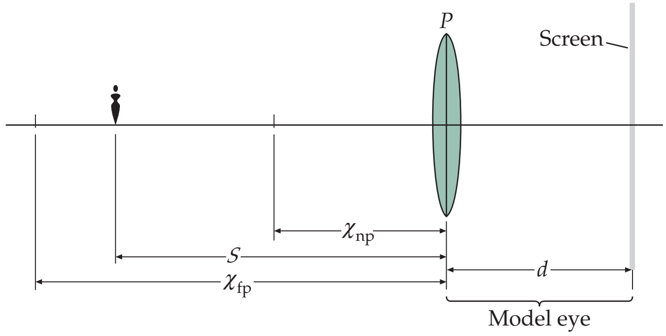

FIGURE 32-62 Problems 67, 68, and 69

70 •• **BIOLOGICAL APPLICATION** A person who has a near point of 80 cm needs to read from a computer screen that is only 45 cm from her eye. (*a*) Find the focal length of the lenses in reading glasses that will produce an image of the screen at a distance of 80 cm from her eye. (*b*) What is the power of the lenses?

71 •• **BIOLOGICAL APPLICATION** A nearsighted person cannot focus clearly on objects that are more distant than 2.25 m from her eye. What power lenses are required for her to see distant objects clearly?

72 •• **BIOLOGICAL APPLICATION** Because the index of refraction of the lens of the eye is not very different from that of the surrounding material, most of the refraction takes place at the cornea, where the index changes abruptly from 1.00 (air) to approximately 1.38. (*a*) Modeling the cornea, aqueous humor, lens and vitreous humor as a transparent homogeneous solid sphere that has an index of refraction of 1.38, calculate the sphere's radius if it focuses parallel light on the retina a distance 2.50 cm away. (*b*) Do you expect your result to be larger or smaller than the actual radius of the cornea? Explain your answer.

73 •• **Biological Application** The near point of a certain person's eyes is 80 cm. Reading glasses are prescribed so that he can read a book at 25 cm from his eye. The glasses are 2.0 cm from the eye. What diopter lenses should be used in the glasses?

74 ••• **Biological Application** At age 45, a person is fitted for reading glasses that have a power equal to 2.10 D in order to read at 25 cm. By the time she reaches the age of 55, she discovers herself holding her newspaper at a distance of 40 cm in order to see it clearly with her glasses on. (*a*) Where was her near point at age 45? (*b*) Where is her near point at age 55? (*c*) What power is now required for the lenses of her reading glasses so that she can again read at 25 cm? Assume the glasses are placed 2.2 cm from her eyes.

*THE SIMPLE MAGNIFIER

75 • What is the magnifying power of a lens that has a focal length equal to 7.0 cm when the image is viewed at infinity by a person whose near point is at 35 cm? SSM

76 •• A lens that has a focal length equal to 6.0 cm is used as a simple magnifier by one person whose near point is 25 cm and by another person whose near point is 40 cm. (*a*) What is the effective magnifying power of the lens for each person? (*b*) Compare the sizes of the images on the retinas when each person looks at the same object with the magnifier.

77 •• In your botany class, you examine a leaf using a convex 12-D lens as a simple magnifier. What is the angular magnification of the leaf if the image formed by the lens is (*a*) at infinity and (*b*) at 25 cm? SSM

*THE MICROSCOPE

78 •• Your laboratory microscope objective has a focal length of 17.0 mm. It forms an image of a tiny specimen at 16.0 cm from its second focal point. (*a*) How far from the objective is the specimen located? (*b*) What is the magnifying power for you if your near point distance is 25.0 cm and the focal length of the eyepiece is 51.0 mm?

79 •• A microscope has an objective that has a focal length equal to 8.5 mm. The eyepiece provides an angular magnification of 10 for a person whose near point distance is 25 cm. The tube length is 16 cm. (*a*) What is the lateral magnification of the objective? (*b*) What is the magnifying power of the microscope? SSM

80 •• A crude, symmetric handheld microscope consists of two 20-D lenses fastened at the ends of a tube 30 cm long. (*a*) What is the tube length of this microscope? (*b*) What is the lateral magnification of the objective? (*c*) What is the magnifying power of the microscope? (*d*) How far from the objective should the object be placed?

81 •• A compound microscope has an objective lens that has a power of 45 D and an eyepiece that has a power of 80 D. The lenses are separated by 28 cm. Assuming that the final image formed by the microscope is 25 cm from the eye, what is the magnifying power?

82 ••• A microscope has a magnifying power of 600. The eyepiece has an angular magnification of 15.0. The objective lens is 22.0 cm from the eyepiece. Calculate (*a*) the focal length of the eyepiece, (*b*) the location of the object so that it is in focus for a normal relaxed eye, and (*c*) the focal length of the objective lens.

*THE TELESCOPE

83 • You have a simple telescope that has an objective which has a focal length of 100 cm and an eyepiece which has a focal length of 5.00 cm. You are using it to look at the moon, which subtends an angle of about 9.00 mrad. (*a*) What is the diameter of the image formed by the objective? (*b*) What angle is subtended by the image formed at infinity by the eyepiece? (*c*) What is the magnifying power of your telescope? SSM

84 • The objective lens of the refracting telescope at the Yerkes Observatory has a focal length of 19.5 m. The moon subtends an angle of about 9.00 mrad. When the telescope is used to look at the moon, what is the diameter of the image of the moon formed by the objective?

85 •• The 200-in (5.10-m) diameter mirror of the reflecting telescope at Mt. Palomar has a focal length of 16.8 m. (*a*) By what factor is the light-gathering power increased over the 40.0-in (1.02-m) diameter refracting lens of the Yerkes Observatory telescope? (*b*) If the focal length of the eyepiece is 1.25 cm, what is the magnifying power of the 200-in telescope?

86 •• An astronomical telescope has a magnifying power of 7.0. The two lenses are 32 cm apart. Find the focal length of each lens.

87 •• A disadvantage of the astronomical telescope for terrestrial use (for example, at a football game) is that the image is inverted. A Galilean telescope uses a converging lens as its objective, but a diverging lens as its eyepiece. The image formed by the objective is at the second focal point of the eyepiece (the focal point on the refracted-light side of the eyepiece), so that the final image is virtual, upright, and at infinity. (*a*) Show that the magnifying power is given by $M = -f_o/f_e$, where f_o is the focal length of the objective and f_e is that of the eyepiece (which is negative). (*b*) Draw a ray diagram to show that the final image is indeed virtual, upright, and at infinity. SSM

88 •• A Galilean telescope (see Problem 87) is designed so that the final image is at the near point, which is 25 cm (rather than at infinity). The focal length of the objective is 100 cm and the focal length of the eyepiece is −5.0 cm. (*a*) If the object distance is 30.0 m, where is the image of the objective? (*b*) What is the object distance for the eyepiece so that the final image is at the near point? (*c*) How far apart are the lenses? (*d*) If the object height is 1.5 m, what is the height of the final image? What is the angular magnification?

89 ••• If you look into the wrong end of a telescope, that is, into the objective, you will see distant objects reduced in angular size. For a refracting telescope that has an objective with a focal length equal to 2.25 m and an eyepiece with a focal length equal to 1.50 cm, by what factor is the angular size of the object changed?

GENERAL PROBLEMS

90 • To focus a camera, the distance between the lens and the image-sensing surface is varied. A wide-angle lens of a camera has a focal length of 28 mm. By how much must the lens move to change from focusing on an object at infinity to an object at a distance of 5.00 m in front of the camera?

91 • A converging lens that has a focal length equal to 10 cm is used to obtain an image that is twice the height of the object. Find the object and image distances if (*a*) the image is to be upright and (*b*) the image is to be inverted. Draw a ray diagram for each case.

92 •• You are given two converging lenses that have focal lengths of 75 mm and 25 mm. (*a*) Show how the lenses should be arranged to form a telescope. State which lens to use as the objective, which lens to use as the eyepiece, how far apart to place the lenses, and what angular magnification you expect. (*b*) Draw a ray diagram to show how rays from a distant object are refracted by the two lenses.

93 •• (*a*) Show how the same two lenses in Problem 92 should be arranged to form a compound microscope that has a tube length of 160 mm. State which lens to use as the objective, which lens to use as the eyepiece, how far apart to place the lenses, and what

overall magnification you expect to get, assuming the user has a near point of 25 cm. (*b*) Draw a ray diagram to show how rays from a close object are refracted by the lenses. SSM

94 •• **CONTEXT-RICH** On a vacation, you are scuba diving and using a diving mask that has a face plate that bulges outward with a radius of curvature of 0.50 m. As a result, a convex spherical surface exists between the water and the air in the mask. A fish swims by you 2.5 m in front of your mask. (*a*) How far in front of the mask does the fish appear to be? (*b*) What is the lateral magnification of the image of the fish?

95 •• A 35-mm digital camera has a rectangular array of CCDs (light sensors) that is 24 mm by 36 mm. It is used to take a picture of a person 175 cm tall so that the image just fills the height (24 mm) of the CCD array. How far should the person stand from the camera if the focal length of the lens is 50 mm? SSM

96 •• A 35-mm camera that has interchangeable lenses is used to take a picture of a hawk that has a wingspan of 2.0 m. The hawk is 30 m away. What would be the ideal focal length of the lens used so that the image of the wings just fills the width of the light-sensitive area of the camera, which is 36 mm?

97 •• An object is placed 12.0 cm in front of a lens that has a focal length equal to 10.0 cm. A second lens that has a focal length equal to 12.5 cm is placed 20.0 cm in back of the first lens. (*a*) Find the position of the final image. (*b*) What is the magnification of the image? (*c*) Sketch a ray diagram showing the final image.

98 •• (*a*) Show that if f_a is the focal length of a thin lens in air, its focal length in water is given by $f_w = -(n_w/n_a)(n - n_a)/(n - n_w)f_a$, where n_w is the index of refraction of water, n is that of the lens material and n_a is that of air. (*b*) Calculate the focal length in air and in water of a double concave lens that has an index of refraction of 1.50 and radii of magnitudes 30 cm and 35 cm.

99 •• While parked in your car, you see a jogger in your rear view mirror, which is convex and has a radius of curvature whose magnitude is equal to 2.00 m. The jogger is 5.00 m from the mirror and is approaching at 3.50 m/s. How fast is the image of the jogger moving relative to the mirror?

100 •• A 2.00-cm-thick layer of water ($n = 1.33$) floats on top of a 4.00-cm-thick layer of carbon tetrachloride ($n = 1.46$) in a tank. How far below the top surface of the water does the bottom of the tank appear, according to an observer looking down from above at normal incidence?

101 ••• An object is 15.0 cm in front of a thin converging lens that has a focal length equal to 10.0 cm. A concave mirror that has a radius equal to 10.0 cm is 25.0 cm in back of the lens. (*a*) Find the position of the final image formed by the mirror–lens combination. (*b*) Is the image real or virtual? Is the image upright or inverted? (*c*) On a diagram, show where your eye must be to see this image. SSM

102 ••• When a bright light source is placed 30 cm in front of a lens, there is an upright image 7.5 cm from the lens. There is also a faint inverted image 6.0 cm from the lens on the incident-light side due to reflection from the front surface of the lens. When the lens is turned around, this weaker, inverted image is 10 cm in front of the lens. Find the index of refraction of the lens.

103 ••• A concave mirror that has a radius of curvature equal to 50.0 cm is oriented with its axis vertical. The mirror is filled with water that has an index of refraction equal to 1.33 and a maximum depth of 1.00 cm. At what height above the vertex of the mirror must an object be placed so that its image is at the same position as the object?

104 ••• The concave side of a lens has a radius of curvature that has a magnitude equal to 17.0 cm, and the convex side of the lens has a radius of curvature that has a magnitude equal to 8.00 cm. The focal length of the lens in air is 27.5 cm. When the lens is placed in a liquid that has an unknown index of refraction, the focal length increases to 109 cm. What is the index of refraction of the liquid?

105 ••• A solid glass ball of radius 10.0 cm has an index of refraction equal to 1.500. The right half of the ball is silvered so that it acts as a concave mirror (Figure 32-63). Find the position of the final image formed for an object located at (*a*) 40.0 cm and (*b*) 30.0 cm to the left of the center of the ball.

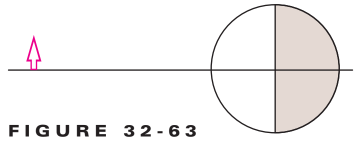

FIGURE 32-63 Problem 105

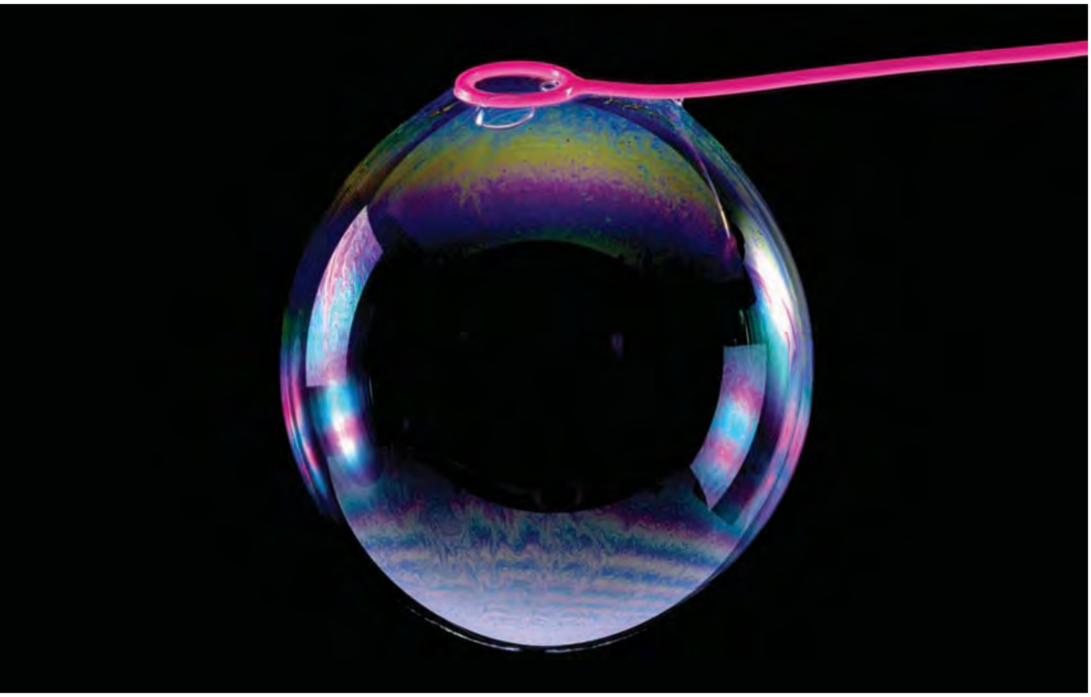
106 ••• (*a*) Show that a small change dn in the index of refraction of a lens material produces a small change in the focal length df given approximately by $df/f = -dn/(n - n_{air})$. (*b*) Use this result to estimate the focal length of a thin lens for blue light, for which $n = 1.530$, if the focal length for red light, for which $n = 1.470$, is 20.0 cm.

107 ••• The lateral magnification of a spherical mirror or a thin lens is given by $m = -s'/s$. Show that for objects of small horizontal extent, the longitudinal magnification is approximately $-m^2$. *Hint: Show that* $ds'/ds = -s'^2/s^2$. SSM



CHAPTER 33

WHITE LIGHT IS REFLECTED OFF A SOAP BUBBLE. WHEN LIGHT OF ONE WAVELENGTH IS INCIDENT ON A THIN SOAP-AND-WATER FILM, LIGHT IS REFLECTED FROM BOTH THE FRONT AND THE BACK SURFACES OF THE FILM. IF THE ORDER OF MAGNITUDE OF THE THICKNESS OF THE FILM IS ONE WAVELENGTH OF THE LIGHT, THE TWO REFLECTED LIGHT WAVES INTERFERE. IF THE TWO REFLECTED WAVES ARE 180° OUT OF PHASE, THE REFLECTED WAVES INTERFERE DESTRUCTIVELY, SO THE NET RESULT IS THAT NO LIGHT IS REFLECTED. IF WHITE LIGHT, WHICH CONTAINS A CONTINUUM OF WAVELENGTHS, IS INCIDENT ON THE THIN FILM, THEN THE REFLECTED WAVES WILL INTERFERE DESTRUCTIVELY ONLY FOR CERTAIN WAVELENGTHS, AND FOR OTHER WAVELENGTHS THEY WILL INTERFERE CONSTRUCTIVELY. THIS PROCESS PRODUCES THE COLORED FRINGES THAT YOU SEE IN THE SOAP BUBBLE. *(Aaron Haupt/Photo Researchers.)*

Interference and Diffraction

? Have you ever wondered if the phenomenon that produces the bands that you see in the light reflected off a soap bubble has any practical applications? (See Example 33-2.)

Interference and diffraction are the important phenomena that distinguish waves from particles.* Interference is the formation of a lasting intensity pattern by two or more waves that superpose in space. Diffraction is the bending of waves around corners that occurs when a portion of a wavefront is cut off by a barrier or obstacle.

In this chapter, we will see how the pattern of the resulting wave can be calculated by treating each point on the original wavefront as a point source, according to Huygens's principle, and calculating the interference pattern resulting from these sources.

* Before you study this chapter, you may wish to review Chapter 15 and Chapter 16, where the general topics of interference and diffraction of waves are first discussed.

33-1 PHASE DIFFERENCE AND COHERENCE

When two harmonic sinusoidal waves of the same frequency and wavelength but of different phase combine, the resultant wave is a harmonic wave whose amplitude depends on the phase difference. If the phase difference is zero, or an integer multiplied by 360°, the waves are in phase and interfere constructively. The resultant amplitude equals the sum of the two individual amplitudes, and the intensity (which is proportional to the square of the amplitude) is maximum. (If the amplitudes are equal and the waves are in phase, the intensity is four times that of either individual wave.) If the phase difference is 180° or any odd integer multiplied by 180°, the waves are out of phase and interfere destructively. The resultant amplitude is then the difference between the two individual amplitudes, and the intensity is a minimum. (If the amplitudes are equal and the waves are 180° out of phase, the intensity is zero.)

A phase difference between two waves is often the result of a difference in path lengths. When a light wave reflects from a thin transparent film, such as a soap bubble, the reflected light is a superposition of the light reflected from the front surface of the film and the light reflected from the back surface of the film. The additional distance traveled by the light reflected from the back surface is called the path-length difference between the two reflected waves. A path-length difference of one wavelength produces a phase difference of 360°, which is equivalent to no phase difference at all. A path-length difference of one-half wavelength produces a 180° phase difference. In general, a path-length difference of Δr contributes a phase difference δ given by

$$\delta = \frac{\Delta r}{\lambda}2\pi = \frac{\Delta r}{\lambda}360° \qquad 33\text{-}1$$

PHASE DIFFERENCE DUE TO A PATH-LENGTH DIFFERENCE

Example 33-1 Phase Difference

(*a*) What is the minimum path-length difference that will produce a phase difference of 180° for light of wavelength 800 nm? (*b*) What phase difference will that path-length difference produce in light of wavelength 700 nm?

PICTURE The phase difference is to 360° as the path-length difference is to the wavelength.

SOLVE

(*a*) The phase difference δ is to 360° as the path-length difference Δr is to the wavelength λ. We know that $\lambda = 800$ nm and $\delta = 180°$:

$$\frac{\delta}{360°} = \frac{\Delta r}{\lambda}$$

$$\Delta r = \frac{\delta}{360°}\lambda = \frac{180°}{360°}(800\text{ nm}) = \boxed{400\text{ nm}}$$

(*b*) Set $\lambda = 700$ nm, $\Delta r = 400$ nm, and solve for δ:

$$\delta = \frac{\Delta r}{\lambda}360° = \frac{400\text{ nm}}{700\text{ nm}}360° = \boxed{206° = 3.59\text{ rad}}$$

CHECK The Part (*b*) result is somewhat larger than 180°. This result is expected because 400 nm is longer than half of the 700-nm wavelength.

Another cause of phase difference is the 180° phase change a wave sometimes undergoes upon reflection from a surface. This phase change is analogous to the inversion of a pulse on a string when it reflects from a point where the density suddenly increases, such as when a light string is attached to a heavier string or rope. The inversion of the reflected pulse is equivalent to a phase change of 180° for a sinusoidal wave (which can be thought of as a series of pulses). When light traveling in air strikes the surface of a medium in which light travels more slowly, such as glass or water, there is a 180° phase change in the reflected light.

When light is traveling in the liquid wall of a soap bubble, there is no phase change in the light reflected from the surface between the liquid and the air. This situation is analogous to the reflection without inversion of a pulse on a heavy string at a point where the heavy string is attached to a lighter string.

> If light traveling in one medium strikes the surface of a medium in which light travels more slowly, there is a 180° phase change in the reflected light.
>
> PHASE DIFFERENCE DUE TO REFLECTION

As we saw in Chapter 16, interference of waves is observed when two or more coherent waves overlap. Interference of overlapping waves from two sources is not observed unless the sources are coherent. Because the light from each source is usually the result of millions of atoms radiating independently, the phase difference between the waves from such sources fluctuates randomly many times per second, so two light sources are usually not coherent. Coherence in optics is often achieved by splitting the light beam from a single source into two or more beams that can then be combined to produce an interference pattern. The light beam can be split by reflecting the light from the two surfaces of a thin film (Section 33-2), by diffracting the beam through two small openings or slits in an opaque barrier (Section 33-3), or by using a single point source and its image in a plane mirror for the two sources (Section 33-3). Today, lasers are the most important sources of coherent light in the laboratory.

Light from an ideal monochromatic source is a sinusoidal wave of infinite duration, and light from certain lasers approaches this ideal. However, light from conventional *monochromatic* sources, such as gas discharge tubes designed for this purpose, consists of packets of sinusoidal light that are only a few million wavelengths long. The light from such a source consists of many such packets, each approximately the same length. The packets have essentially the same wavelength, but the packets differ in phase in a random manner. The length of the individual packets is called the **coherence length** of the light, and the time it takes one of the packets to pass a point in space is the **coherence time.** The light emitted by a gas discharge tube designed to produce monochromatic light has a coherence length of only a few millimeters. By comparison, some highly stable lasers produce light that has a coherence length many kilometers long.

33-2 INTERFERENCE IN THIN FILMS

You have probably noticed the colored bands in a soap bubble or in the film on the surface of oily water. These bands are due to the interference of light reflected from the top and bottom surfaces of the film. The different colors arise because of variations in the thickness of the film, causing interference for different wavelengths at different points.

When waves traveling in a medium cross a surface where the wave speed changes, part of the wave is reflected and part is transmitted. In addition, the reflected wave undergoes a 180° phase shift upon reflection if the transmitted wave travels at a slower speed than do the incident and reflected waves. (This 180° phase shift is established for waves on a string in Section 15-4 of Chapter 15.) The reflected wave does not undergo a phase shift upon reflection if the transmitted wave travels at a faster speed than do the incident and reflected waves.

Consider a thin film of water (such as a small section of a soap bubble) of uniform thickness viewed at small angles with the normal, as shown in Figure 33-1. Part of the light is reflected from the upper air–water interface where it undergoes a 180° phase change. Most of the light enters the film and part of it is reflected by the bottom water–air interface. There is no phase change in this reflected light. If the light is nearly perpendicular to the surfaces, both the light reflected from the top surface and the light reflected from the bottom surface can enter the eye. The path-length

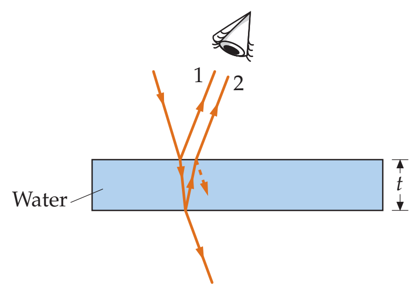


FIGURE 33-1 Light rays reflected from the top and bottom surfaces of a thin film are coherent because both rays come from the same source. If the light is incident almost normally, the two reflected rays will be very close to each other and will produce interference.

difference between these two rays is $2t$, where t is the thickness of the film. This path-length difference produces a phase difference of $(2t/\lambda')360°$, where $\lambda' = \lambda/n$ is the wavelength of the light in the film, n is the index of refraction of the film, and λ is the wavelength of the light in vacuum. The total phase difference between the two rays is thus 180° plus the phase difference due to the path-length difference. Destructive interference occurs when the path-length difference $2t$ is zero or a whole number of wavelengths λ' (in the film). Constructive interference occurs when the path-length difference is an odd number of half-wavelengths.

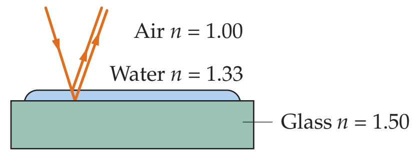

FIGURE 33-2 The interference of light reflected from a thin film of water resting on a glass surface. In this case, both rays undergo a change in phase of 180° upon reflection.

When a thin film of water lies on a glass surface, as in Figure 33-2, the ray that reflects from the lower water–glass interface also undergoes a 180° phase change, because the index of refraction of glass (approximately 1.50) is greater than that of water (approximately 1.33). Thus, both the rays shown in the figure have undergone a 180° phase change upon reflection. The phase difference δ between these rays is due solely to the path-length difference and is given by $\delta = (2t/\lambda')360°$.

When a thin film of varying thickness is viewed with monochromatic light, such as the yellow light from a sodium lamp, alternating bright and dark bands or lines, called **interference fringes,** are observed. The distance between a bright fringe and a dark fringe is that distance over which the film's thickness t changes so that the path-length difference $2t$ changes by $\lambda'/2$. Figure 33-3*a* shows the interference pattern observed when light is reflected from an air film between a spherical glass surface and a plane glass surface in contact. These circular interference fringes are known as **Newton's rings.** Typical rays reflected at the top and bottom of the air film are shown in Figure 33-3*b*. Near the point of contact of the surfaces, where the path-length difference between the ray reflected from the upper glass–air interface and the ray reflected from the lower air–glass interface is approximately zero (it is small compared with the wavelength of light) the interference is destructive because of the 180° phase shift of the ray reflected from the lower air–glass interface. This central region in Figure 33-3*a* is therefore dark. The first bright fringe occurs at the radius at which the path-length difference is $\lambda/2$, which contributes a phase difference of 180°. This adds to the phase shift due to reflection to produce a total phase difference of 360°, which is equivalent to a zero phase difference. The second dark region occurs at the radius at which the path-length difference is λ, and so on.

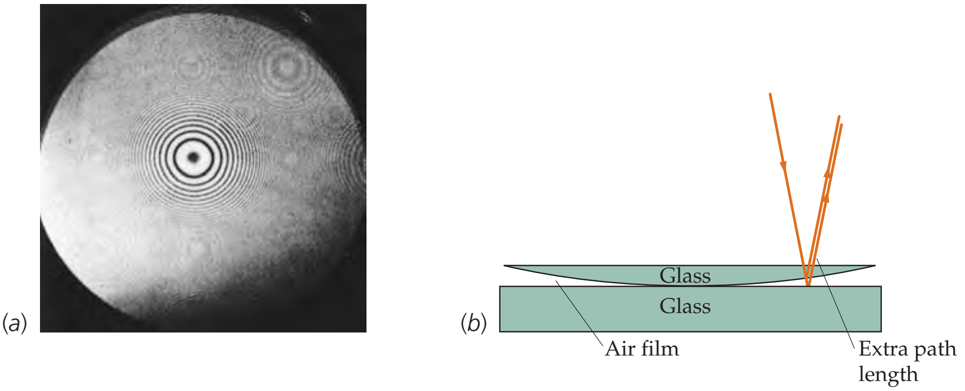

FIGURE 33-3 (*a*) Newton's rings observed when light is reflected from a thin film of air between a plane glass surface and a spherical glass surface. At the center, the thickness of the air film is negligible and the interference is destructive because of the 180° phase change of one of the rays upon reflection. (*b*) Glass surfaces for the observation of Newton's rings shown in Figure 33-3*a*. The thin film in this case is the film of air between the glass surfaces. *(Courtesy of Bausch & Lomb.)*

Example 33-2 A Wedge of Air

A wedge-shaped film of air is made by placing a small slip of paper between the edges of two flat pieces of glass, as shown in Figure 33-4. Light of wavelength 500 nm is incident normally on the glass, and interference fringes are observed by reflection. If the angle θ made by the plates is 3.0×10^{-4} rad (0.017°), how many dark interference fringes per centimeter are observed?

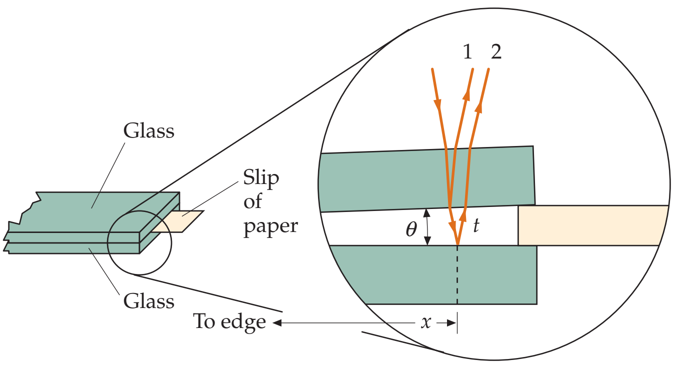

FIGURE 33-4 The angle θ, which is less than 0.02°, is exaggerated. The incoming and outgoing rays are virtually perpendicular to all air–glass interfaces.

PICTURE We find the number of fringes per centimeter by finding the horizontal distance x to the mth fringe and solving for m/x. Because the ray reflected from the bottom plate undergoes a 180° phase shift, the point of contact (where the path-length difference is zero) will be dark. The mth dark fringe after the contact point occurs when $2t = m\lambda'$, where $\lambda' = \lambda$ is the wavelength in the air film, and t is the plate separation at x, as shown in Figure 33-4. Because the angle θ is small, we can use the small-angle approximation $\theta \approx \tan\theta = t/x$.

SOLVE

1. The mth dark fringe from the contact point occurs when the path-length difference $2t$ equals m wavelengths:
$$2t = m\lambda' = m\lambda$$
$$m = \frac{2t}{\lambda}$$
2. The thickness t is related to the angle θ:
$$\theta = \frac{t}{x}$$
3. Substitute $t = x\theta$ into the equation for m:
$$m = \frac{2x\theta}{\lambda}$$
4. Calculate m/x:
$$\frac{m}{x} = \frac{2\theta}{\lambda} = \frac{2(3.0 \times 10^{-4})}{5.0 \times 10^{-7}\text{ m}} = 1200\text{ m}^{-1} = \boxed{12\text{ cm}^{-1}}$$

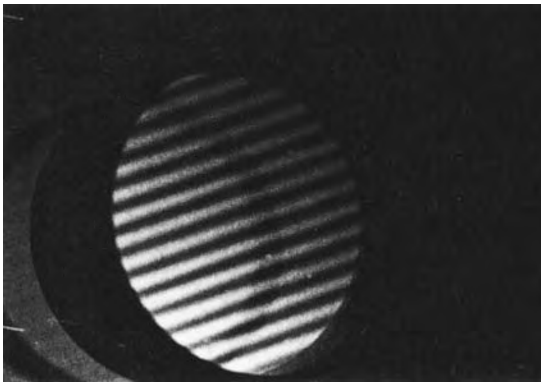
CHECK The expression for the number of dark fringes per unit length in step 4 shows that the number per centimeter would decrease if light of a longer wavelength is used. This result is as expected.

TAKING IT FURTHER We observe 12 dark fringes per centimeter. In practice, the number of fringes per centimeter, which is easy to count, can be used to determine the angle. Note that if the angle of the wedge is increased, the fringes become more closely spaced.

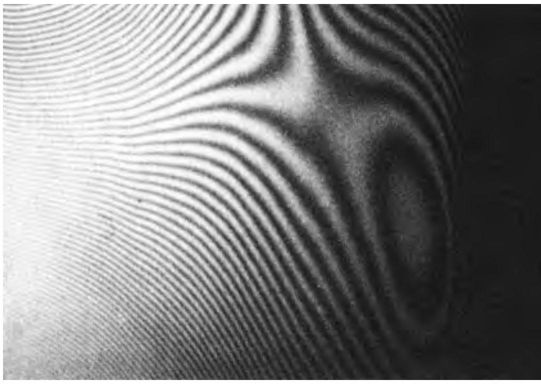
PRACTICE PROBLEM 33-1 How many dark fringes per centimeter are observed if light of wavelength 650 nm is used?

Figure 33-5*a* shows interference fringes produced by a wedge-shaped air film between two flat glass plates, as in Example 33-2. Plates that produce straight fringes, such as those in Figure 33-5*a*, are said to be **optically flat.** To be optically flat, a surface must be flat to within a small fraction of a wavelength. A similar wedge-shaped air film formed by two ordinary glass plates yields the irregular fringe pattern in Figure 33-5*b*, which indicates that these plates are not optically flat.

One application of interference effects in thin films is in nonreflecting lenses, which are made by coating the surface of a lens with a thin film of a material that has an index of refraction equal to approximately 1.38, which is between the index of refraction of glass and that of air. The intensities of the light reflected from the top and bottom surfaces of the film are approximately equal, and because the reflected rays undergo a 180° phase change at both surfaces there is no phase difference due to reflection between the two rays. The thickness of the film is chosen to be $\frac{1}{4}\lambda' = \frac{1}{4}\lambda n$, where λ is the wavelength, in vacuum, that is in the middle of the visible spectrum, so that there is a phase change of 180° due to the path-length difference of $\lambda'/2$ for light of normal incidence. Reflection from the coated surface is thus minimized, which means that transmission through the surface is maximized.



(*a*)



(*b*)

FIGURE 33-5 (*a*) Straight-line fringes from a wedge-shaped film of air, like that shown in Figure 33-4. The straightness of the fringes indicates that the glass plates are optically flat. (*b*) Fringes from a wedge-shaped film of air between glass plates that are not optically flat. *(Courtesy T. A. Wiggins.)*

33-3 TWO-SLIT INTERFERENCE PATTERN

Interference patterns of light from two or more sources can be observed only if the sources are coherent. The interference in thin films discussed previously can be observed because the two beams come from the same light source but are separated by reflection. In Thomas Young's famous 1801 experiment, in which he demonstrated the wave nature of light, two coherent light sources are produced by illuminating two very narrow parallel slits using a single light source. We saw in Chapter 15 that when a wave encounters a barrier that has a very small opening, the opening acts as a point source of waves (Figure 33-6).

During Young's experiment, diffraction causes each slit to act as a line source (which is equivalent to a point source in two dimensions). The interference pattern is observed on a screen far from the slits (Figure 33-7*a*). At very large distances from the slits, the lines from the two slits to some point P on the screen are approximately parallel, and the path-length difference is approximately $d\sin\theta$, where d is the separation of the slits, as shown in Figure 33-7*b*. When the path-length difference is equal to an integral number of wavelengths, the interference is constructive. We thus have interference maxima at an angle θ_m given by

$$d\sin\theta_m = m\lambda \qquad m = 0, 1, 2, \ldots \tag{33-2}$$

TWO-SLIT INTERFERENCE MAXIMA

where m is called the **order number.** The interference minima occur at

$$d\sin\theta_m = \left(m - \tfrac{1}{2}\right)\lambda \qquad m = 1, 2, 3, \ldots \tag{33-3}$$

TWO-SLIT INTERFERENCE MINIMA

The phase difference δ at a point P is related to the path-length difference $d\sin\theta$ by

$$\delta = \frac{\Delta r}{\lambda}2\pi = \frac{d\sin\theta}{\lambda}2\pi \tag{33-4}$$

We can relate the distance y_m measured along the screen from the central point to the mth bright fringe (see Figure 33-7*b*) to the distance L from the slits to the screen:

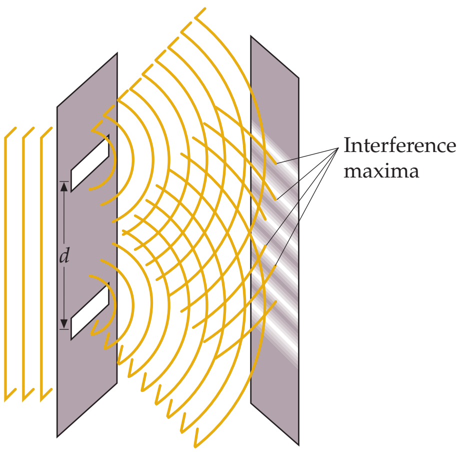
$$\tan\theta_m = \frac{y_m}{L}$$

For small angles, $\tan\theta \approx \sin\theta$. Substituting y_m/L for $\sin\theta_m$ in Equation 33-2 and solving for y_m gives

$$y_m = m\frac{\lambda L}{d} \tag{33-5}$$

From this result, we see that for small angles the fringes are equally spaced on the screen.

FIGURE 33-6 Plane water waves in a ripple tank encountering a barrier that has a small opening. The waves to the right of the barrier are circular waves that are concentric about the opening, just as if there were a point source at the opening. *(From PSSC Physics, 2nd Edition, 1965. D. C. Heath & Co. and Education Development Center, Newton MA.)*



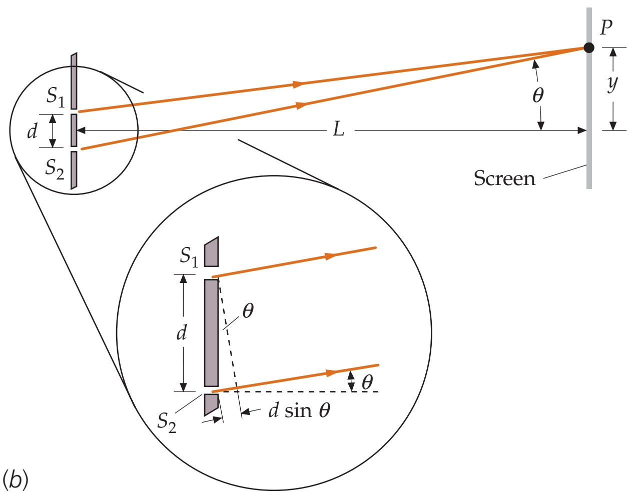


FIGURE 33-7 (*a*) Two slits act as coherent sources of light for the observation of interference in Young's experiment. Cylindrical waves from the slits overlap and produce an interference pattern on a screen. (*b*) Geometry for relating the distance y measured along the screen to L and θ. When the screen is very far away compared with the slit separation, the rays from the slits to a point on the screen are approximately parallel, and the path-length difference between the two rays is $d\sin\theta$.

Example 33-3 Fringe Spacing from Slit Spacing *Try It Yourself*

Two narrow slits separated by 1.50 mm are illuminated by yellow light from a sodium lamp that has a wavelength equal to 589 nm. Find the spacing of the bright fringes observed on a screen 3.00 m away.

PICTURE The distance y_m measured along the screen to the mth bright fringe is given by Equation 33-5, where $L = 3.00$ m, $d = 1.50$ mm, and $\lambda = 589$ nm.

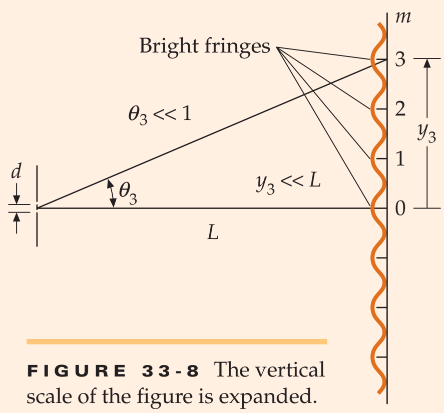

FIGURE 33-8 The vertical scale of the figure is expanded.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. Make a sketch of the situation (Figure 33-8).	
2. The fringe spacing is the distance between the mth bright fringe and the $(m + 1)$th bright fringe. Using the sketch, obtain an expression for the spacing between fringes.	fringe spacing $= y_{m+1} - y_m$
3. Apply Equation 33-5 to the mth and $(m + 1)$th fringe.	$y_m = m\dfrac{\lambda L}{d}$ and $y_{m+1} = (m+1)\dfrac{\lambda L}{d}$
4. Substitute into the step-2 result and simplify.	$y_{m+1} - y_m = \dfrac{\lambda L}{d}$
5. Substitute into the step-4 result and solve for the fringe spacing.	fringe spacing $= \boxed{1.18 \text{ mm}}$

TAKING IT FURTHER The fringes are uniformly spaced only to the degree that the small-angle approximation is valid, that is, to the degree that $\lambda/d \ll 1$. In this example, $\lambda/d = (589 \text{ nm})/(1.50 \text{ mm}) \approx 0.0004$.

See **Math Tutorial** *for more information on* **Trigonometry**

Example 33-4 How Many Fringes? *Conceptual Example*

Two narrow slits are illuminated by monochromatic light. If the distance between the slits is equal to 2.75 wavelengths, what is the maximum number of bright fringes that can be seen on a screen? (*a*) 1, (*b*) 2, (*c*) 3, (*d*) 4, (*e*) 5, (*f*) 6 or more

PICTURE A bright fringe (constructive interference) exists at points on the screen for which the distance to the two slits differs by an integer multiplied by the wavelength. However, the maximum difference in distance possible is equal to the distance between the two slits.

SOLVE

1. Find the maximum difference in distance from points on the screen to the two slits:	At all points on the screen, the difference in distance from the two slits is 2.75 wavelengths or less.
2. A bright fringe (constructive interference) exists at points on the screen for which the distance to the two slits differs by an integer multiplied by the wavelength:	Bright fringes exist on the screen at places where the difference in distance to the slits is 2 wavelengths, 1 wavelength, or zero wavelengths.
3. Count up the bright fringes. There is the central maximum and two on either side of the central maximum:	$\boxed{(e)\ 5}$

CONCEPT CHECK 33-1

What is the maximum number of dark fringes that can be seen on a screen?

CALCULATION OF INTENSITY

To calculate the intensity of the light on the screen at a general point P, we need to add two harmonic wave functions that differ in phase.* The wave functions for electromagnetic waves are the electric field vectors. Let E_1 be the electric field at some point P on the screen due to the waves from slit 1, and let E_2 be the electric field at that point due to waves from slit 2. Because the angles of interest are small, we can treat the fields as though they are parallel. Both electric fields oscillate with the same frequency (they result from a single source that illuminates both slits) and they have the same amplitude. (The path-length difference is only of the order of a few wavelengths of light at most.) They have a phase difference δ given by Equation 33-4. If we represent the wave functions by

$$E_1 = A_0 \sin \omega t$$

and

$$E_2 = A_0 \sin(\omega t + \delta)$$

the resultant wave function is

$$E = E_1 + E_2 = A_0 \sin \omega t + A_0 \sin(\omega t + \delta) \qquad \text{33-6}$$

By making use of the identity

$$\sin \alpha + \sin \beta = 2 \cos \tfrac{1}{2}(\alpha - \beta) \sin \tfrac{1}{2}(\alpha + \beta)$$

the resultant wave function is given by

$$E = \left[2A_0 \cos \tfrac{1}{2}\delta\right] \sin\left(\omega t + \tfrac{1}{2}\delta\right) \qquad \text{33-7}$$

The amplitude of the resultant wave is thus $2A_0 \cos \frac{1}{2}\delta$. It has its maximum value of $2A_0$ when the waves are in phase and is zero when they are 180° out of phase. Because the intensity is proportional to the square of the amplitude, the intensity at any point P is

$$I = 4I_0 \cos^2 \tfrac{1}{2}\delta \qquad \text{33-8}$$

INTENSITY IN TERMS OF PHASE DIFFERENCE

where I_0 is the intensity of the light reaching the screen from either slit separately. The phase angle δ is related to the position on the screen by $\delta = (d \sin\theta/\lambda)2\pi$ (Equation 33-4).

Figure 33-9*a* shows the intensity pattern as seen on a screen. A graph of the intensity as a function of $\sin\theta$ is shown in Figure 33-9*b*. For small θ, this graph is equivalent to a plot of intensity versus y (because $y = L \tan\theta \approx L \sin\theta$). The intensity I_0 is the intensity from each slit separately. The dashed line in Figure 33-9*b* shows the average intensity $2I_0$, which is the result of averaging over a distance containing many interference maxima and minima. This is the intensity that would arise from the two sources if they acted independently without interference, that is, if they were not coherent. Then, the phase difference between the two sources would fluctuate randomly, so that only the average intensity would be observed.

Figure 33-10 shows another method of producing the two-slit interference pattern, an arrangement known as **Lloyd's mirror.** A monochromatic horizontal line source is placed at a distance $\frac{1}{2}d$ above the plane of a mirror. Light striking the screen directly from the source interferes with the light that is reflected from the mirror. The reflected light can be considered to come from the virtual image of the line source formed by the mirror. Because of the 180° change in phase upon reflection at the mirror, the interference pattern is that of two coherent line sources that differ in phase by 180°. The pattern is the same as that shown in Figure 33-9 for two slits, except that the maxima and minima are interchanged. Constructive interference occurs at points for which the path-length difference is a half-wavelength or any odd number of half-wavelengths. At those points, the 180° phase difference due to the path-length difference combines with the 180° phase difference of the sources to produce constructive interference.

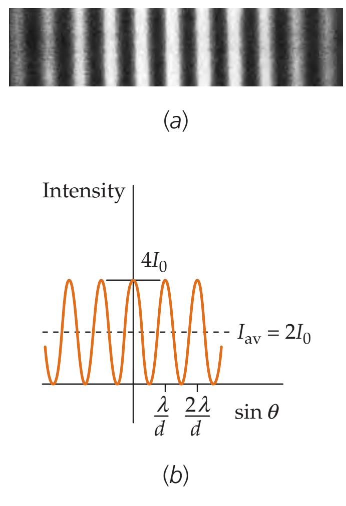

FIGURE 33-9 (*a*) The interference pattern observed on a screen far away from the two slits shown in Figure 33-7. (*b*) Plot of intensity versus $\sin\theta$. The maximum intensity is $4I_0$, where I_0 is the intensity due to each slit separately. The average intensity (dashed line) is $2I_0$. *(Courtesy of Michael Cagnet.)*

* We did this in Chapter 16 where we first discussed the superposition of two waves.

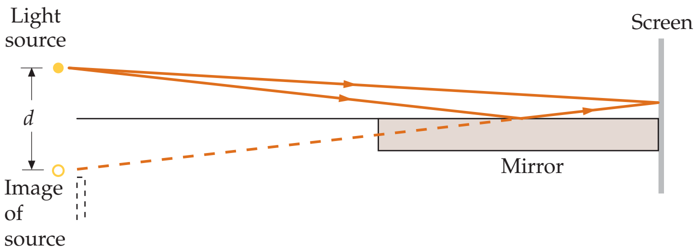

FIGURE 33-10 Lloyd's mirror for producing a two-slit interference pattern. The two sources (the source and its virtual image) are coherent and are 180° out of phase.

PRACTICE PROBLEM 33-2

A point source of light ($\lambda = 589$ nm) is placed 0.40 mm above the surface of a glass mirror. Interference fringes are observed on a screen 6.0 m away, and the interference is between the light reflected from the front surface of the glass and the light traveling from the source directly to the screen. Find the spacing of the fringes on the screen.

The physics of Lloyd's mirror was used in the early days of radio astronomy to determine the location of distant radio sources on the celestial sphere. A radio-wave receiver was placed on a cliff overlooking the sea, and the surface of the sea served as the mirror.

33-4 DIFFRACTION PATTERN OF A SINGLE SLIT

In our discussion of the interference patterns produced by two or more slits, we assumed that the slits were very narrow so that we could consider the slits to be line sources of cylindrical waves, which in our two-dimensional diagrams are point sources of circular waves. We could therefore assume that the value of the intensity due to one slit acting alone was the same (I_0) at any point P on the screen, independent of the angle θ made between the ray to point P and the normal line between the slit and the screen. When the slit is not narrow, the intensity on a screen far away is not independent of angle but decreases as the angle increases. Consider a slit of width a. Figure 33-11 shows the intensity pattern on a screen far away from the slit of width a as a function of $\sin\theta$. We can see that the intensity is maximum in the forward direction ($\sin\theta = 0$) and decreases to zero at an angle that depends on the slit width a and the wavelength λ.

Most of the light intensity is concentrated in the broad **central diffraction maximum,** although there are minor secondary maxima bands on either side of the central maximum. The first zeroes in the intensity occur at angles specified by

$$\sin\theta_1 = \lambda/a \qquad 33\text{-}9$$

Note that for a given wavelength λ, Equation 33-9 describes how variations in the slit width result in variations in the angular width of the central maximum. If we *increase* the slit width a, the angle θ_1 at which the intensity first becomes zero *decreases*, giving a more narrow central diffraction maximum. Conversely, if we *decrease* the slit width, the angle of the first zero *increases*, giving a wider central diffraction maximum. When a is smaller than λ, then $\sin\theta_1$ would have to exceed 1

(a)

(b)

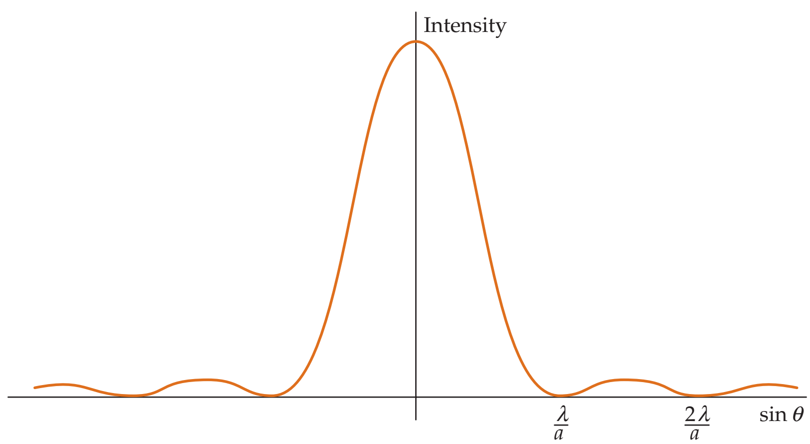

FIGURE 33-11 *(a)* Diffraction pattern of a single slit as observed on a screen far away. *(b)* Plot of intensity versus $\sin\theta$ for the pattern in Figure 33-11*a*. *(Courtesy of Michael Cagnet.)*

to satisfy Equation 33-9. Thus, for a less than λ, there are no points of zero intensity in the pattern, and the slit acts as a line source (a point source in two dimensions) radiating light energy essentially equal in all directions.

Multiplying both sides of Equation 33-9 by $a/2$ gives

$$\tfrac{1}{2}a \sin\theta_1 = \tfrac{1}{2}\lambda \qquad 33\text{-}10$$

The quantity $\frac{1}{2}a \sin\theta_1$ is the path-length difference between a light ray leaving the middle of the upper half of the slit and one leaving the middle of the lower half of the slit. We see that the first diffraction *minimum* occurs when these two rays are 180° out of phase, that is, when their path-length difference equals a half-wavelength. We can understand this result by considering each point on a wavefront to be a point source of light in accordance with Huygens's principle. In Figure 33-12, we have placed a line of dots on the wavefront at the slit to represent these point sources schematically. Suppose, for example, that we have 100 such dots and that we look at an angle θ_1 for which $a \sin\theta_1 = \lambda$. Let us consider the slit to be divided into two halves, with sources 1 through 50 in the upper half and sources 51 through 100 in the lower half. When the path-length difference between the middle of the upper half and the middle of the lower half of the slit equals a half-wavelength, the path-length difference between source 1 (the first source in the upper half) and source 51 (the first source in the lower half) is also $\frac{1}{2}\lambda$. The waves from those two sources will be out of phase by 180° and will thus cancel. Similarly, waves from the second source in each region (source 2 and source 52) will cancel. Continuing this argument, we can see that the waves from each pair of sources separated by $a/2$ will cancel. Thus, there will be no light energy at that angle. We can extend this argument to the second and third minima in the diffraction pattern of Figure 33-11. At an angle θ_2 where $a \sin\theta_2 = 2\lambda$, we can divide the slit into four regions, two regions for the top half and two regions for the bottom half. Using this same argument, the light intensity from the top half is zero because of the cancellation of pairs of sources; similarly, the light intensity from the bottom half is zero. The general expression for the points of zero intensity in the diffraction pattern of a single slit is thus

$$a \sin\theta_m = m\lambda \qquad m = 1, 2, 3, \ldots \qquad 33\text{-}11$$

POINTS OF ZERO INTENSITY FOR A SINGLE-SLIT DIFFRACTION PATTERN

Usually, we are just interested in the first occurrence of a minimum in the light intensity because nearly all of the light energy is contained in the central diffraction maximum.

In Figure 33-13, the distance y_1 from the central maximum to the first diffraction minimum is related to the angle θ_1 and the distance L from the slit to the screen by

$$\tan\theta_1 = \frac{y_1}{L}$$

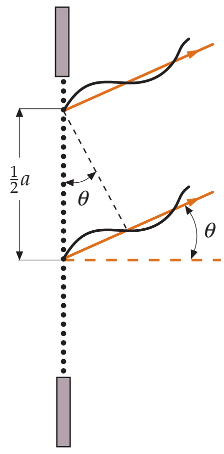

FIGURE 33-12 A single slit is represented by a large number of point sources of equal amplitude. At the first diffraction minimum of a single slit, the waves from each point source in the upper half of the slit are 180° out of phase with the wave from the point source a distance $a/2$ lower in the slit. Thus, the interference from each such pair of point sources is destructive.

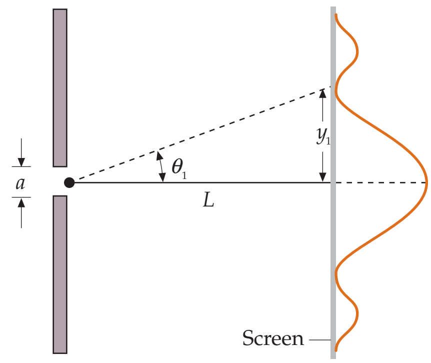

FIGURE 33-13 The distance y_1 measured along the screen from the central maximum to the first diffraction minimum is related to the angle θ_1 by $\tan\theta_1 = y_1/L$, where L is the distance to the screen.

Example 33-5 Width of the Central Diffraction Maximum

During a lecture demonstration of single-slit diffraction, a laser beam that has a wavelength equal to 700 nm passes through a vertical slit 0.20 mm wide and hits a screen 6.0 m away. Find the width of the central diffraction maximum on the screen; that is, find the distance between the first minimum on the left and the first minimum on the right of the central maximum.

PICTURE Referring to Figure 33-13, the width of the central diffraction maximum is $2y_1$.

SOLVE

1. The half-width of the central maximum y_1 is related to the angle θ_1 by: $\qquad \tan\theta_1 = \dfrac{y_1}{L}$

2. The angle θ_1 is related to the slit width a by Equation 33-11: $\sin\theta_1 = \lambda/a$

3. Solve the step-2 result for θ_1, substitute into the step-1 result, and solve for $2y_1$:

$$2y_1 = 2L\tan\theta_1 = 2L\tan\left(\sin^{-1}\frac{\lambda}{a}\right)$$
$$= 2(6.0\text{ m})\tan\left(\sin^{-1}\frac{700\times10^{-9}\text{ m}}{0.00020\text{ m}}\right)$$
$$= 4.2\times10^{-2}\text{ m} = \boxed{4.2\text{ cm}}$$

CHECK Because $\sin\theta_1 = \lambda/a = (700\text{ nm})/(0.20\text{ mm}) = 0.0035$, we can use the small-angle approximation to evaluate $2y_1$. In this approximation, $\sin\theta_1 = \tan\theta_1$, so $\lambda/a = y_1/L$ and $2y_1 = 2L\lambda/a = 2(6.0\text{ m})(700\text{ nm})/(0.20\text{ mm}) = 4.2$ cm. (This approximate value is in agreement with the exact value to within 0.0006 percent.)

INTERFERENCE–DIFFRACTION PATTERN OF TWO SLITS

When there are two or more slits, the intensity pattern on a screen far away is a combination of the single-slit diffraction pattern of the individual slits and the multiple-slit interference pattern we have studied. Figure 33-14 shows the intensity pattern on a screen far from two slits whose separation d is $10a$, where a is the width of each slit. The pattern is the same as the two-slit pattern that has very narrow slits (Figure 33-11) except that it is modulated by the single-slit diffraction pattern; that is, the intensity due to each slit separately is now not constant but decreases with angle, as shown in Figure 33-14*b*.

Note that the central diffraction maximum in Figure 33-14 has 19 interference maxima—the central interference maximum and 9 maxima on either side. The tenth interference maximum on either side of the central one is at the angle θ_{10}, given by $\sin\theta_{10} = 10\lambda/d = \lambda/a$, because $d = 10a$. This coincides with the position of the first diffraction minimum, so this interference maximum is not seen. At these points, the light from the two slits would be in phase and would interfere constructively, but there is no light coming from either slit because the points are at diffraction minima of each slit. In general, we can see that if $m = d/a$, the mth interference maximum will fall at the first diffraction minimum. Because the mth fringe is not seen, there will be $m - 1$ fringes on each side of the central fringe for a total of N fringes in the central maximum, where N is given by

$$N = 2(m-1) + 1 = 2m - 1 \qquad 33\text{-}12$$

(a)

(b)

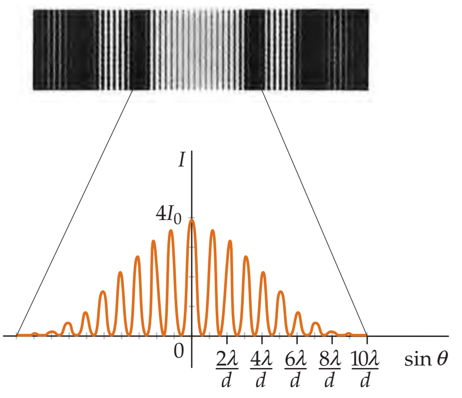

FIGURE 33-14 (*a*) Interference–diffraction pattern for two slits whose separation d is equal to 10 times their width a. The tenth interference maximum on either side of the central interference maximum is missing because it falls at the first diffraction minimum. (*b*) Plot of intensity versus $\sin\theta$ for the central band of the pattern in Figure 33-14*a*. *(Courtesy of Michael Cagnet.)*

Example 33-6 Interference and Diffraction

Two slits that each have a width $a = 0.015$ mm are separated by a distance $d = 0.060$ mm and are illuminated by light of wavelength $\lambda = 650$ nm. How many bright fringes are seen in the central diffraction maximum?

PICTURE We need to find the value of m for which the mth interference maximum coincides with the first diffraction minimum. Then there will be $N = 2m - 1$ fringes in the central maximum.

SOLVE

1. Relate the angle θ_1 of the first diffraction minimum to the slit width a: $\sin\theta_1 = \dfrac{\lambda}{a}$ (first diffraction minimum)

2. Relate the angle θ_m of the mth interference maxima to the slit separation d: $\sin\theta_m = \dfrac{m\lambda}{d}$ (mth interference maxima)

3. Set the angles equal and solve for m:

$$\frac{m\lambda}{d} = \frac{\lambda}{a}$$

$$m = \frac{d}{a} = \frac{0.060\text{ mm}}{0.015\text{ mm}} = 4.0$$

4. The first diffraction minimum coincides with the fourth bright fringe. Therefore, there are 3 bright fringes visible on either side of the central diffraction maximum. These 6 maxima, plus the central interference maximum, combine for a total of 7 bright fringes in the central diffraction maximum:

$$N = \boxed{7\text{ bright fringes}}$$

* 33-5 USING PHASORS TO ADD HARMONIC WAVES

To calculate the interference pattern produced by three, four, or more coherent light sources and to calculate the diffraction pattern of a single slit, we need to combine several harmonic waves of the same frequency that differ in phase. A simple geometric interpretation of harmonic wave functions leads to a method of adding harmonic waves of the same frequency by geometric construction.

Let the wave functions for two waves at some point be $E_1 = A_1 \sin\alpha$ and $E_2 = A_2 \sin(\alpha + \delta)$, where $\alpha = \omega t$. Our problem is then to find the sum:

$$E_1 + E_2 = A_1 \sin\alpha + A_2 \sin(\alpha + \delta)$$

We can represent each wave function by the y component of a two-dimensional vector, as shown in Figure 33-15. The geometric method of addition is based on the fact that the y component of the sum of two or more vectors equals the sum of the y components of the vectors, as illustrated in the figure. The wave function E_1 is represented by the y component of the vector $\vec{A}_1$. As the time continues on, this vector rotates in the xy plane with angular frequency ω. The vector $\vec{A}_1$ is called a **phasor.** (We encountered phasors in our study of ac circuits in Section 29-5.) The wave function E_2 is the y component of a phasor of magnitude A_2 that makes an angle $\alpha + \delta$ with the x axis. By the laws of vector addition, the sum of the y components of the individual phasors equals the y component of the resultant phasor $\vec{A}$, as shown in Figure 33-15. The y component of the resultant phasor, $A \sin(\alpha + \delta')$, is a harmonic wave function that is the sum of the two original wave functions. That is,

$$A_1 \sin\alpha + A_2 \sin(\alpha + \delta) = A \sin(\alpha + \delta') \qquad 33\text{-}13$$

where A (the amplitude of the resultant wave) and δ' (the phase of the resultant wave relative to the phase of the first wave) are found by adding the phasors representing the waves. As time varies, α varies. The phasors representing the two wave functions and the resultant phasor representing the resultant wave function rotate in space, but their relative positions do not change because they all rotate with the same angular velocity ω.

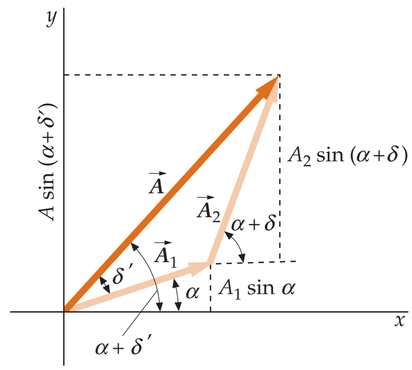

FIGURE 33-15 Phasor representation of wave functions.

Example 33-7 Wave Superposition Using Phasors — *Try It Yourself*

Use the phasor method of addition to derive $E = \left[2A_0 \cos\frac{1}{2}\delta\right] \sin\left(\omega t + \frac{1}{2}\delta\right)$ (Equation 33-7) for the superposition of two waves of the same amplitude.

PICTURE Represent the waves $y_1 = A_0 \sin\alpha$ and $y_2 = A_0 \sin(\alpha + \delta)$ by vectors (phasors) of length A_0 making an angle δ with one another. The resultant wave $y_r = A \sin(\alpha + \delta')$ is represented by the sum of these vectors, which form an isosceles triangle, as shown in Figure 33-16.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. Relate δ and δ' using the theorem: "An external angle to a triangle is equal to the sum of the two non-adjacent internal angles."	$\delta' + \delta' = \delta$
2. Solve for δ'.	$\delta' = \frac{1}{2}\delta$
3. Write $\cos\delta'$ in terms of A and A_0.	$\cos\delta' = \dfrac{\frac{1}{2}A}{A_0}$
4. Solve for A in terms of δ.	$A = 2A_0\cos\delta' = 2A_0\cos\frac{1}{2}\delta$
5. Use your results for A and δ' to write the resultant wave function.	$y_r = A\sin(\alpha + \delta')$ $= \boxed{[2A_0\cos\frac{1}{2}\delta]\sin\left(\alpha + \frac{1}{2}\delta\right)}$

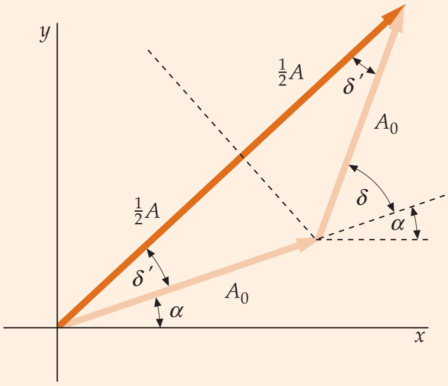

FIGURE 33-16

CHECK The step-5 result is identical to Equation 33-7 (see Problem statement).

PRACTICE PROBLEM 33-3 Find the amplitude and phase constant of the resultant wave function produced by the superposition of the two waves $E_1 = (4.0\ \text{V/m})\sin(\omega t)$ and $E_2 = (3.0\ \text{V/m})\sin(\omega t + 90°)$.

*THE INTERFERENCE PATTERN OF THREE OR MORE EQUALLY SPACED SOURCES

We can apply the phasor method of addition to calculate the interference pattern of three or more coherent sources that are equally spaced and in phase. We are most interested in the location of the interference maxima and minima. Figure 33-17 illustrates the case of three such sources. The geometry is the same as for two sources. At a great distance from the sources, the rays from the sources to a point P on the screen are approximately parallel. The path-length difference between the first and second source is then $d\sin\theta$, as before, and the path-length difference between the first and third source is $2d\sin\theta$. The wave at point P is the sum of the three waves. Let $\alpha = \omega t$ be the phase of the first wave at point P. We thus have the problem of adding three waves of the form

$$E_1 = A_0\sin\alpha$$

$$E_2 = A_0\sin(\alpha + \delta) \qquad 33\text{-}14$$

$$E_3 = A_0\sin(\alpha + 2\delta)$$

where

$$\delta = \frac{2\pi}{\lambda}d\sin\theta \approx \frac{2\pi}{\lambda}\frac{yd}{L} \qquad 33\text{-}15$$

as in the two-slit problem.

At $\theta = 0$, $\delta = 0$, so all the waves are in phase. The amplitude of the resultant wave is 3 times that of each individual wave and the intensity is 9 times that due to each source acting separately. As the angle θ increases from $\theta = 0$, the phase angle δ increases and the intensity decreases. The position $\theta = 0$ is thus a position of maximum intensity.

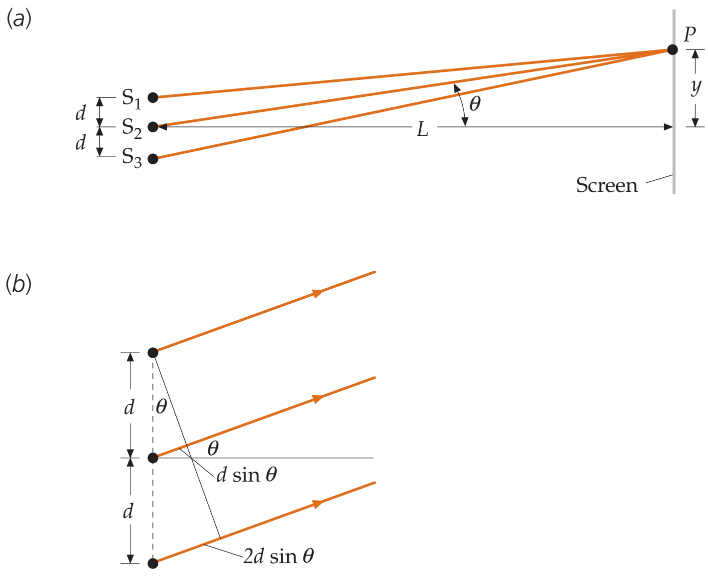

FIGURE 33-17 Geometry for calculating the intensity pattern far away from three equally spaced, coherent sources that are in phase.

Figure 33-18 shows the phasor addition of three waves for a phase angle $\delta = 30° = \pi/6$ rad. This corresponds to a point P on the screen for which θ is given by $\sin\theta = \lambda\delta/(2\pi d) = \lambda/(12d)$. The resultant amplitude A is considerably less than 3 times the amplitude A_0 of each source. As δ increases, the resultant amplitude decreases until the amplitude is zero at $\delta = 120°$. For this value of δ, the three phasors form an equilateral triangle (Figure 33-19). This first interference minimum for three sources occurs at a smaller value of δ (and therefore at a smaller angle θ) than it does for only two sources (for which the first interference minimum occurs at $\delta = 180°$). As δ increases from 120°, the resultant amplitude increases, reaching a secondary maximum at $\delta = 180°$. At the phase angle $\delta = 180°$, the amplitude is the same as that from a single source, because the waves from the first two sources cancel each other, leaving only the third. The intensity of the secondary maximum is one-ninth that of the maximum at $\theta = 0$. As δ increases beyond 180°, the amplitude again decreases and is zero at $\delta = 180° + 60° = 240°$. For δ greater than 240°, the amplitude increases and is again 3 times that of each source when $\delta = 360°$. This phase angle corresponds to a path-length difference of 1 wavelength for the waves from the first two sources and 2 wavelengths for the waves from the first and third sources. Hence, the three waves are in phase at this point. The largest maxima, called the principal maxima, are at the same positions as for just two sources, which are those points corresponding to the angles θ given by

$$d\sin\theta_m = m\lambda \quad m = 0, 1, 2, \ldots \tag{33-16}$$

These maxima are stronger and narrower than those for two sources. They occur at points for which the path-length difference between adjacent sources is zero or an integral number of wavelengths.

These results can be generalized to more than three sources. For four coherent sources that are equally spaced and in phase, the principal interference maxima are again given by Equation 33-16, but the maxima are even more intense, they are narrower, and there are two small secondary maxima between each pair of principal maxima. At $\theta = 0$, the intensity is 16 times that due to a single source. The first interference minimum occurs when δ is 90°, as can be seen from the phasor diagram of Figure 33-20. The first secondary maximum is near $\delta = 132°$. The intensity of the secondary maximum is about one-fourteenth that of the central maximum. There is another minimum at $\delta = 180°$, another secondary maximum near $\delta = 228°$, and another minimum at $\delta = 270°$ before the next principal maximum at $\delta = 360°$.

Figure 33-21 shows the intensity patterns for two, three, and four equally spaced coherent sources. Figure 33-22 shows a graph of I/I_0, where I_0 is the intensity due to each source acting separately. For three sources, there is a very small secondary maximum between each pair of principal maxima, and the principal maxima are sharper and more intense than those due to just two sources. For four sources, there are two small secondary maxima between each pair of principal maxima, and the principal maxima are even more narrow and intense.

From this discussion, we can see that as we increase the number of sources, the intensity becomes more and more concentrated in the principal maxima given by Equation 33-16, and these maxima become narrower. For N sources, the intensity of the principal maxima is N^2 times that due to a single source. The first minimum occurs at a phase angle of $\delta = 360°/N$, for which the N phasors form a closed polygon of N sides. There are $N - 2$ secondary maxima between each pair of principal maxima. These secondary maxima are very weak compared with the principal maxima.

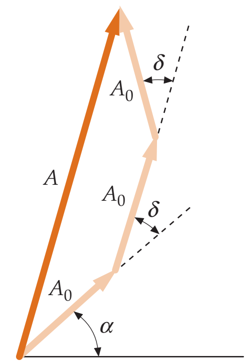

FIGURE 33-18 Phasor diagram for determining the resultant amplitude A due to three waves, each of amplitude A_0, that have phase differences of δ and 2δ due to path-length differences of $d\sin\theta$ and $2d\sin\theta$. The angle $\alpha = \omega t$ varies with time, but this does not affect the calculation of A.

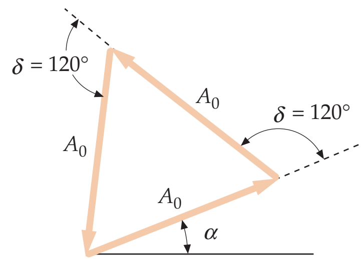

FIGURE 33-19 The resultant amplitude for the waves from three sources is zero when δ is 120°. This interference minimum occurs at a smaller angle θ than does the first minimum for two sources, which occurs when δ is 180°.

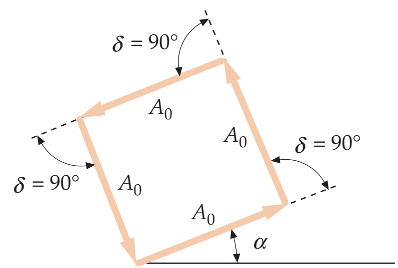

FIGURE 33-20 Phasor diagram for the first minimum for four coherent sources that are equally spaced and in phase. The amplitude is zero when the phase difference of the waves from adjacent sources is 90°.

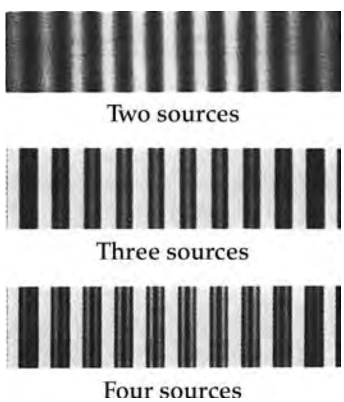

FIGURE 33-21 Intensity patterns for two, three, and four coherent sources that are equally spaced and in phase. There is a secondary maximum between each pair of principal maxima for three sources, and two secondary maxima between each pair of principal maxima for four sources. *(Courtesy of Michael Cagnet.)*

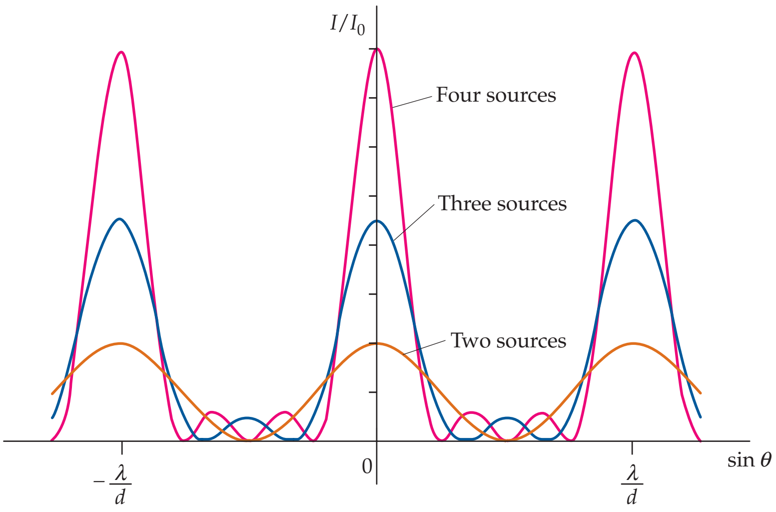

FIGURE 33-22 Plot of relative intensity versus $\sin\theta$ for two, three, and four coherent sources that are equally spaced and in phase.

As the number of sources is increased, the principal maxima become sharper and more intense, and the intensities of the secondary maxima become negligible compared to those of the principal maxima.

*CALCULATING THE SINGLE-SLIT DIFFRACTION PATTERN

We now use the phasor method for the addition of harmonic waves to calculate the intensity pattern shown in Figure 33-11. We assume that the slit of width a is divided into N equal intervals and that there is a point source of waves at the midpoint of each interval (Figure 33-23). If d is the distance between two adjacent sources and a is the width of the opening, we have $d = a/N$. Because the screen on which we are calculating the intensity is far from the sources, the rays from the sources to a point P on the screen are approximately parallel. The path-length difference between any two adjacent sources is $\delta \sin\theta$, and the phase difference δ is related to the path-length difference by

$$\delta = \frac{d \sin\theta}{\lambda} 2\pi$$

If A_0 is the amplitude due to a single source, the amplitude at the central maximum, where $\theta = 0$ and all the waves are in phase, is $A_{max} = NA_0$ (Figure 33-24).

We can find the amplitude at some other point at an angle θ by using the phasor method for the addition of harmonic waves. As in the addition of two, three, or four waves, the intensity is zero at any point where the phasors representing the waves form a closed polygon. In this case, the polygon has N sides (Figure 33-25). At the first minimum, the wave from the first source just below the top of the opening and the wave from the source just below the middle of the opening are 180° out of phase. In this case, the waves from the source near the top of the opening differ

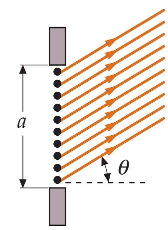

FIGURE 33-23 Diagram for calculating the diffraction pattern far away from a narrow slit. The slit width a is assumed to contain a large number of in-phase, equally spaced point sources separated by a distance d. The rays from the sources to a point far away are approximately parallel. The path-length difference for the waves from adjacent sources is $d \sin\theta$.

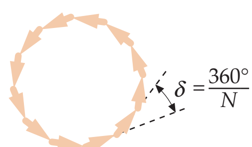

FIGURE 33-25 Phasor diagram for calculating the first minimum in the single-slit diffraction pattern. When the waves from the N sources completely cancel, the N phasors form a closed polygon. The phase difference between the waves from adjacent sources is then $\delta = 360°/N$. When N is very large, the waves from the first and last sources are approximately in phase.

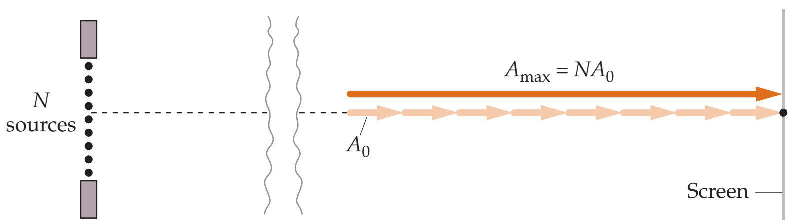

FIGURE 33-24 A single slit is represented by N sources, each of amplitude A_0. At the central maximum point, where $\theta = 0$, the waves from the sources add in phase, giving a resultant amplitude $A_{max} = NA_0$.

from those from the bottom of the opening by nearly 360°. [The phase difference is, in fact, $360° - (360°/N)$.] Thus, if the number of sources is very large, $360°/N$ is negligible and we get complete cancellation if the waves from the first and last sources are out of phase by 360°, corresponding to a path-length difference of one wavelength, in agreement with Equation 33-11.

We will now calculate the amplitude at a general point at which the waves from two adjacent sources differ in phase by δ. Figure 33-26 shows the phasor diagram for the addition of N waves, where the subsequent waves differ in phase from the first wave by $\delta, 2\delta, \ldots, (N-1)\delta$. When N is very large and δ is very small, the phasor diagram approximates the arc of a circle. The resultant amplitude A is the length of the chord of this arc. We will calculate this resultant amplitude in terms of the phase difference ϕ between the first wave and the last wave. From Figure 33-26, we have

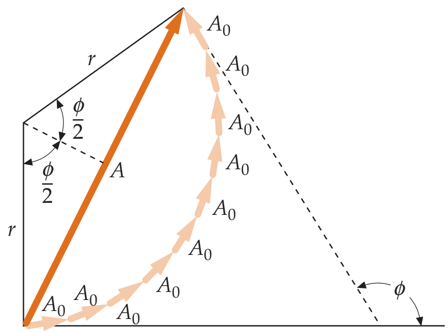

FIGURE 33-26 Phasor diagram for calculating the resultant amplitude due to the waves from N sources in terms of the phase difference ϕ between the wave from the first source just below the top of the slit and the wave from the last source just above the bottom of the slit. When N is very large, the resultant amplitude A is the chord of a circular arc of length $NA_0 = A_{max}$.

$$\sin \tfrac{1}{2}\phi = \frac{A/2}{r}$$

or

$$A = 2r \sin \tfrac{1}{2}\phi \qquad 33\text{-}17$$

where r is the radius of the arc. Because the length of the arc is $A_{max} = NA_0$ and the angle subtended is ϕ, we have

$$\phi = \frac{A_{max}}{r} \qquad 33\text{-}18$$

or

$$r = \frac{A_{max}}{\phi}$$

Substituting this into Equation 33-17 gives

$$A = \frac{2A_{max}}{\phi}\sin \tfrac{1}{2}\phi = A_{max}\frac{\sin \frac{1}{2}\phi}{\frac{1}{2}\phi}$$

Because the amplitude at the center of the central maximum ($\theta = 0$) is A_{max}, the ratio of the intensity at any other point to that at the center of the central maximum is

$$\frac{I}{I_0} = \frac{A^2}{A_{max}^2} = \left(\frac{\sin \frac{1}{2}\phi}{\frac{1}{2}\phi}\right)^2$$

or

$$I = I_0\left(\frac{\sin \frac{1}{2}\phi}{\frac{1}{2}\phi}\right)^2 \qquad 33\text{-}19$$

INTENSITY FOR A SINGLE-SLIT DIFFRACTION PATTERN

The phase difference ϕ between the first and last waves is related to the path-length difference $a \sin\theta$ between the top and bottom of the opening by

$$\phi = \frac{a \sin\theta}{\lambda}2\pi \qquad 33\text{-}20$$

Equation 33-19 and Equation 33-20 describe the intensity pattern shown in Figure 33-11. The first minimum occurs at $a \sin\theta = \lambda$, which is the point where the waves from the middle of the upper half and the middle of the lower half of the slit have a path-length difference of $\lambda/2$ and are 180° out of phase. The second minimum occurs at $a \sin\theta = 2\lambda$, where the waves from the upper half of the upper half of the slit and those from the lower half of the upper half of the slit have a path-length difference of $\lambda/2$ and are 180° out of phase.

There is a secondary maximum approximately midway between the first and second minima at $a \sin\theta \approx \frac{3}{2}\lambda$. Figure 33-27 shows the phasor diagram for determining the approximate intensity of this secondary maximum. The phase difference ϕ between the first and last waves is approximately $2\pi + \pi$. The phasors thus complete $1\frac{1}{2}$ circles. The resultant amplitude is the diameter of a circle that has a circumference which is two-thirds the total length A_{max}. If $C = \frac{2}{3}A_{max}$ is the circumference, the diameter A is

$$A = \frac{C}{\pi} = \frac{\frac{2}{3}A_{max}}{\pi} = \frac{2}{3\pi}A_{max}$$

and

$$A^2 = \frac{4}{9\pi^2}A_{max}^2$$

The intensity at this point is

$$I = \frac{4}{9\pi^2}I_0 = \frac{1}{22.2}I_0 \qquad 33\text{-}21$$

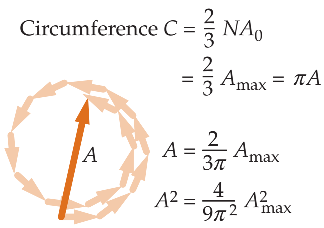

FIGURE 33-27 Phasor diagram for calculating the approximate amplitude of the first secondary maximum of the single-slit diffraction pattern. The secondary maximum occurs near the midpoint between the first and second minima when the N phasors complete $1\frac{1}{2}$ circles.

*CALCULATING THE INTERFERENCE–DIFFRACTION PATTERN OF MULTIPLE SLITS

The intensity of the two-slit interference–diffraction pattern can be calculated from the two-slit pattern (Equation 33-8) where the intensity of each slit (I_0 in that equation) is replaced by the diffraction pattern intensity due to each slit, I, given by Equation 33-19. The intensity for the two-slit interference–diffraction pattern is thus

$$I = 4I_0\left(\frac{\sin\frac{1}{2}\phi}{\frac{1}{2}\phi}\right)^2 \cos^2\tfrac{1}{2}\delta \qquad 33\text{-}22$$

INTERFERENCE–DIFFRACTION INTENSITY FOR TWO SLITS

where ϕ is the difference in phase between rays from the top and bottom of each slit, which is related to the width of each slit by

$$\phi = \frac{a\sin\theta}{\lambda}2\pi$$

and δ is the difference in phase between rays from the centers of two adjacent slits, which is related to the slit separation by

$$\delta = \frac{d\sin\theta}{\lambda}2\pi$$

In Equation 33-22, the intensity I_0 is the intensity at $\theta = 0$ due to one slit alone.

Example 33-8 Five-Slit Interference–Diffraction Pattern

Find the interference–diffraction intensity pattern for five equally spaced slits, where a is the width of each slit and d is the distance between adjacent slits.

PICTURE First, find the interference intensity pattern for the five slits, assuming no angular variations in the intensity due to diffraction. To do this, first construct a phasor diagram to find the amplitude of the resultant wave in an arbitrary direction θ. Intensity is proportional to the square of the amplitude. Next, correct for the variation of intensity with θ by using the single-slit diffraction pattern intensity relation (Equation 33-20 and Equation 33-20).

SOLVE

1. The diffraction pattern intensity I' due to a slit of width a is given by Equation 33-19 and Equation 33-20:

$$I' = I_0\left(\frac{\sin\frac{1}{2}\phi}{\frac{1}{2}\phi}\right)^2$$

where

$$\phi = \frac{2\pi}{\lambda}a\sin\theta$$

2. The interference pattern intensity I is proportional to the square of the amplitude A of the superposition of the wave functions for the light from the five slits:

$$I \propto A^2$$

where

$$A\sin(\alpha + \delta') = A_0\sin\alpha + A_0\sin(\alpha + \delta) + A_0\sin(\alpha + 2\delta) + A_0\sin(\alpha + 3\delta) + A_0\sin(\alpha + 4\delta)$$

and where $\alpha = \omega t$ and $\delta = \dfrac{d\sin\theta}{\lambda}2\pi$

3. To solve for A, we construct a phasor diagram (Figure 33-28). The amplitude A equals the sum of the projections of the individual phasors onto the resultant phasor:

$$\delta' = \beta + \delta$$

so

$$\beta = \delta' - \delta = 2\delta - \delta = \delta$$

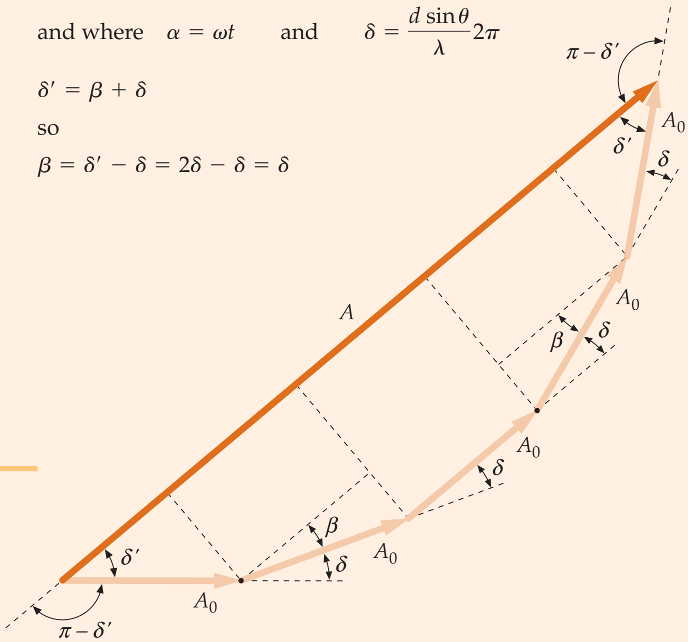

FIGURE 33-28

4. To find δ', we add the exterior angles. The sum of the exterior angles equals 2π (if you walk the perimeter of any polygon you rotate through the sum of the exterior angles, and you rotate through 2π radians):

$$2(\pi - \delta') + 4\delta = 2\pi \quad \Rightarrow \quad \delta' = 2\delta$$

5. Solve for A from the figure:

$$A = 2A_0\cos\delta' + 2A_0\cos\beta + A_0$$

6. Substitute for δ' using the step-4 result, and substitute for β using the relation $\beta = \delta$. (That β and δ are equal follows from the theorem "If two parallel lines are cut by a transversal, the interior and exterior angles on the same side of the transversal are equal."):

$$A = A_0(2\cos 2\delta + 2\cos\delta + 1)$$

7. Square both sides to relate the intensities. Recall, I' is the intensity from a single slit, and A_0 is the amplitude from a single slit:

$$A^2 = A_0^2(2\cos 2\delta + 2\cos\delta + 1)^2$$

so

$$I = I'(2\cos 2\delta + 2\cos\delta + 1)^2$$

8. Substitute for I' using the step-1 result:

$$\boxed{I = I_0\left(\frac{\sin\frac{1}{2}\phi}{\frac{1}{2}\phi}\right)^2(2\cos 2\delta + 2\cos\delta + 1)^2 \quad \text{where } \phi = \frac{a\sin\theta}{\lambda}2\pi \quad \text{and} \quad \delta = \frac{d\sin\theta}{\lambda}2\pi}$$

CHECK If $\theta = 0$, both $\phi = 0$ and $\delta = 0$. So, for $\theta = 0$, step 5 becomes $A = 5A_0$ and step 8 becomes $I = 5^2I_0 = 25I_0$ as expected.

33-6 FRAUNHOFER AND FRESNEL DIFFRACTION

Diffraction patterns, like the single-slit pattern shown in Figure 33-11, that are observed at points for which the rays from an aperture or an obstacle are nearly parallel are called **Fraunhofer diffraction patterns.** Fraunhofer patterns can be observed at great distances from the obstacle or the aperture so that the rays reaching any point are approximately parallel, or they can be observed using a lens to focus parallel rays on a viewing screen placed in the focal plane of the lens.

The diffraction pattern observed near an aperture or an obstacle is called a **Fresnel diffraction pattern.** Because the rays from an aperture or an obstacle close to a screen cannot be considered parallel, Fresnel diffraction is much more difficult to analyze. Figure 33-29 illustrates the difference between the Fresnel and the Fraunhofer patterns for a single slit.*

Figure 33-30*a* shows the Fresnel diffraction pattern of an opaque disk. Note the bright spot at the center of the pattern caused by the constructive interference of the light waves diffracted from the edge of the disk. This pattern is of some historical interest. In an attempt to discredit Augustin Fresnel's wave theory of light, Siméon Poisson pointed out that it predicted a bright spot at the center of the shadow, which he assumed was a ridiculous contradiction of fact. However, Fresnel immediately demonstrated experimentally that such a spot does, in fact, exist. This demonstration convinced many doubters of the validity of the wave theory of light. The Fresnel diffraction pattern of a circular aperture is shown in Figure 33-30*b*. Comparing this with the pattern of the opaque disk in Figure 33-30*a*, we can see that the two patterns are complements of each other.

Figure 33-31*a* shows the Fresnel diffraction pattern of a straightedge illuminated by light from a point source. A graph of the intensity versus distance (measured along a line perpendicular to the edge) is shown in Figure 33-31*b*. The light intensity does not fall abruptly to zero in the geometric shadow, but it decreases rapidly and is negligible within a few wavelengths of the edge. The Fresnel diffraction pattern

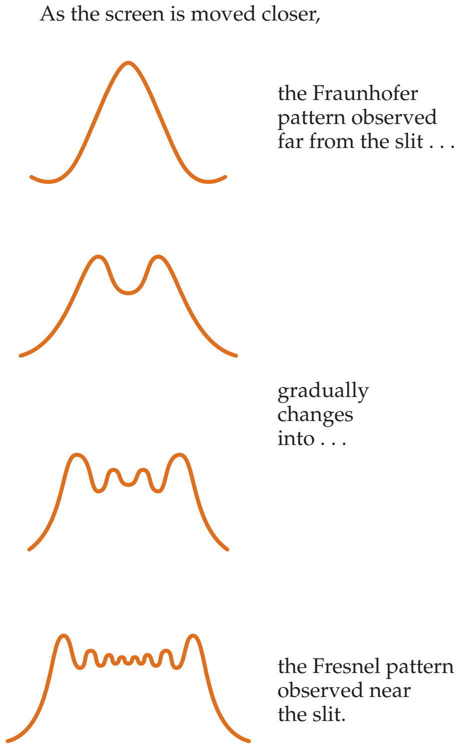

FIGURE 33-29 Diffraction patterns for a single slit at various screen distances.

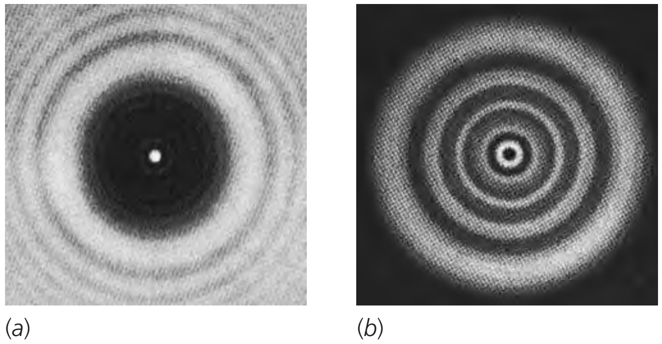

FIGURE 33-30 (*a*) The Fresnel diffraction pattern of an opaque disk. At the center of the shadow, the light waves diffracted from the edge of the disk are in phase and produce a bright spot called the *Poisson spot.* (*b*) The Fresnel diffraction pattern of a circular aperture. Compare this with Figure 33-30*a*. *((a) and (b) M. Cagnet, M. Françon, J. C. Thrierr, Atlas of Optical Phenomena.)*

of a rectangular aperture is shown in Figure 33-32. These patterns cannot be seen using extended light sources like an ordinary lightbulb, because the dark fringes of the pattern produced by light from one point on the source overlap the bright fringes of the pattern produced by light from another point.

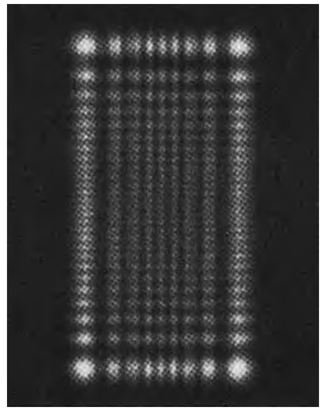

FIGURE 33-32 The Fresnel diffraction pattern of a rectangular aperture. *(Courtesy of Michael Cagnet.)*

33-7 DIFFRACTION AND RESOLUTION

Diffraction due to a circular aperture has important implications for the resolution of many optical instruments. Figure 33-33 shows the Fraunhofer diffraction pattern of a circular aperture. The angle θ subtended by the first diffraction minimum is related to the wavelength and the diameter of the opening D by

$$\sin\theta = 1.22\frac{\lambda}{D} \qquad \text{33-23}$$

Equation 33-23 is similar to Equation 33-9 except for the factor 1.22, which arises from the mathematical analysis, and is similar to the equation for a single slit but more complicated because of the circular geometry. In many applications, the angle θ is small, so $\sin\theta$ can be replaced by θ. The first diffraction minimum is then at an angle θ given by

$$\theta \approx 1.22\frac{\lambda}{D} \qquad \text{33-24}$$

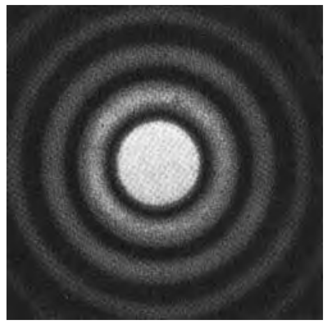

FIGURE 33-33 The Fraunhofer diffraction pattern of a circular aperture. *(Courtesy of Michael Cagnet.)*

Figure 33-34 shows two point sources that subtend an angle α at a circular aperture far from the sources. The intensities of the Fraunhofer diffraction pattern are also indicated in this figure. If α is much greater than $1.22\lambda/D$, the sources will be seen as two sources. However, as α is decreased, the overlap of the diffraction patterns increases, and it becomes difficult to distinguish the two sources from one source. At the critical angular separation, α_c, given by

$$\alpha_c = 1.22\frac{\lambda}{D} \qquad \text{33-25}$$

the first minimum of the diffraction pattern of one source falls on the central maximum of the other source. These objects are said to be just resolved by **Rayleigh's criterion for resolution.** Figure 33-35 shows the diffraction patterns for two sources when α is greater than the critical angle for resolution and when α is just equal to the critical angle for resolution.

Equation 33-25 has many applications. The *resolving power* of an optical instrument, such as a microscope or telescope, is the ability of the instrument to resolve two objects that are close together. The images of the objects tend to overlap because of diffraction at the entrance aperture of the instrument. We can see from Equation 33-25 that the resolving power can be increased either by increasing the diameter D of the lens (or mirror) or by decreasing the wavelength λ. Astronomical telescopes use large objective lenses or mirrors to increase their resolution as well as to increase their light-gathering power. An array of 27 radio antennas (Figure 33-36) mounted on rails can be configured to form a single telescope that has a resolution distance D of 36 km (22 mi). In a microscope, a film of transparent oil that has an index of refraction

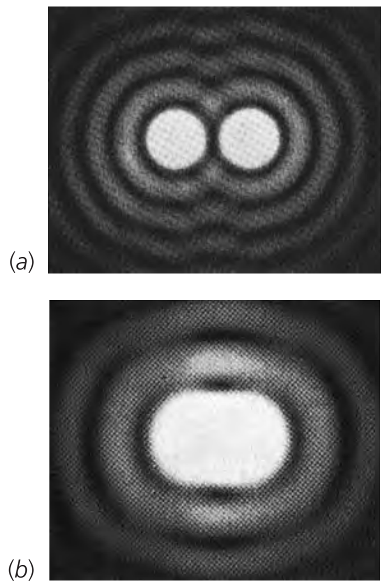

FIGURE 33-35 The diffraction patterns for a circular aperture and two incoherent point sources when (*a*) α is a factor of 2 or so greater than $\alpha_c = 1.22\lambda/D$ and (*b*) when α is equal to the limit of resolution, $\alpha_c = 1.22\lambda/D$. *((a) and (b) Courtesy of Michael Cagnet.)*

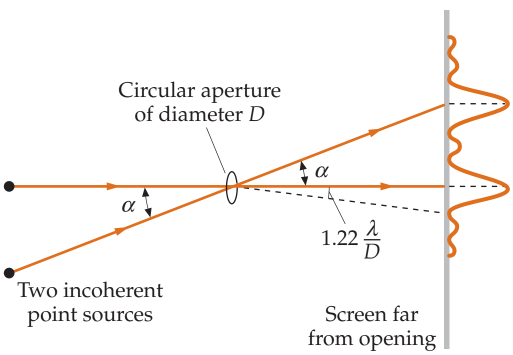

FIGURE 33-34 Two distant sources that subtend an angle α. If α is much greater than $1.22\lambda/D$, where λ is the wavelength of light and D is the diameter of the aperture, the diffraction patterns have little overlap and the sources are easily seen as two distinct sources. If α is not much greater than $1.22\lambda/D$, the overlap of the diffraction patterns makes it difficult to distinguish two sources from one.

of approximately 1.55 is sometimes used under the objective to decrease the wavelength of the light ($\lambda' = \lambda/n$). The wavelength can be reduced further by using ultraviolet light and photographic film; however, ordinary glass is opaque to ultraviolet light, so the lenses in an ultraviolet microscope must be made from quartz or fluorite. To obtain very high resolutions, electron microscopes are used—microscopes that use electrons rather than light. The wavelengths of electrons vary inversely with the square root of their kinetic energy and can be made as small as desired.*

FIGURE 33-36 The very large array (VLA) of radio antennas is located near Socorro, New Mexico. The 25-m-diameter antennas are mounted on rails, which can be arranged in several configurations, and can be extended over a diameter of 36 km. The data from the antennas are combined electronically, so the array is really a single high-resolution telescope. *(Courtesy of National Radio Astronomy Observatory/Associated Universities, Inc./National Science Foundation. Photographer: Kelly Gatlin. Digital composite: Patricia Smiley.)*

Example 33-9 Physics in the Library *Context-Rich*

While studying in the library, you lean back in your chair and ponder the small holes you notice in the ceiling tiles. You notice that the holes are approximately 5.0 mm apart. You can clearly see the holes directly above you, about 2 m up, but the tiles far away do not appear to have the holes. You wonder if the reason you cannot see the distant holes is because they are not within the criteria for resolution established by Rayleigh. Is this a feasible explanation for the disappearance of the holes? You notice the holes disappear about 20 m from you.

PICTURE We will need to make assumptions about the situation. If we use Equation 33-25, we will need to know the wavelength of light and the aperture diameter. Assuming our pupil is the aperture, we can assume approximately 5.0 mm for the diameter. (This is the value used in this physics textbook.) The wavelength of the light is probably about 500 nm or so.

SOLVE

1. The angular limit for resolution by the eye depends on the ratio of the wavelength and the diameter of the pupil:

$$\theta_c \approx 1.22\frac{\lambda}{D}$$

2. The angle subtended by two holes depends on their separation distance d and their distance L from your eye:

$$\theta \approx \frac{d}{L}$$

3. Equating the two angles and putting in the numbers give:

$$\frac{d}{L} \approx 1.22\frac{\lambda}{D}$$

$$\frac{5.0\text{ mm}}{L} \approx 1.22\frac{500\text{ nm}}{5.0\text{ mm}}$$

4. Solving for L gives:

$$L = 41\text{ m}$$

5. By a factor of 2, 41 m is too large. However, you are suspect of the value given for the pupil diameter in your physics textbook. You know the pupil is smaller when the light is bright, and the library ceiling is very bright and colored white. An online search for eye pupil diameter soon yields the information you need. The pupil diameter ranges from 2 to 3 mm up to 7 mm:

Sucess. If the pupil diameter is 2.5 mm, the value of L is 20 m.

It is instructive to compare the limitation on resolution of the eye due to diffraction, as seen in Example 33-9, with the limitation on resolution due to the separation of the receptors (cones) on the retina. To be seen as two distinct objects, the images of the objects must fall on the retina on two nonadjacent cones. (See Problem 65 in Chapter 32.) Because the retina is about 2.5 cm from the cornea, the distance y on the retina corresponding to an angular separation of 1.5×10^{-4} rad is found from

$$\alpha_c = 1.5 \times 10^{-4}\text{ rad} = \frac{y}{2.5\text{ cm}}$$

or

$$y = 3.8 \times 10^{-4}\text{ cm} = 3.8 \times 10^{-6}\text{ m} = 3.8\ \mu\text{m}$$

The actual separation of the cones in the fovea centralis, where the cones are the most tightly packed, is about 1 μm. Outside this region, they are about 3 μm to 5 μm apart.

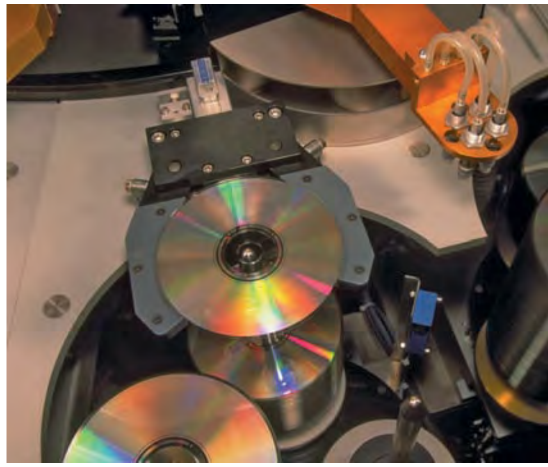
CONCEPT CHECK 33-2

True or False:
Fraunhofer diffraction is a limiting case of Fresnel diffraction.

* The wave properties of electrons are discussed in Chapter 34.

* 33-8 DIFFRACTION GRATINGS

A widely used tool for measuring the wavelength of light is the **diffraction grating,** which consists of a large number of equally spaced lines or slits on a flat surface. Such a grating can be made by cutting parallel, equally spaced grooves on a glass or metal plate with a precision ruling machine. With a reflection grating, light is reflected from the ridges between the lines or grooves. Phonograph records and compact disks exhibit some of the properties of reflection gratings. In a transmission grating, the light passes through the clear gaps between the rulings. Inexpensive, optically produced plastic gratings that have 10 000 or more slits per centimeter are common items in teaching laboratories. The spacing of the slits in a grating that has 10 000 slits per centimeter is $d = (1\text{ cm})/10\,000\text{ slits} = 10^{-4}\text{ cm slit}$.



Compact disks act as reflection gratings. *(Kevin R. Morris/Corbis.)*

Consider a plane wave of monochromatic light that is incident normally on a transmission grating (Figure 33-37). Assume that the width of each slit is very small so that it produces a widely diffracted beam. The interference pattern produced on a screen a large distance from the grating is due to a large number of coherent, equally spaced light sources. Suppose we have N slits that have separation d between adjacent slits. At $\theta = 0$, the light from each slit is in phase with that from all the other slits, so the amplitude of the wave is NA_0, where A_0 is the amplitude from each slit, and the intensity is N^2I_0, where I_0 is the intensity due to a single slit alone. At an angle θ_1, where $d\sin\theta_1 = \lambda_1$, the path-length difference between any two successive slits is λ_1, so again the light from each slit is in phase with that from all the other slits and the intensity is N^2I_0. The interference maxima are thus at angles θ given by

$$d\sin\theta_m = m\lambda \qquad m = 0, 1, 2, \ldots \tag{33-26}$$

The positions of the interference maxima do not depend on the number of sources, but the more sources there are, the sharper (narrower) and more intense the maxima will be.

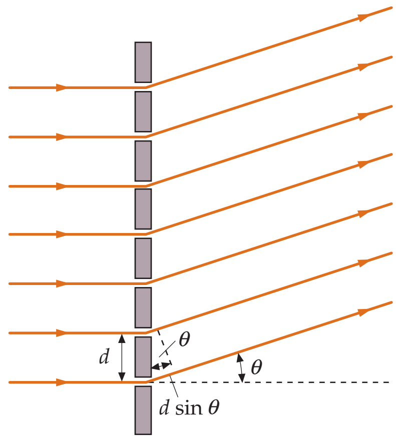


FIGURE 33-37 Light incident normally on a diffraction grating. At an angle θ, the path-length difference between rays from adjacent slits is $d\sin\theta$.

To see that the interference maxima will be sharper when there are many slits, consider the case of N illuminated slits, where N is large ($N \gg 1$). The distance from the first slit to the Nth slit is $(N - 1)d \approx Nd$. When the path-length difference for the light from the first slit and that from the Nth slit is λ, the resulting intensity will be zero because the light from any two slits separated by $\frac{1}{2}Nd$ interferes destructively. (We saw this in our discussion of single-slit diffraction in Section 33-4.) Because the first and Nth slits are separated by approximately Nd, the intensity will be zero at angle θ_{min} given by

$$Nd\sin\theta_{\text{min}} = \lambda$$

so

$$\theta_{\text{min}} \approx \sin\theta_{\text{min}} = \frac{\lambda}{Nd}$$

The angular width of the interference maximum, which is equal to $2\theta_{\text{min}}$, is thus inversely proportional to N. Therefore, the greater the number of illuminated slits N, the sharper the maximum. Because the intensity in the maximum is proportional to N^2I_0, the intensity in the maximum multiplied by the width of the maximum is proportional to NI_0. The intensity multiplied by the width is a measure of power per unit length in the maximum.

Figure 33-38*a* shows a student spectroscope that uses a diffraction grating to analyze light. In student laboratories, the light source is typically a glass tube containing atoms of a gas (for example, helium or sodium vapor) that are excited by a bombardment of electrons accelerated by high voltage across the tube. The light emitted by such a source contains only certain wavelengths that are characteristic of the atoms in the source. Light from the source passes through a narrow collimating slit and is made parallel by a lens. Parallel light from the lens is incident on the grating. Instead of falling on a screen a large distance away, the parallel light from the grating is focused by a telescope and viewed by the eye. The telescope is

(a)  (b) 

mounted on a rotating platform that has been calibrated so that the angle θ can be measured. In the forward direction ($\theta = 0$), the central maximum for all wavelengths is seen. If light of a particular wavelength λ is emitted by the source, the first interference maximum is seen at the angle θ given by $d \sin\theta_m = m\lambda$ (Equation 33-26) with $m = 1$. Each wavelength emitted by the source produces a separate image of the collimating slit in the spectroscope called a **spectral line.** The set of lines corresponding to $m = 1$ is called the **first-order spectrum.** The **second-order spectrum** corresponds to $m = 2$ for each wavelength. Higher orders may be seen, providing the angle θ given by $d \sin\theta_m = m\lambda$ is less than 90°. Depending on the wavelengths, the orders may be mixed; that is, the third-order line for one wavelength may occur at a smaller value of θ than does the second-order line for another wavelength. If the spacing of the slits in the grating is known, the wavelengths emitted by the source can be determined by measuring the angles.

FIGURE 33-38 (*a*) A typical student spectroscope. Light from a collimating slit near the source is made parallel by a lens and falls on a grating. The diffracted light is viewed with a telescope at an angle that can be accurately measured. (*b*) Aerial view of the very large array (VLA) radio telescope in New Mexico. Radio signals from distant galaxies add constructively when Equation 33-26 is satisfied, where d is the distance between two adjacent telescopes. *((a) Clarence Bennett/ Oakland University, Rochester, Michigan. (b) NRAO/AUI/Science Photo Library/ Photo Researchers.)*

Example 33-10 Sodium D Lines

Sodium light is incident on a diffraction grating with 12 000 lines per centimeter. At what angles will the two yellow lines (called the sodium D lines) of wavelengths 589.00 nm and 589.59 nm be seen in the first order?

PICTURE Apply $d \sin\theta_m = m\lambda$ to each wavelength, with $m = 1$ and $d = (1/12\,000)$ cm.

SOLVE

1. The angle θ_m is given by $d \sin\theta_m = m\lambda$ with $m = 1$:
$$\sin\theta_1 = \frac{\lambda}{d}$$

2. Calculate θ_1 for $\lambda = 589.00$ nm:
$$\theta_1 = \sin^{-1}\left[\frac{589.00 \times 10^{-9}\text{ m}}{(1/12\,000)\text{ cm}} \times \left(\frac{100\text{ cm}}{1\text{ m}}\right)\right] = \boxed{44.98°}$$

3. Repeat the calculation for $\lambda = 589.59$ nm:
$$\theta_1 = \sin^{-1}\left[\frac{589.59 \times 10^{-9}\text{ m}}{(1/12\,000)\text{ cm}} \times \left(\frac{100\text{ cm}}{1\text{ m}}\right)\right] = \boxed{45.03°}$$

CHECK The first-order intensity maximum for the longer wavelength appears at the larger angle, as expected.

PRACTICE PROBLEM 33-4 Find the angles for the first-order intensity maxima of the two yellow lines if the grating has 15 000 lines per centimeter.

An important feature of a spectroscope is its ability to resolve spectral lines of two nearly equal wavelengths λ_1 and λ_2. For example, the two prominent yellow lines in the spectrum of sodium have wavelengths 589.00 and 589.59 nm. These can be seen as two separate wavelengths if their interference maxima do not overlap. According to Rayleigh's criterion for resolution, these wavelengths are resolved if the angular separation of their interference maxima is greater than the angular separation between an interference maximum and the first interference minimum on either side of it. The **resolving power** of a diffraction grating is defined to be $\lambda/|\Delta\lambda|$, where $|\Delta\lambda|$ is the smallest observable difference between two nearby wavelengths, each approximately equal to λ, that may be resolved. The resolving power is proportional to the number of slits illuminated because the more slits illuminated, the sharper the interference maxima. The resolving power R can be shown to be

$$R = \frac{\lambda}{|\Delta\lambda|} = mN \qquad 33\text{-}27$$

where N is the number of illuminated slits and m is the order number (see Problem 78). We can see from Equation 33-27 that to resolve the two yellow lines in the first order ($m = 1$) of the sodium spectrum the resolving power must be

$$R = 1 \times \frac{589.00 \text{ nm}}{589.59 \text{ nm} - 589.00 \text{ nm}} = 998$$

Thus, to resolve the two yellow sodium lines in the first order, we need a grating containing 998 or more slits in the area illuminated by the light.

*HOLOGRAMS

An interesting application of diffraction gratings is the production of a three-dimensional photograph called a **hologram** (Figure 33-39). In an ordinary photograph, the intensity of reflected light from an object is focused on a light-sensitive surface. As a result, a two-dimensional image is recorded. In a hologram, a beam from a laser is split into two beams, a reference beam and an object beam. The object beam reflects from the object to be photographed, and the interference pattern between it and the reference beam is recorded on a transparent film coated with a photosensitive emulsion. This can be done because the laser beam is coherent so that the relative phase difference between the reference beam and the object beam can be kept constant during the exposure. The film can be used to produce a holographic image after the emulsion is developed (chemically processed). The interference fringes on the film act as a diffraction grating. When the developed film is illuminated with a laser, a three-dimensional holographic image of the object is produced.

Holograms that you see on credit cards or postage stamps, called rainbow holograms, are more complicated. A horizontal strip of the original hologram is used to make a second hologram. The three-dimensional image can be seen as the viewer moves from side to side, but if viewed using monochromatic light, the image disappears when the viewer's eyes move above or below the slit image. When viewed using white light, the image is seen in different colors as the viewer moves in the vertical direction.

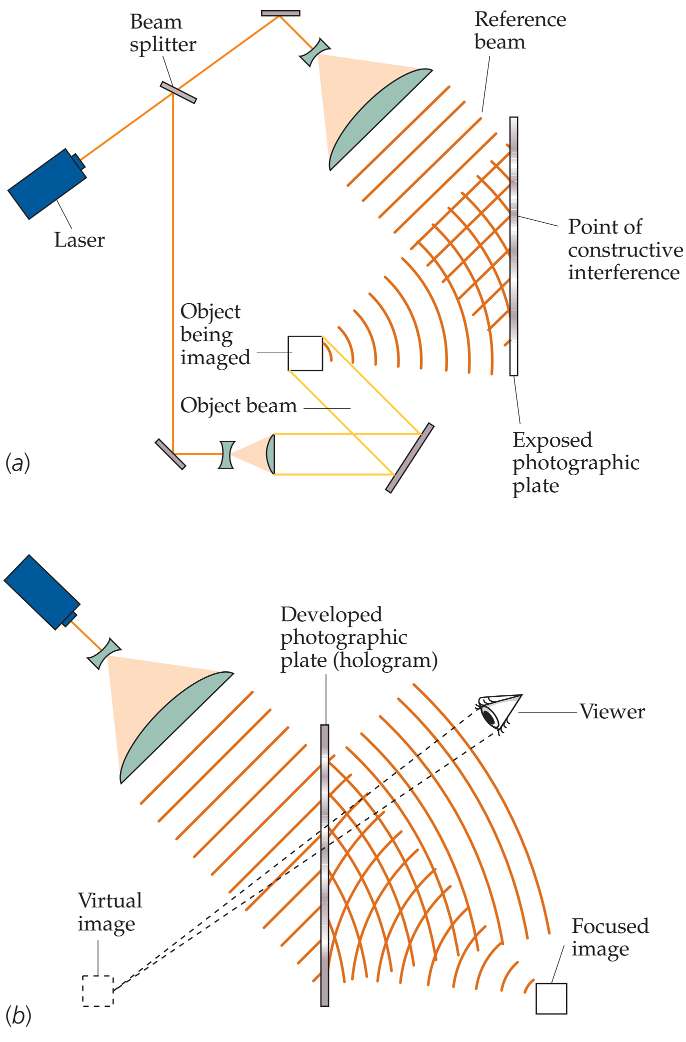

FIGURE 33-39 (*a*) The production of a hologram. The interference pattern produced by the reference beam and object beam is recorded on a photographic film. (*b*) When the film is developed and illuminated by coherent laser light, a three-dimensional image is seen.

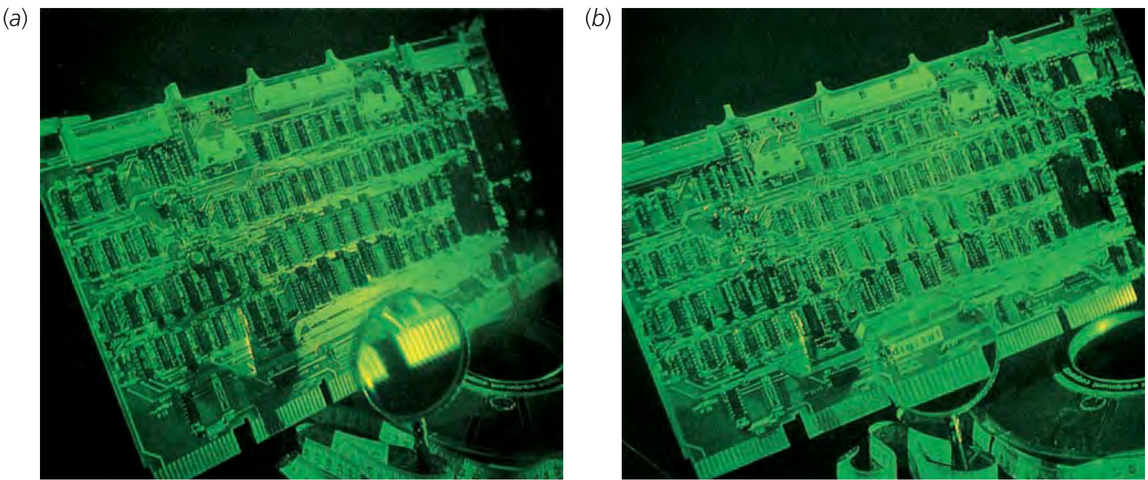
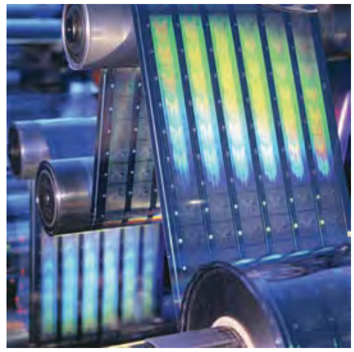


A hologram viewed from two different angles. Note that different parts of the circuit board appear behind the front magnifying lens. (*© 1981 by Ronald R. Erickson, Hologram by Nicklaus Phillips, 1978, for Digital Equipment Corporation.*)

Holograms: Guided Interference



The machine is using heat to emboss holograms on plastic cards (perhaps credit cards). Such holograms serve as both a security feature and aesthetic enrichment. *(Pascal Goetgheluck/Photo Researchers.)*

Holography was invented by Dennis Gabor in 1948 when he tried to improve the resolution of electron microscopy.[*] He reconstructed wavefronts using interference on the photographic plate to make a picture that contained phase information as well as intensity information. He named this type of imagery holography, after the Greek words for "whole" and "writing," for he felt that including the phase information gave a complete picture.[†]

It was extremely difficult to create those first few holograms, and they did not achieve the desired resolution. He used mercury vapor lamps as a light source. The light was highly monochromatic, but incoherent. (The phase of the light fluctuated randomly.) A decade or so later, after the laser was invented, the use of coherent laser light made holography practical for many purposes.

Embossed holograms are frequently used because they are inexpensive. Embossed holograms are made by hot-stamping a metallized plastic film[‡] with a die that is a negative copy of the extremely shallow (around 0.3–0.5 micron deep) interference lines present in a hologram.[#] The plastic film is then a duplicate of the very tiny interference lines in the original hologram. When light shines through the film and reflects from the metallic backing, the holographic image is reconstructed. Almost all embossed holograms are rainbow holograms—able to be viewed without a laser. Creating the master of a rainbow hologram is a complex process involving multiple exposures at precise angles.[°]

Embossed holograms are highly visible, easy to recognize, and difficult to forge.[§] Because they can take the place of paper labels or be added to paper or plastic, they are used on credit cards, pharmaceutical packaging, currency, and traveler's checks as a quick method for authentication.[¶,**]

In January 1999, the Ford Motor Company used a series of digital holograms to create a 10 foot by 4 foot hologram of a concept car. The holograms were printed directly from computer design data.[††] Digital holography is now used to help physicians visualize the results of either computed tomography scans or magnetic resonance scans.[‡‡] The output from a series of MR or CT slices is collected, digitally processed, and then printed onto a single hologram, which can be viewed on a portable viewer. The resulting hologram allows surgeons to prepare for difficult surgeries[##] and may also have biomedical and industrial engineering applications.[°°] Digital holography is beginning to be used in holographic video applications.[§§]

Holograms have also been used as substitutes for traditional lenses. Holographic optical elements allow smaller and more compact displays to be built. Heads-up displays for airplane pilots are created using holographic optical elements.[¶¶] An extremely compact system that uses digitally calculated holograms as the optical element has been tested for use as a cell-phone based projector.[***] The use of holograms as optical elements and in optical data storage depends on advances in materials that are lightweight, tough, and have the desired optical properties.[†††]

Recently, holograms have been used to measure the electrostatic potential[‡‡‡] and magnetic fields[###] of very small objects. They have also been used to create higher resolution optics for X-ray lenses.[°°°] More than fifty years after holograms were invented, they are used to improve the resolution of microscopic images.

Summary

TOPIC	RELEVANT EQUATIONS AND REMARKS
1. Interference	Two superposing light waves interfere if their phase difference remains constant for a time long enough to observe. They interfere constructively if their phase difference is zero or an integer multiplied by 360°. They interfere destructively if their phase difference is 180° or an odd integer multiplied by 180°.
Phase difference due to a path-length difference	$\delta = \frac{\Delta r}{\lambda} 2\pi$ — 33-1
Phase difference due to reflection	A phase difference of 180° is introduced when a light wave is reflected from a boundary between two media for which the wave speed is greater on the incident-wave side of the boundary.
Thin films	The interference of light waves reflected from the front and back surfaces of a thin film produces interference fringes, commonly observed in soap films or oil films. The difference in phase between the two reflected waves results from the path-length difference of twice the thickness of the film plus any phase change due to reflection of one or both of the rays.
Two slits	The path-length difference at an angle θ on a screen far away from two narrow slits separated by a distance d is $d \sin\theta$. If the intensity due to each slit separately is I_0, the intensity at points of constructive interference is $4I_0$, and the intensity at points of destructive interference is zero.
Two slit interference maxima (sources in phase)	$d \sin\theta_m = m\lambda \qquad m = 0, 1, 2, \ldots$ — 33-2
Two slit interference maxima (sources 180° out of phase)	$d \sin\theta_m = (m - \frac{1}{2})\lambda \qquad m = 1, 2, 3, \ldots$ — 33-3
2. Diffraction	Diffraction occurs whenever a portion of a wavefront is limited by an obstacle or an aperture. The intensity of light at any point in space can be computed using Huygens's construction by taking each point on the wavefront to be a point source and computing the resulting interference pattern.
Fraunhofer patterns	Fraunhofer patterns are observed at great distances from the obstacle or aperture so that the rays reaching any point are approximately parallel, or they can be observed using a lens to focus parallel rays on a viewing screen placed in the focal plane of the lens.
Fresnel patterns	Fresnel patterns are observed at points not necessarily far from the source.
Single slit	When light is incident on a single slit of width a, the intensity pattern on a screen far away shows a broad central diffraction maximum that decreases to zero at an angle θ_1 given by $\sin\theta_1 = \frac{\lambda}{a}$ — 33-9 The width of the central maximum is inversely proportional to the width of the slit. The zeros in the single-slit diffraction pattern occur at angles given by $a \sin\theta_m = m\lambda \qquad m = 1, 2, 3, \ldots$ — 33-11 The maxima on either side of the central maximum have intensities that are much smaller than the intensity of the central maximum.
Two slits	The interference-diffraction pattern of two slits is the two-slit interference pattern modulated by the single-slit diffraction pattern.
Resolution of two sources	When light from two point sources that are close together passes through an aperture, the diffraction patterns of the sources may overlap. If the overlap is too great, the two sources cannot be resolved as two separate sources. When the central diffraction maximum of one source falls at the diffraction minimum of the other source, the two sources are said to be just resolved by Rayleigh's criterion for resolution. For a circular aperture of diameter D, the critical angular separation of two sources for resolution by Rayleigh's criterion is given by
Rayleigh's criterion	$\alpha_c = 1.22 \frac{\lambda}{D}$ — 33-25

TOPIC	RELEVANT EQUATIONS AND REMARKS
*Gratings	A diffraction grating consisting of a large number of equally spaced lines or slits is used to measure the wavelength of light emitted by a source. The positions of the mth-order interference maxima from a grating are at angles given by $$d\sin\theta_m = m\lambda \qquad m = 0, 1, 2, \ldots \quad (33\text{-}26)$$ The resolving power of a grating is $$R = \frac{\lambda}{\lvert\Delta\lambda\rvert} = mN \quad (33\text{-}27)$$ where N is the number of slits of the grating that are illuminated and m is the order number.
3. *Phasors	Two or more harmonic waves can be added by representing each wave as the y component of a two-dimensional vector called a phasor. The phase difference between two harmonic waves is represented as the angle between the phasors.

Answers to Concept Checks

33-1 6

33-2 True. Fresnel diffraction is the name that describes the observations when the observing screen is any distance from the source of the diffraction. Fraunhofer diffraction is the name that describes the observations in the limit that the observing screen is far from the source of the diffraction.

Answers to Practice Problems

33-1 $9.2\ \text{cm}^{-1}$

33-2 4.4 mm

33-3 $A = 5.0\ \text{V/m}$, $\delta = 37°$

33-4 62.07° and 62.18°

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • A phase difference due to a path-length difference is observed for monochromatic visible light. Which phase difference requires the least (minimum) path-length difference? (*a*) 90°,(*b*) 180°, (*c*) 270°,(*d*) The answer depends on the wavelength of the light.

2 • Which of the following pairs of light sources are coherent: (*a*) two candles, (*b*) one point source and its image in a plane mirror, (*c*) two pinholes uniformly illuminated by the same point source, (*d*) two headlights of a car, (*e*) two images of a point source due to reflection from the front and back surfaces of a soap film?

3 • The spacing between Newton's rings decreases rapidly as the diameter of the rings increases. Explain why this result occurs. SSM

4 • If the angle of a wedge-shaped air film such as the angle in Example 33-2 is too large, fringes are not observed. Why?

5 • Why must a film that is used to observe interference colors be thin?

6 • A loop of wire is dipped in soapy water and held up so that the soap film is vertical. (*a*) Viewed by reflection using white light, the top of the film appears black. Explain why. (*b*) Below the black region are colored bands. Is the first band red or violet?

7 • A two-slit interference pattern is formed using monochromatic laser light that has a wavelength of 640 nm. At the second maximum from the central maximum, what is the path-length difference between the light coming from each of the slits? (*a*) 640 nm, (*b*) 320 nm, (*c*) 960 nm, (*d*) 1280 nm SSM

8 • A two-slit interference pattern is formed using monochromatic laser light that has a wavelength of 640 nm. At the first minimum from the central maximum, what is the path-length difference between the light coming from each of the slits? (*a*) 640 nm, (*b*) 320 nm, (*c*) 960 nm, (*d*) 1280 nm

9 • A two-slit interference pattern is formed using monochromatic laser light that has a wavelength of 450 nm. What happens to the distance between the first maximum and the central maximum as the two slits are moved closer together? (*a*) The distance increases. (*b*) The distance decreases. (*c*) The distance remains the same.

10 • A two-slit interference pattern is formed using two different monochromatic lasers, one green and one red. Which color light has its first maximum closer to the central maximum? (*a*) green, (*b*) red, (*c*) Both maxima are at the same location.

11 • A single-slit diffraction pattern is formed using monochromatic laser light that has a wavelength of 450 nm. What happens to the distance between the first maximum and the central maximum as the slit is made narrower? (*a*) The distance increases. (*b*) The distance decreases. (*c*) The distance remains the same.

12 • Equation 33-2, which is $d\sin\theta_m = m\lambda$, and Equation 33-11, which is $a\sin\theta_m = m\lambda$, are sometimes confused. For each equation, define the symbols and explain the equation's application.

13 • When a diffraction grating is illuminated by white light, the first-order maximum of green light (*a*) is closer to the central maximum than the first-order maximum of red light, (*b*) is closer to the central maximum than the first-order maximum of blue light, (*c*) overlaps the second-order maximum of red light, (*d*) overlaps the second-order maximum of blue light.

14 • A double-slit interference experiment is set up in a chamber that can be evacuated. Using light from a helium–neon laser, an interference pattern is observed when the chamber is open to air. As the chamber is evacuated, one will note that (*a*) the interference fringes remain fixed, (*b*) the interference fringes move closer together, (*c*) the interference fringes move farther apart, (*d*) the interference fringes disappear completely.

15 • True or false:

(*a*) When waves interfere destructively, the energy is converted into heat.
(*b*) Interference patterns are observed only if the relative phases of the waves that superpose remain constant.
(*c*) In the Fraunhofer diffraction pattern for a single slit, the narrower the slit, the wider the central maximum of the diffraction pattern.
(*d*) A circular aperture can produce both a Fraunhofer diffraction pattern and a Fresnel diffraction pattern.
(*e*) The ability to resolve two point sources depends on the wavelength of the light. SSM

16 • You observe two very closely spaced sources of white light through a circular opening using various filters. Which color filter is most likely to prevent your resolving the images on your retinas as coming from two distinct sources? (*a*) red, (*b*) yellow, (*c*) green, (*d*) blue, (*e*) The filter choice is irrelevant.

17 •• Explain why the ability to distinguish the two headlights of an oncoming car at a given distance is easier for a human eye at night than during the daytime. Assume the headlights of the oncoming car are on both during both daytime and nighttime hours.

ESTIMATION AND APPROXIMATION

18 • It is claimed that the Great Wall of China is the only human-made object that can be seen from space using no equipment. Check to see if this claim is true, based on the resolving power of the human eye. Assume the observers are in a low-Earth orbit that has an altitude of about 250 km.

19 •• (*a*) Estimate how close an approaching car at night on a flat, straight part of a highway must be before its headlights can be distinguished from the single headlight of a motorcycle. (*b*) Estimate how far ahead of you a car is if its two red taillights merge to look as if they were one. SSM

20 •• A small loudspeaker is located at a large distance to the east from you. The loudspeaker is driven by a sinusoidal current whose frequency can be varied. Estimate the lowest frequency for which one of your ears would receive the sound waves exactly out of phase with that received by your other ear when you are facing north.

21 •• Estimate the maximum distance at which a binary star system could be resolvable by the human eye. Assume the two stars are about fifty times farther apart than Earth and the Sun are. Neglect any atmospheric effects. (A test similar to this "eye test" was used in ancient Rome to test for eyesight acuity before entering the army. A person who had normal eyesight could just barely resolve two well-known stars that appear close in the sky. Anyone who could not tell there were two stars failed the test.) SSM

PHASE DIFFERENCE AND COHERENCE

22 • Light that has a wavelength of 500 nm is incident normally on a film of water 1.00 μm thick. (*a*) What is the wavelength of the light in the water? (*b*) How many wavelengths are contained in the distance $2t$, where t is the thickness of the film? (*c*) The film has air on both sides. What is the phase difference between the wave reflected from the front surface and the wave reflected from the back surface in the region where the two reflected waves superpose?

23 •• Two coherent microwave sources both produce waves that each have a wavelength equal to 1.50 cm. The sources are located in the $z = 0$ plane, one at $x = 0$, $y = 15.0$ cm and the other at $x = 3.00$ cm, $y = 14.0$ cm. If the sources are in phase, find the difference in phase between the two waves for a receiver located at the origin. SSM

INTERFERENCE IN THIN FILMS

24 • A wedge-shaped film of air is made by placing a small slip of paper between the edges of two flat plates of glass. Light that has a wavelength of 700 nm is incident normally on the glass plates, and interference fringes are observed by reflection. (*a*) Is the first fringe near the point of contact of the plates dark or bright? Why? (*b*) If there are five dark fringes per centimeter, what is the angle of the wedge?

25 •• The diameters of fine fibers can be accurately measured using interference patterns. Two optically flat pieces of glass that each have a length L are arranged with the fiber between them, as shown in Figure 33-40. The setup is illuminated by monochromatic light, and the resulting interference fringes are observed. Suppose that L is 20.0 cm and that yellow sodium light (590 nm) is used for illumination. If 19 bright fringes are seen along this 20.0-cm distance, what are the limits on the diameter of the fiber? *Hint: The nineteenth fringe might not be right at the end, but you do not see a twentieth fringe at all.* SSM

26 •• Light that has a wavelength equal to 600 nm is used to illuminate two glass plates at normal incidence. The plates are 22 cm in length, touch at one end, and are separated at the other end by a wire that has a radius equal to 0.025 mm. How many bright fringes appear along the total length of the plates?

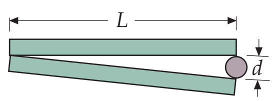

FIGURE 33-40 Problem 25

27 •• A thin film having an index of refraction of 1.50 is surrounded by air. It is illuminated normally by white light. Analysis of the reflected light shows that the wavelengths 360, 450, and 602 nm are the only missing wavelengths in or near the visible portion of the spectrum. That is, for those wavelengths, there is destructive interference. (*a*) What is the thickness of the film? (*b*) What visible wavelengths are brightest in the reflected interference pattern? (*c*) If this film were resting on glass that has an index of refraction of 1.60, what wavelengths in the visible spectrum would be missing from the reflected light?

28 •• A drop of oil (refractive index of 1.22) floats on water (refractive index of 1.33). When reflected light is observed from above, as shown in Figure 33-41, what is the thickness of the drop at the point where the second red fringe, counting from the edge of the drop, is observed? Assume red light has a wavelength of 650 nm.

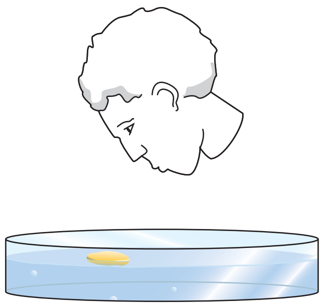

FIGURE 33-41 Problem 28

29 •• A film of oil that has an index of refraction of 1.45 rests on an optically flat piece of glass that has an index of refraction of 1.60. When illuminated by white light at normal incidence, light of wavelengths 690 nm and 460 nm is predominant in the reflected light. Determine the thickness of the oil film. SSM

30 •• A film of oil that has an index of refraction equal to 1.45 floats on water. When illuminated by white light at normal incidence, light of wavelengths 700 nm and 500 nm is predominant in the reflected light. Determine the thickness of the oil film.

NEWTON'S RINGS

31 •• A Newton's ring apparatus consists of a plano-convex glass lens that has a radius of curvature R and rests on a flat glass plate, as shown in Figure 33-42. The thin film is air of variable thickness. The apparatus is illuminated from above by light from a sodium lamp that has a wavelength equal to 590 nm. The pattern is viewed by reflected light. (*a*) Show that for a thickness t the condition for a bright (constructive) interference ring is $2t = \left(m + \frac{1}{2}\right)\lambda$, where $m = 0, 1, 2, \ldots$. (*b*) Show that for $t \ll R$, the radius r of a fringe is related to t by $r = \sqrt{2tR}$. (*c*) For a radius of curvature of 10.0 m and a lens diameter of 4.00 cm, how many bright fringes would you see in the reflected light? (*d*) What would be the diameter of the sixth bright fringe? (*e*) If the glass used in the apparatus has an index of refraction $n = 1.50$ and water replaces the air between the two pieces of glass, explain qualitatively the changes that will take place in the bright-fringe pattern. SSM

32 •• A plano-convex glass lens of radius of curvature 2.00 m rests on an optically flat glass plate. The arrangement is illuminated from above using monochromatic light that has a 520-nm wavelength. The indices of refraction of the lens and plate are 1.60. Determine the radii of the first and second bright fringe from the center in the reflected light.

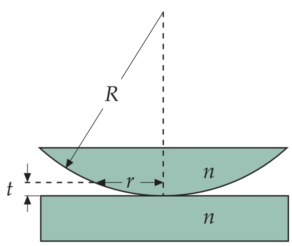

FIGURE 33-42 Problem 31

33 ••• Suppose that before the lens of Problem 32 is placed on the plate, a film of oil that has a refractive index equal to 1.82 is deposited on the plate. What will then be the radii of the first and second bright fringes?

TWO-SLIT INTERFERENCE PATTERNS

34 • Two narrow slits separated by 1.00 mm are illuminated by light that has a 600-nm wavelength, and the interference pattern is viewed on a screen 2.00 m away. Calculate the number of bright fringes per centimeter on the screen in the region near the center fringe.

35 • Using a conventional two-slit apparatus and light that has a 589-nm wavelength, 28 bright fringes per centimeter are observed near the center of a screen 3.00 m away. What is the slit separation? SSM

36 • Light that has a 633-nm wavelength and is from a helium–neon laser is shone normal to a plane having two slits. The first interference maximum is 82 cm from the central maximum on a screen 12 m away. (*a*) Find the separation of the slits. (*b*) How many interference maxima is it, in principle, possible to observe?

37 •• Two narrow slits are separated by a distance d. Their interference pattern is to be observed on a screen a large distance L away. (*a*) Calculate the spacing between successive maxima near the center fringe for light that has a 500-nm wavelength, when L is 1.00 m and d is 1.00 cm. (*b*) Would you expect to be able to observe the interference of light on the screen for this situation? (*c*) How close together should the slits be placed for the maxima to be separated by 1.00 mm for this wavelength and screen distance?

38 •• Light is incident at an angle ϕ with the normal to a vertical plane that has two slits of separation d (Figure 33-43). Show that the interference maxima are located at angles θ_m given by $\sin\theta_m + \sin\phi = m\lambda/d$.

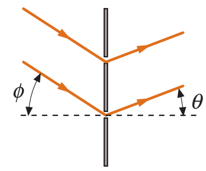

FIGURE 33-43 Problems 38 and 39

39 •• White light falls at an angle of 30° to the normal of a plane that has a pair of slits separated by 2.50 μm. What visible wavelengths give a bright interference maximum in the transmitted light in the direction normal to the plane? (See Problem 38.) SSM

40 •• Two small loudspeakers are separated by a distance of 5.0 cm, as shown in Figure 33-44. The speakers are driven in phase with a sine wave signal of frequency 10 kHz. A small microphone is placed a distance 1.00 m away from the speakers on the axis running through the middle of the two speakers, and the microphone is then moved perpendicular to the axis. Where does the microphone record the first minimum and the first maximum of the interference pattern from the speakers? The speed of sound in air is 343 m/s.

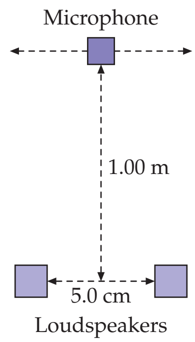

FIGURE 33-44 Problem 40

DIFFRACTION PATTERN OF A SINGLE SLIT

41 • Light that has a 600-nm wavelength is incident on a long narrow slit. Find the angle of the first diffraction minimum if the width of the slit is (*a*) 1.0 mm, (*b*) 0.10 mm, and (*c*) 0.010 mm.

42 • Plane microwaves are incident on a thin metal sheet that has a long, narrow slit of width 5.0 cm in it. The microwave radiation strikes the sheet at normal incidence. The first diffraction minimum is observed at $\theta = 37°$. What is the wavelength of the microwaves?

43 ••• Measuring the distance to the moon (lunar ranging) is routinely done by firing short-pulse lasers and measuring the time it takes for the pulses to reflect back from the moon. A pulse is fired from Earth. To send the pulse out, the pulse is expanded so that it fills the aperture of a 6.00-in-diameter telescope. Assuming the only thing spreading the beam out is diffraction and that the light wavelength is 500 nm, how large will the beam be when it reaches the moon, 3.82×10^5 km away? SSM

INTERFERENCE–DIFFRACTION PATTERN OF TWO SLITS

44 • How many interference maxima will be contained in the central diffraction maximum in the interference–diffraction pattern of two slits if the separation of the slits is exactly 5 times their width? How many will there be if the slit separation is an integral multiple of the slit width (that is, $d = na$ for any value of n)?

45 •• A two-slit Fraunhofer interference–diffraction pattern is observed using light that has a wavelength equal to 500 nm. The slits have a separation of 0.100 mm and an unknown width. (*a*) Find the width if the fifth interference maximum is at the same angle as the first diffraction minimum. (*b*) For that case, how many bright interference fringes will be seen in the central diffraction maximum? SSM

46 •• A two-slit Fraunhofer interference–diffraction pattern is observed using light that has a wavelength equal to 700 nm. The slits have widths of 0.010 mm and are separated by 0.20 mm. How many bright fringes will be seen in the central diffraction maximum?

47 •• Suppose that the *central* diffraction maximum for two slits has 17 interference fringes for some wavelength of light. How many interference fringes would you expect in the diffraction maximum adjacent to one side of the central diffraction maximum?

48 •• Light that has a wavelength equal to 550 nm illuminates two slits that both have widths equal to 0.030 mm and separations equal to 0.15 mm. (*a*) How many interference maxima fall within the full width of the central diffraction maximum? (*b*) What is the ratio of the intensity of the third interference maximum to one side of the center interference maximum to the intensity of the center interference maximum?

*USING PHASORS TO ADD HARMONIC WAVES

49 • Find the resultant of the two waves whose electric fields at a given location vary with time as follows: $\vec{E}_1 = 2.0A_0 \sin\omega t\hat{i}$ and $\vec{E}_2 = 3.0A_0 \sin\left(\omega t + \frac{3}{2}\pi\right)\hat{i}$. SSM

50 • Find the resultant of the two waves whose electric fields at a given location vary with time as follows: $\vec{E}_1 = 4.0A_0 \sin\omega t\hat{i}$ and $\vec{E}_2 = 3.0A_0 \sin\left(\omega t + \frac{1}{6}\pi\right)\hat{i}$.

51 •• Monochromatic light is incident on a sheet with a long narrow slit (Figure 33-45). Let I_0 be the intensity at the central maximum of the diffraction pattern on a distant screen, and let I be the intensity at the second intensity maximum from the central intensity maximum. The distance from this second intensity maximum to the far edge of the slit is longer than the distance from the second intensity maximum to the near edge of the slit by approximately 2.5 wavelengths. What is the ratio of I to I_0?

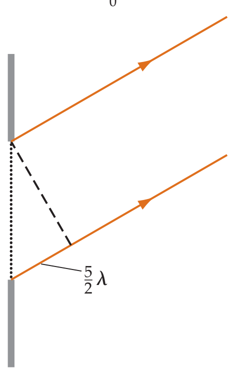

FIGURE 33-45 Problem 51

52 •• Monochromatic light is incident on a sheet that has three long narrow parallel equally spaced slits a distance d apart. (*a*) Show that the positions of the interference minima on a screen a large distance L away from the sheet that has the three equally spaced slits (spacing d, with $d \gg \lambda$) are given approximately by $y_m = m\lambda L/3d$, where $m = 1, 2, 4, 5, 7, 8, 10, \ldots$, that is, m is *not* a multiple of 3. (*b*) For a screen distance of 1.00 m, a light wavelength of 500 nm, and a source spacing of 0.100 mm, calculate the width of the principal interference maxima (the distance between successive minima) for three sources.

53 •• Monochromatic light is incident on a sheet that has four long narrow parallel equally spaced slits a distance d apart. (*a*) Show that the positions of the interference minima on a screen a large distance L away from the sheet that has the four equally spaced slits (spacing d, with $d \gg \lambda$) are given approximately by $y_m = m\lambda L/4d$, where $m = 1, 2, 3, 5, 6, 7, 9, 10, \ldots$, that is, m is *not* a multiple of 4. (*b*) For a screen distance of 2.00 m, a light wavelength of 600 nm, and a source spacing of 0.100 mm, calculate the width of the principal interference maxima (the distance between successive minima) for four sources. Compare the width with that for two sources with the same spacing. SSM

54 •• Light that has a wavelength equal to 480 nm falls normally on four slits. Each slit is 2.00 μm wide and the center-to-center separation between it and the next slit is 6.00 μm. (*a*) Find the angular width of the central intensity maximum of the single-slit diffraction pattern on a distant screen. (*b*) Find the angular position of all interference intensity maxima that lie inside the central diffraction maximum. (*c*) Find the angular width of the central interference maximum. That is, find the angle between the first interference intensity minima on either side of the central interference maximum. (*d*) Sketch the relative intensity as a function of the sine of the angle.

55 ••• Three slits, each separated from its neighbor by 60.0 μm, are illuminated at the central intensity maximum by a coherent light source that has a wavelength equal to 550 nm. The slits are extremely narrow. A screen is located 2.50 m from the slits. The intensity is 50.0 mW/m^2. Consider a location 1.72 cm from the central maximum. (*a*) Draw a phasor diagram suitable for the addition of the three harmonic waves at that location. (*b*) From the phasor diagram, calculate the intensity of light at that location. SSM

56 ••• In single-slit Fraunhofer diffraction, the intensity pattern (Figure 33-11) consists of a broad central maximum with a sequence of secondary maxima to either side of the central maximum. The intensity is given by $I = I_0\left(\frac{\sin\frac{1}{2}\phi}{\frac{1}{2}\phi}\right)^2$, where ϕ is the phase difference between the wavelets arriving from the opposite edges of the slits. Calculate the values of ϕ for the first three seconday maxima to one side of the central maximum by finding the values of ϕ for which $dI/d\phi$ is equal to zero. Check your results by comparing your answers with approximate values for ϕ of 3π, 5π and 7π. (That these values for ϕ are approximatly correct at the secondary intensity maxima is discussed in the discussion surrounding Figure 33-27.)

DIFFRACTION AND RESOLUTION

57 • Light that has a wavelength equal to 700 nm is incident on a pinhole of diameter 0.100 mm. (*a*) What is the angle between the central maximum and the first diffraction minimum for a Fraunhofer diffraction pattern? (*b*) What is the distance between the central maximum and the first diffraction minimum on a screen 8.00 m away? SSM

58 • Two sources of light that both have wavelengths equal to 700 nm are 10.0 m away from the pinhole of Problem 57. How far apart must the sources be for their diffraction patterns to be resolved by Rayleigh's criterion?

59 • Two sources of light that both have wavelengths equal to 700 nm are separated by a horizontal distance x. They are 5.00 m from a vertical slit of width 0.500 mm. What is the smallest value of x for which the diffraction pattern of the sources can be resolved by Rayleigh's criterion?

60 •• The ceiling of your lecture hall is probably covered with acoustic tile, which has small holes separated by about 6.0 mm. (*a*) Using light that has a wavelength of 500 nm, how far could you be from this tile and still resolve the holes? Assume the diameter of the pupil of each of your eyes is about 5.0 mm. (*b*) Could you resolve the holes better using red light or violet light? Explain your answer.

61 •• The telescope on Mount Palomar has a diameter of 200 in. Suppose a double star were 4.00 light-years away. Under ideal conditions, what must be the minimum separation of the two stars for their images to be resolved using light that has a wavelength equal to 550 nm? SSM

62 •• The star Mizar in Ursa Major is a binary system of stars that have nearly equal magnitudes. The angular separation between the two stars is 14 seconds of arc. What is the minimum diameter of the pupil that allows resolution of the two stars using light that has a wavelength equal to 550 nm?

*DIFFRACTION GRATINGS

63 • A diffraction grating that has 2000 slits per centimeter is used to measure the wavelengths emitted by hydrogen gas. (*a*) At what angles in the first-order spectrum would you expect to find the two violet lines that have wavelengths of 434 nm and 410 nm? (*b*) What are the angles if the grating has 15 000 slits per centimeter? SSM

64 • Using a diffraction grating that has 2000 slits per centimeter, two lines in the first-order hydrogen spectrum are found at angles of 9.72×10^{-2} rad and 1.32×10^{-1} rad. What are the wavelengths of the lines?

65 • The colors of many butterfly wings and beetle carapaces are due to the effects of diffraction. The *Morpho* butterfly has structural elements on its wings that effectively act as a diffraction grating that has an 880-nm spacing. At what angle will the first diffraction maximum occur for normally incident light diffracted by the butterfly's wings? Assume the light is blue and has a wavelength of 440 nm.

66 •• A diffraction grating that has 2000 slits per centimeter is used to analyze the spectrum of mercury. (*a*) Find the angular separation in the first-order spectrum of the two lines that have wavelengths equal to 579 nm and 577 nm. (*b*) How wide must the beam on the grating be for the lines to be resolved?

67 •• A diffraction grating that has 4800 lines per centimeter is illuminated at normal incidence using white light (wavelength range of 400 nm to 700 nm). How many orders of complete spectra can one observe in the transmitted light? Do any of these orders overlap? If so, describe the overlapping regions. SSM

68 •• A square diffraction grating that has an area of 25.0 cm^2 has a resolution of 22 000 in the fourth order. At what angle should you look to see a wavelength of 510 nm in the fourth order?

69 •• Sodium light that has a wavelength equal to 589 nm falls normally on a 2.00-cm-square diffraction grating ruled with 4000 lines per centimeter. The Fraunhofer diffraction pattern is projected onto a screen a distance of 1.50 m from the grating by a 1.50-m-focal-length lens that is placed immediately in front of the grating. Find (*a*) the distances of the first and second order intensity maxima from the central intensity maximum, (*b*) the width of the central maximum, and (*c*) the resolution in the first order. (Assume the entire grating is illuminated.)

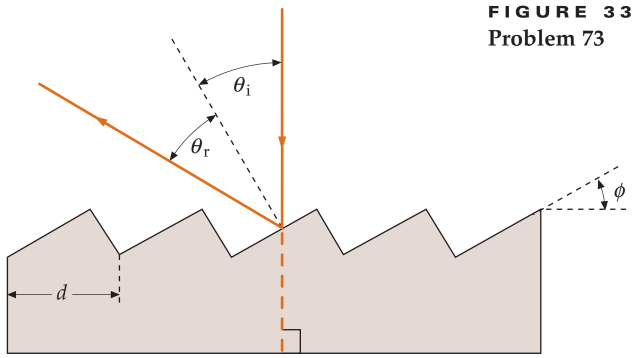
70 •• The spectrum of neon is exceptionally rich in the visible region. Among the many lines are two lines at wavelengths of 519.313 nm and 519.322 nm. If light from a neon discharge tube is normally incident on a transmission grating that has 8400 lines per centimeter and the spectrum is observed in second order, what must be the width of the grating that is illuminated, so that the two lines can be resolved?

71 •• Mercury has several stable isotopes, among them ^{198}Hg and ^{202}Hg. The strong spectral line of mercury, at about 546.07 nm, is a composite of spectral lines from the various mercury isotopes. The wavelengths of the line for ^{198}Hg and ^{202}Hg are 546.07532 nm and 546.07355 nm, respectively. What must be the resolving power of a grating capable of resolving the two isotopic lines in the third-order spectrum? If the grating is illuminated over a 2.00-cm-wide region, what must be the number of lines per centimeter of the grating? SSM

72 ••• A diffraction grating has n lines per unit length. Show that the angular separation ($\Delta\theta$) of two lines of wavelengths λ and $\lambda + \Delta\lambda$ is approximately $\Delta\theta = \Delta\lambda / \sqrt{\dfrac{1}{n^2 m^2} - \lambda^2}$, where m is the order number.

73 ••• For a diffraction grating in which all the surfaces are normal to the incident radiation, most of the energy goes into the zeroth order, which is useless from a spectroscopic point of view, because in zeroth order all the wavelengths are at 0°. Therefore, modern reflection gratings have shaped, or *blazed*, grooves, as shown in Figure 33-46. This shifts the specular reflection, which contains most of the energy, from the zeroth order to some higher order. (*a*) Calculate the *blaze angle* ϕ_m in terms of the groove separation d, the wavelength λ, and the order number m in which specular reflection is to occur for $m = 1, 2, \ldots$. (*b*) Calculate the proper blaze angle for the specular reflection to occur in the second order for light of wavelength 450 nm incident on a grating with 10 000 lines per centimeter. SSM

FIGURE 33-46 Problem 73



74 ••• In this problem, you will derive the relation $R = \lambda/|\Delta\lambda| = mN$ (Equation 33-27) for the resolving power of a diffraction grating having N slits separated by a distance d. To do this, you will calculate the angular separation between the intensity maximum and intensity minimum for some wavelength λ and set it equal to the angular separation of the mth-order maximum for two nearby wavelengths. (*a*) First show that the phase difference ϕ waves between the waves from two adjacent slits is given by $\phi = \dfrac{2\pi d}{\lambda}\sin\theta$. (*b*) Next, differentiate that expression to show that a small change in angle $d\theta$ results in a change in phase of $d\phi$ given by $d\phi = \dfrac{2\pi d}{\lambda}\cos\theta\, d\theta$. (*c*) Then for N slits, the angular separation between an interference maximum and an interference minimum corresponds to a phase change of $d\phi = 2\pi/N$. Use that to show that the angular separation $d\theta$ between the intensity maximum and intensity minimum for some wavelength λ is given by $d\theta = \dfrac{\lambda}{Nd\cos\theta}$. (*d*) Next, use the fact that the angle of the mth-order interference maximum for wavelength λ is specified by $d\sin\theta = m\lambda$ (Equation 33-26). Compute the differential of each side of the equation to show that angular separation of the mth-order

maximum for two nearly equal wavelengths differing by $d\lambda$ is given by $d\theta = \frac{m\, d\lambda}{d\cos\theta}$. (*e*) According to Rayleigh's criterion, two wavelengths will be resolved in the mth order if the angular separation of the wavelengths, given by the Part (*d*) result, equals the angular separation of the interference maximum and the interference minimum given by the Part (*c*) result. Use this to arrive at $R = \lambda/|\Delta\lambda| = mN$ (Equation 33-27) for the resolving power of a grating.

GENERAL PROBLEMS

75 • Naturally occuring coronas (brightly colored rings) are sometimes seen around the moon or the Sun when viewed through a thin cloud. (Warning: When viewing a Sun corona, be sure that the entire Sun is blocked by the edge of a building, a tree, or a traffic pole to safeguard your eyes.) These coronas are due to diffraction of light by small water droplets in the cloud. A typical angular diameter for a coronal ring is about 10°. From this, estimate the size of the water droplets in the cloud. Assume that the water droplets can be modeled as opaque disks that have the same radius as the droplet, and that the Fraunhofer diffraction pattern from an opaque disk is the same as the pattern from an aperture of the same diameter. (This last statement is known as *Babinet's principle*.) SSM

76 • An artificial corona (see Problem 75) can be made by placing a suspension of polystyrene microspheres in water. Polystyrene microspheres are small, uniform spheres that are made of plastic and have indices of refraction equal to 1.59. Assuming that the water has an index of refraction equal to 1.33, what is the angular diameter of such an artificial corona if 5.00-μm-diameter particles are illuminated by light from a helium–neon laser that has a wavelength in air of 632.8 nm?

77 • Coronas (see Problem 75) can be caused by pollen grains, typically of birch or pine. Such grains are irregular in shape, but they can be treated as if they had an average diameter of about 25 μm. What is the angular diameter (in degrees) of the corona for blue light? What is the angular diameter (in degrees) of the corona for red light?

78 • Light from a He–Ne laser (632.8 nm) is directed upon a human hair, in an attempt to measure its diameter by examining the diffraction pattern. The hair is mounted in a frame 7.5 m from a wall, and the central diffraction maximum is measured to be 14.6 cm wide. What is the diameter of the hair? (The diffraction pattern of a hair that has a diameter d is the same as the diffraction pattern of a single slit that has a width $a = d$. See Babinet's principle discussed in Problem 75.)

79 • A long, narrow horizontal slit lies 1.00 μm above a plane mirror, which is in the horizontal plane. The interference pattern produced by the slit and its image is viewed on a screen 1.00 m from the slit. The wavelength of the light is 600 nm. (*a*) Find the distance from the mirror to the first maximum. (*b*) How many dark bands per centimeter are seen on the screen? SSM

80 • A radio telescope is situated at the edge of a lake. The telescope is looking at light from a radio galaxy that is just rising over the horizon. If the height of the antenna is 20 m above the surface of the lake, at what angle above the horizon will the radio galaxy be when the telescope is centered in the first intensity interference maximum of the radio waves? Assume the wavelength of the radio waves is 20 cm. *Hint: The interference is caused by the light reflecting off the lake and remember that this reflection will result in a 180° phase shift.*

81 • The diameter of the radio telescope at Arecibo, Puerto Rico, is 300 m. What is the smallest angular separation of two objects that this telescope can detect when it is tuned to detect microwaves of 3.2-cm wavelength?

82 •• A thin layer of a transparent material that has an index of refraction of 1.30 is used as a nonreflective coating on the surface of glass that has an index of refraction of 1.50. What should the minimum thickness of the material be for the material to be nonreflecting for light that has a wavelength of 600 nm?

83 •• A *Fabry–Perot interferometer* (Figure 33-47) consists of two parallel, half-silvered mirrors that face each other and are separated by a small distance a. A half-silvered mirror is one that transmits 50% of the incident intensity and reflects 50% of the incident intensity. Show that when light is incident on the interferometer at an angle of incidence θ, the transmitted light will have maximum intensity when $2a = m\lambda\cos\theta$. SSM

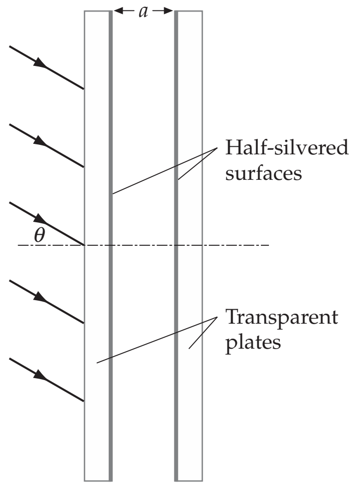


FIGURE 33-47 Problem 83

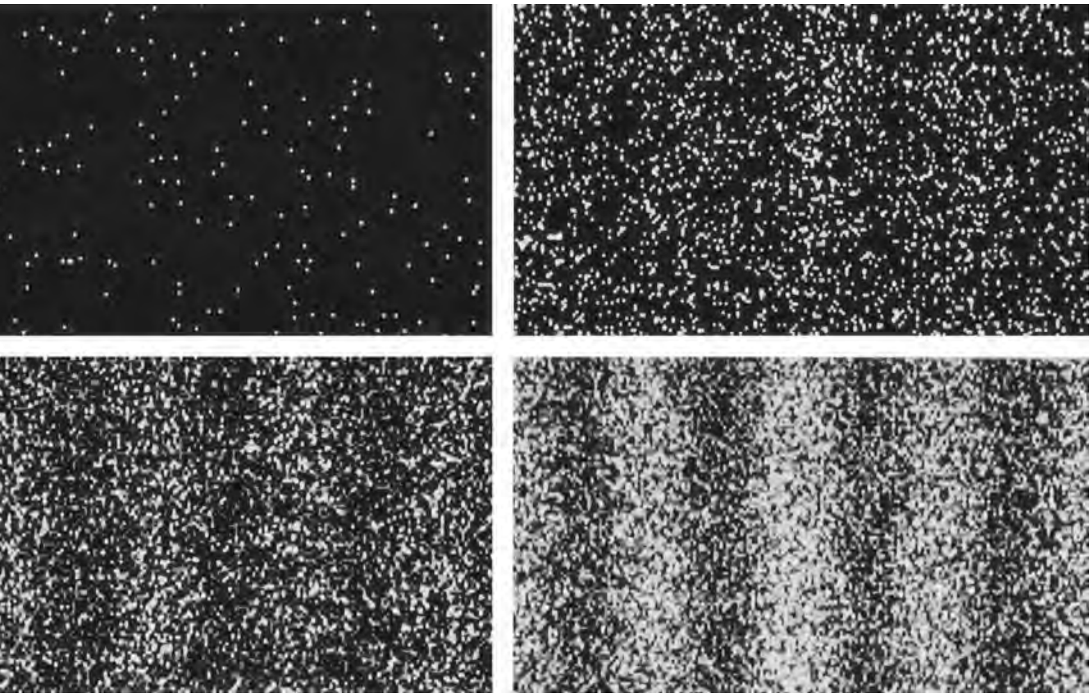
84 •• A mica sheet that is 1.20 μm thick is suspended in air. In reflected light, there are gaps in the visible spectrum at 421, 474, 542, and 633 nm. Find the index of refraction of the mica sheet.

85 •• A camera lens is made of glass that has an index of refraction of 1.60. This lens is coated with a magnesium fluoride film (index of refraction equal to 1.38) to enhance its light transmission. The purpose of this film is to produce zero reflection for light that has a wavelength of 540 nm. Treat the lens surface as a flat plane and the film as a uniformly thick flat film. (*a*) What minimum thickness of this film will accomplish its objective? (*b*) Would there be destructive interference for any other visible wavelengths? (*c*) By what factor would the reflection for light of 400 nm wavelength be reduced by the presence of this film? Neglect the variation in the reflected light amplitudes from the two surfaces. SSM

86 •• In a pinhole camera, the image is fuzzy because of geometry (rays arrive at the film after passing through different parts of the pinhole) and because of diffraction. As the pinhole is made smaller, the fuzziness due to geometry is reduced, but the fuzziness due to diffraction is increased. The optimum size of the pinhole for the sharpest possible image occurs when the spread due to diffraction equals the spread due to the geometric effects of the pinhole. Estimate the optimum size of the pinhole if the distance from the pinhole to the film is 10.0 cm and the wavelength of the light is 550 nm.

87 •• The Impressionist painter Georges Seurat used a technique called *pointillism*, in which his paintings are composed of small, closely spaced dots of pure color, each about 2.0 mm in diameter. The illusion of the colors blending together smoothly is produced in the eyes of the viewer by diffraction effects. Calculate the minimum viewing distance for this effect to work properly. Use the wavelength of visible light that requires the *greatest* distance between dots, so that you are sure the effect will work for *all* visible wavelengths. Assume the pupil of the eye has a diameter of 3.0 mm. SSM

PART VI MODERN PHYSICS: Quantum Mechanics, Relativity, and the Structure of Matter



CHAPTER 34

Wave–Particle Duality and Quantum Physics

ELECTRON INTERFERENCE PATTERN PRODUCED BY ELECTRONS INCIDENT ON A BARRIER CONTAINING TWO SLITS: (*A*) 10 ELECTRONS, (*B*) 100 ELECTRONS, (*C*) 3000 ELECTRONS, AND (*D*) 70,000 ELECTRONS. THE MAXIMA AND MINIMA DEMONSTRATE THE WAVE NATURE OF THE ELECTRON AS IT TRAVERSES THE SLITS. INDIVIDUAL DOTS ON THE SCREEN INDICATE THE PARTICLE NATURE OF THE ELECTRON AS IT EXCHANGES ENERGY WITH THE DETECTOR. THE PATTERN IS THE SAME WHETHER ELECTRONS OR PHOTONS (PARTICLES OF LIGHT) ARE USED. *(Courtesy of Akira Tononmura, Advanced Research Laboratory, Hitachi, Ltd.)*

? How do you calculate the wavelength of an electron? (See Example 34-4.)

At the beginning of the twentieth century, it was thought that sound, light, and other electromagnetic radiation (such as radio waves) were waves, and electrons, protons, atoms, and similar units were particles. The first 30 years of that century revealed startling developments in theoretical and experimental physics, such as the finding that light actually exchanges energy in discrete lumps or quanta, just like particles, and the finding that an electron exhibits diffraction and interference as it propagates through space, just like a wave. The fact that light exchanges energy like a particle implies that light energy is not continuous but is *quantized*. Similarly, the wave nature of the electron, along with the fact that the standing wave condition requires a discrete set of frequencies, implies that the energy of an electron in a confined region of space is not continuous, but is quantized to a discrete set of values.

In this chapter, we begin by discussing some basic properties of light and electrons, examining their wave and particle characteristics. We then consider some of the detailed properties of matter waves, showing, in particular, how standing waves imply the quantization of energy. Finally, we discuss some of the important features of the theory of quantum physics, which was developed in the 1920s and which has been extremely successful in describing nature. Quantum physics is now the basis of our understanding of both atomic and subatomic systems and systems that have very low temperatures.

34-1 WAVES AND PARTICLES

We have seen that the propagation of waves through space is quite different from the propagation of particles. Waves bend around corners (diffraction) and interfere with one another, producing interference patterns. If a wave encounters a small aperture, the wave spreads out on the other side as if the aperture were a point source. The propagation of particles is quite unlike the propagation of waves. Particles travel in straight lines until they collide with something, after which the particles again travel in straight lines. If two particle beams meet in space, they never produce an interference pattern.

Particles and waves also exchange energy differently. Particles exchange energy in collisions that occur at specific points in space and in time. The energy of waves, on the other hand, is spread out in space and deposited continuously as the wave fronts interact with matter.

Sometimes the propagation of a wave cannot be distinguished from the propagation of a beam of particles. If the wavelength λ is very small compared to distances from the edges of objects, diffraction effects are negligible and the wave travels in straight lines. Also, interference maxima and minima are so close together in space as to be unobservable. The result is that the wave interacts with a detector, like a beam of numerous small particles each exchanging a small amount of energy; the exchange cannot distinguish particles from waves. For example, you do not observe the individual air molecules bouncing off your face if the wind blows on it. Instead, the interaction of billions of particles appears to be continuous, like that of a wave.

34-2 LIGHT: FROM NEWTON TO MAXWELL

The question of whether light consists of a beam of particles or waves in motion is one of the most interesting in the history of science (see Chapter 31). Isaac Newton used a particle theory of light to explain the laws of reflection and refraction; however, for refraction, Newton needed to assume that light travels faster in water or glass than in air, an assumption later shown to be incorrect. The chief early proponents of the wave theory were Robert Hooke and Christian Huygens, who explained refraction by assuming that light travels more slowly in glass or water than it does in air.* Newton favored the theory that light consists of particles and does not consist of waves because, in his time, light was believed to travel through a medium only in straight lines—diffraction had not yet been observed.

Because of Newton's great reputation and authority, his particle theory of light was accepted for more than a century. Then, in 1801, Thomas Young demonstrated the wave nature of light in a famous experiment in which two coherent light sources are produced by illuminating a pair of narrow, parallel slits with a single source (Figure 34-1*a*).† In Chapter 33, we saw that when light encounters a small opening, the opening acts as a point source of waves (Figure 33-7). In Young's experiment, each slit acts as a line source, which is equivalent to a point source in two dimensions.‡ The interference pattern is observed on a screen placed behind the slits. Interference maxima occur at angles so that the path difference is an integral number of wavelengths. Similarly, interference minima occur if the path difference is one-half the wavelength or any odd number of half wavelengths. Figure 34-1*b* shows the intensity pattern as seen on the screen. Remember that if two coherent waves of equal intensity I_0 meet in space, the result can be a wave of intensity $4I_0$ (constructive interference), an intensity of zero (destructive interference), or a wave of intensity between zero and $4I_0$, depending on the phase difference between the waves at the observation point. Young's experiment and many other experiments demonstrate that light propagates like a wave.

In the early nineteenth century, the French physicist Augustin Fresnel (1788–1827) performed extensive experiments on interference and diffraction and put the wave theory on a rigorous mathematical basis. Fresnel showed that the observed straight-line propagation of light is a result of the very short wavelengths of visible light.

The classical wave theory of light culminated in 1860 when James Clerk Maxwell published his mathematical theory of electromagnetism. This theory yielded a wave equation that predicted the existence of electromagnetic waves that propagate with a speed that can be calculated from the laws of electricity and magnetism.# The fact that the result of this calculation was $c \approx 3 \times 10^8$ m/s, the same as the speed of light, suggested to Maxwell that light is an electromagnetic wave. The eye is sensitive to electromagnetic waves that have wavelengths in the range from approximately 400 nm (1 nm = 10^{-9} m) to approximately 700 nm. This range is called *visible light*. Other electromagnetic waves (for example, microwave waves, radio waves, and X rays) differ from visible light waves only in wavelength and in frequency.

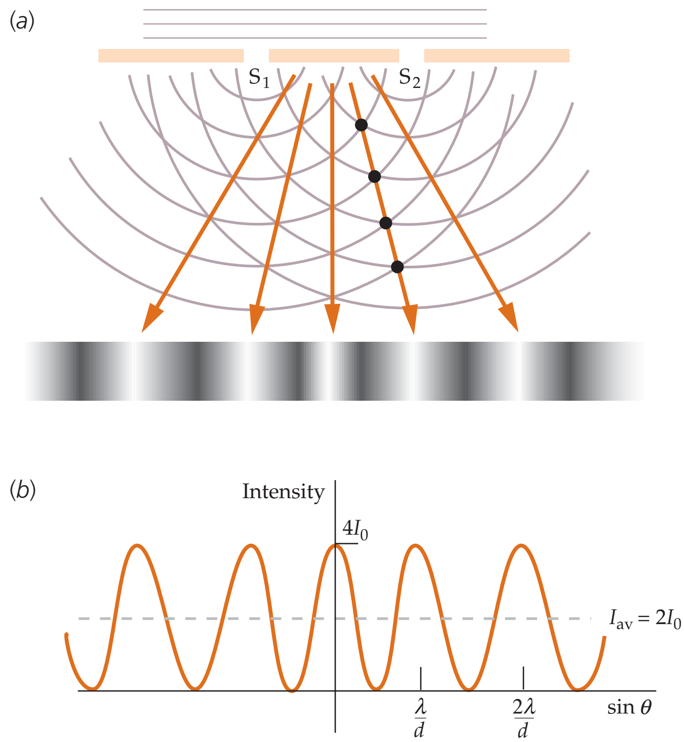


FIGURE 34-1 (*a*) Two slits act as coherent sources of light for the observation of interference in Young's experiment. Cylindrical waves from the slits overlap and produce an interference pattern on a screen far away. (*b*) The intensity pattern produced in Figure 34-1*a*. The intensity is maximum at points where the path difference is an even number of half wavelengths, and the intensity is zero where the path difference is an odd number of half wavelengths.

34-3 THE PARTICLE NATURE OF LIGHT: PHOTONS

The diffraction of light and the existence of an interference pattern in the two-slit experiment give clear evidence that light has wave properties. However, early in the twentieth century, it was found that light energy comes in discrete amounts.

THE PHOTOELECTRIC EFFECT

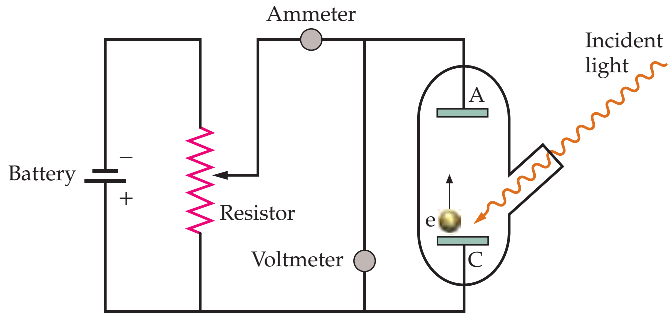

FIGURE 34-2 A schematic drawing of the apparatus for studying the photoelectric effect. Light of a single frequency enters an evacuated chamber and strikes the cathode C, which then ejects electrons (electron in figure is not drawn to scale). The current in the ammeter measures the number of these electrons that reach the anode A per unit time. The anode is made electrically negative with respect to the cathode to repel the electrons. Only those electrons that have enough initial kinetic energy to overcome the repulsion can reach the anode. The voltage between the two plates is slowly increased until the current becomes zero, which happens when even the most energetic electrons do not make it to plate A.

The quantum nature of light and the quantization of energy were suggested by Albert Einstein in 1905 in his explanation of the photoelectric effect. Einstein's work marked the beginning of quantum theory, and for his work, Einstein received the Nobel Prize in Physics. Figure 34-2 shows a schematic diagram of the basic apparatus for studying the photoelectric effect. Light of a single frequency enters an evacuated chamber and falls on a clean metal surface C (C for cathode), causing electrons to be emitted. Some of these electrons strike the second metal plate A (A for anode), constituting an electric current between the plates. Plate A is negatively charged, so the electrons are repelled by it, with only the most energetic electrons reaching plate A. The maximum kinetic energy of the emitted electrons is measured by slowly increasing the voltage until the current becomes zero. Experiments give the surprising result that the maximum kinetic energy of the emitted electrons is *independent of the intensity* of the incident light. Classically, we would expect that increasing the rate at which light energy falls on the metal surface would increase the energy absorbed by individual electrons and, therefore, would increase the maximum kinetic energy of the electrons emitted. Experiments show that this classical result does not happen. The maximum kinetic energy of the emitted electrons is the same for a given wavelength of incident light, no matter how intense the light is. Einstein demonstrated that this experimental result can be explained if light energy is quantized in small bundles called **photons.** The energy E of each photon is given by

$$E = hf = \frac{hc}{\lambda} \qquad 34\text{-}1$$

EINSTEIN EQUATION FOR PHOTON ENERGY

where f is the frequency, and h is a constant now known as **Planck's constant.*** The measured value of this constant is

$$h = 6.626 \times 10^{-34}\,\text{J}\cdot\text{s} = 4.136 \times 10^{-15}\,\text{eV}\cdot\text{s} \qquad 34\text{-}2$$

PLANCK'S CONSTANT

Equation 34-1 is sometimes called the **Einstein equation.**

A light beam consists of a beam of particles—photons—each having energy hf. The intensity (power per unit area) of a monochromatic light beam is the number of photons per unit area per unit of time, multiplied by the energy per photon. The interaction of the light beam with the metal surface consists of collisions between photons and electrons. During each of these collisions, the photon gives all its energy to an electron and the photon no longer exists. The electron is emitted from the surface after it receives the energy from a single photon. If the intensity of light is increased, more photons fall on the surface per unit time, and more electrons are emitted per unit time. However, each photon still has the same energy hf, so the energy absorbed by each electron is unchanged.

* In 1900, the German physicist Max Planck introduced this constant to explain discrepancies between the theoretical curves and experimental data on the spectrum of blackbody radiation. Planck also assumed that the radiation was emitted and absorbed by a blackbody in quanta of energy hf, but he considered his assumption to be just a computational device rather than a fundamental property of electromagnetic radiation. (Blackbody radiation is discussed in Chapter 20.)

If ϕ is the minimum energy necessary to remove an electron from a metal surface, the maximum kinetic energy of the electrons emitted is given by

$$K_{max} = \left(\tfrac{1}{2}mv^2\right)_{max} = hf - \phi \qquad 34\text{-}3$$

EINSTEIN'S PHOTOELECTRIC EQUATION

where f is the frequency of the photons. The quantity ϕ, called the **work function,** is a characteristic of the particular metal. (Some electrons will have kinetic energies less than $hf - \phi$, because of the loss of energy from traveling through the metal.)

According to Einstein's photoelectric equation, a plot of K_{max} versus frequency f should be a straight line that has the slope h. This was a bold prediction, because, at the time, no evidence existed that Planck's constant had any application outside of blackbody radiation. In addition, there was no experimental data on K_{max} versus frequency f, because no one before had even suspected that the frequency of the light was related to K_{max}. This prediction was difficult to verify experimentally, but careful experiments by R. A. Millikan approximately 10 years later showed that Einstein's equation was correct. Figure 34-3 shows a plot of Millikan's data.

Photons that have frequencies less than a **threshold frequency** f_t, and therefore have wavelengths greater than a **threshold wavelength** $\lambda_t = c/f_t$, do not have enough energy to eject an electron from a particular metal. The threshold frequency and the corresponding threshold wavelength can be related to the work function ϕ by setting the maximum kinetic energy of the electrons equal to zero in Equation 34-3. Then

$$\phi = hf_t = \frac{hc}{\lambda_t} \qquad 34\text{-}4$$

Work functions for metals are typically a few electron volts. Because wavelengths are usually given in nanometers and energies in electron volts, it is useful to have the value of hc in electron volt–nanometers:

$$hc = (4.1357 \times 10^{-15}\ \text{eV}\cdot\text{s})(2.9979 \times 10^{8}\ \text{m/s}) = 1.240 \times 10^{-6}\ \text{eV}\cdot\text{m}$$

or

$$hc = 1240\ \text{eV}\cdot\text{nm} \qquad 34\text{-}5$$

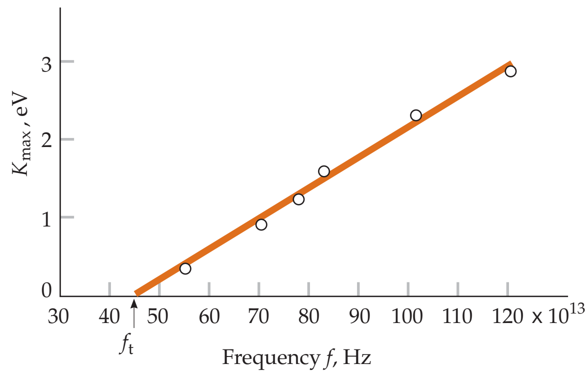

FIGURE 34-3 Millikan's data for the maximum kinetic energy K_{max} versus frequency f for the photoelectric effect. The data fall on a straight line that has a slope h, as predicted by Einstein approximately a decade before the experiment was performed.

Example 34-1 Photon Energies for Visible Light

Calculate the photon energies for light that has a wavelength equal to 400 nm (violet) and light that has a wavelength equal to 700 nm (red). (The wavelengths of 400 nm and 700 nm are the approximate wavelengths for the two extremes of the visible light spectrum.)

PICTURE Photon energies are related to photon frequencies and wavelengths by $E = hf = hc/\lambda$ (Equation 34-1).

SOLVE

1. The energy is related to the wavelength by Equation 34-1: $E = hf = \dfrac{hc}{\lambda}$

2. For $\lambda = 400$ nm, the energy is $E = \dfrac{hc}{\lambda} = \dfrac{1240\ \text{eV}\cdot\text{nm}}{400\ \text{nm}} = \boxed{3.10\ \text{eV}}$

3. For $\lambda = 700$ nm, the energy is $E = \dfrac{hc}{\lambda} = \dfrac{1240\ \text{eV}\cdot\text{nm}}{700\ \text{nm}} = \boxed{1.77\ \text{eV}}$

CHECK The shorter the wavelength of light, the greater the energy and 3.10 eV for 400 nm is greater than 1.77 eV for 700 nm.

TAKING IT FURTHER We can see from these calculations that visible light has photons that have energies which range from approximately 1.8 eV to 3.1 eV. X rays, which have much shorter wavelengths, have photons that have energies of the order of keV. Gamma rays emitted by nuclei have even shorter wavelengths and photons that have energies of the order of MeV.

PRACTICE PROBLEM 34-1 Find the energy of a photon corresponding to electromagnetic radiation in the FM radio band of wavelength 3.00 m.

PRACTICE PROBLEM 34-2 Find the wavelength of a photon whose energy is (*a*) 0.100 eV, (*b*) 1.00 keV, and (*c*) 1.00 MeV.

Example 34-2 The Number of Photons per Second in Sunlight

Try It Yourself

The intensity of sunlight at Earth's surface is approximately 1400 W/m^2. Assuming the average photon energy is 2.00 eV (corresponding to a wavelength of approximately 600 nm), calculate the number of photons that strike an area of 1.00 cm^2 each second.

PICTURE The intensity (power per unit area) is given, as is the area. From these given quantities, we can calculate the power, which is the energy per unit time.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. The energy ΔE is related to the number N of photons and the energy per photon $hf = 2.00$ eV:	$\Delta E = Nhf$
2. The intensity I (power per unit area) and the area A are given, so we can find the power:	$I = \dfrac{P}{A}$
3. Knowing the power (energy per unit time) and the time, we can find the energy:	$\Delta E = P\Delta t$
4. Combine the results from steps 1–3 and solve for N (take care to get the units to cancel):	$N = \boxed{4.38 \times 10^{17}}$

CHECK This is an enormous number of photons. However, in everyday situations we do not notice that the energy of sunlight arrives in discrete amounts. Thus, an enormous number is expected.

PRACTICE PROBLEM 34-3 Calculate the photon density (in photons per cubic centimeter) of the sunlight in Example 34-2. The number arriving on an area of 1.00 cm^2 in one second is the number in a column whose cross section is 1.00 cm^2 and whose height is the distance light travels in one second.

COMPTON SCATTERING

The first use of the photon concept was to explain the results of photoelectric-effect experiments. In the photoelectric effect, all the energy of the photon is transferred to an electron. However, in Compton scattering only some of the energy of the photon is transferred to an electron. The photon concept was also used by Arthur H. Compton to explain the results of his measurements of the scattering of X rays by free electrons in 1923. According to classical theory, if an electromagnetic wave of frequency f_i is incident on material containing free charges, the charges will oscillate with this frequency and reradiate electromagnetic waves of the same frequency.

Compton considered these reradiated waves as scattered photons, and he pointed out that if the scattering process were a collision between a photon and an electron (Figure 34-4), the electron would recoil and thus absorb energy. The scattered photon would then have less energy, and therefore a lower frequency and longer wavelength, than the incident photon.

According to classical electromagnetic theory (see Section 30-3), the energy and momentum of an electromagnetic wave are related by

$$E = pc \tag{34-6}$$

The momentum of a photon is thus related to its wavelength λ by $p = E/c = hf/c = h/\lambda$.

$$p = \frac{h}{\lambda} \tag{34-7}$$

MOMENTUM OF A PHOTON

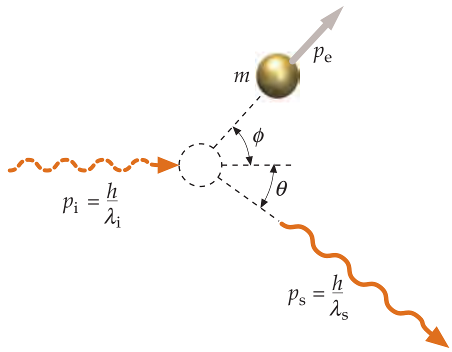

FIGURE 34-4 The scattering of light by an electron is considered as a collision of a photon of momentum h/λ_i and a stationary electron. The scattered photon has less energy and therefore has a longer wavelength than does the incident photon.

Compton applied the laws of conservation of momentum and energy to the collision of a photon and an electron to calculate the momentum p_s and thus the wavelength $\lambda_s = h/p_s$ of the scattered photon (see Figure 34-4). Applying conservation of momentum to the collision gives

$$\vec{p}_i = \vec{p}_s + \vec{p}_e \tag{34-8}$$

where $\vec{p}_i$ is the momentum of the incident photon and $\vec{p}_e$ is the momentum of the electron after the collision. The initial momentum of the electron is zero. Rearranging Equation 34-8, we have $\vec{p}_e = \vec{p}_i - \vec{p}_s$. Taking the dot product of each side with itself gives

$$p_e^2 = p_i^2 + p_s^2 - 2p_i p_s \cos\theta \tag{34-9}$$

where θ is the angle the direction of motion of the scattered photon makes with the direction of motion of the incident photon. Because the kinetic energy of the electron after the collision can be a significant fraction of the rest energy of an electron, the relativistic expression relating the total energy E of the electron to its momentum is used (see Chapter R). This expression (Equation R-17) is

$$E = \sqrt{p_e^2c^2 + (m_ec^2)^2}$$

where m_e is the mass of the electron. Applying conservation of energy to the collision gives

$$p_ic + m_ec^2 = p_sc + \sqrt{p_e^2c^2 + (m_ec^2)^2} \tag{34-10}$$

where pc (Equation 34-6) has been used to express the energies of the photons. Eliminating p_e^2 from Equations 34-9 and 34-10 gives

$$\frac{1}{p_s} - \frac{1}{p_i} = \frac{1}{m_ec}(1 - \cos\theta)$$

and substituting for p_i and p_s, using Equation 34-7, gives

$$\lambda_s - \lambda_i = \frac{h}{m_ec}(1 - \cos\theta) \tag{34-11}$$

COMPTON EQUATION

The increase in wavelength is independent of the wavelength λ_i of the incident photon. The quantity $h/(m_ec)$ has dimensions of length and is called the *Compton wavelength* λ_C. Its value is

$$\lambda_C = \frac{h}{m_ec} = \frac{hc}{m_ec^2} = \frac{1240\ \text{eV}\cdot\text{nm}}{5.110 \times 10^5\ \text{eV}} = 2.426 \times 10^{-12}\ \text{m} = 2.426\ \text{pm} \tag{34-12}$$

Because $\lambda_s - \lambda_i$ is small, it is difficult to observe unless λ_i is so small that the fractional change $(\lambda_s - \lambda_i)/\lambda_i$ is appreciable.

Compton used X rays that have wavelengths equal to 71.1 pm (1 pm $= 10^{-12}$ m $= 10^{-3}$ nm). The energy of a photon of this wavelength is $E = hc/\lambda = (1240\ \text{eV}\cdot\text{nm})/(0.0711\ \text{nm}) = 17.4$ keV. The electrons in the experiment can be considered essentially free because the energy of the X rays is much greater than the binding energies of the valence electrons in atoms (which are of the order of a few eV). Compton's measurements of $\lambda_s - \lambda_i$ as a function of scattering angle θ agreed with Equation 34-11, thereby confirming the correctness of the photon concept (the particle nature of light).

Example 34-3 Finding the Increase in Wavelength

An X-ray photon of wavelength 6.00 pm makes a head-on collision with an electron, so that the scattered photon goes in a direction opposite to that of the incident photon. The electron is initially at rest. (*a*) How much longer is the wavelength of the scattered photon than the wavelength of the incident photon? (*b*) What is the kinetic energy of the recoiling electron?

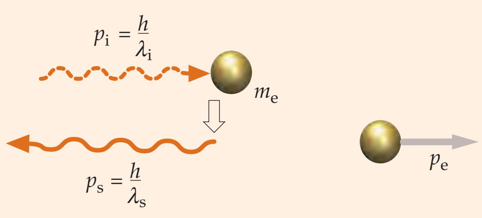

FIGURE 34-5

PICTURE We can calculate the increase in wavelength, and thus the new wavelength, from the Compton equation (Equation 34-11). We then use the new wavelength to find the energy of the scattered photon and then to find the kinetic energy of the recoiling electron from conservation of energy (Figure 34-5).

SOLVE

(*a*) Use Equation 34-11 to calculate the increase in wavelength:

$$\Delta\lambda = \lambda_s - \lambda_i = \frac{h}{m_e c}(1 - \cos\theta)$$
$$= (2.43\ \text{pm})(1 - \cos 180°) = \boxed{4.86\ \text{pm}}$$

(*b*) 1. The kinetic energy of the recoiling electron equals the energy of the incident photon E_i minus the energy of the scattered photon E_s:

$$K_e = E_i - E_s = hf_i - hf_s = \frac{hc}{\lambda_i} - \frac{hc}{\lambda_s}$$

2. Calculate λ_s from the given wavelength of the incident photon and the change found in Part (*a*):

$$\lambda_s = \lambda_i + \Delta\lambda = 6.00\ \text{pm} + 4.86\ \text{pm}$$
$$= 10.86\ \text{pm}$$

3. Substitute the values of λ_i and λ_s into the Part (*b*), step-1 result to find the energy of the recoiling electron:

$$K_e = \frac{hc}{\lambda_i} - \frac{hc}{\lambda_s}$$
$$= \frac{1240\ \text{eV}\cdot\text{nm}}{6.00\ \text{pm}} - \frac{1240\ \text{eV}\cdot\text{nm}}{10.86\ \text{pm}}$$
$$= \frac{1.240\ \text{keV}\cdot\text{nm}}{6.00\times10^{-3}\ \text{nm}} - \frac{1.240\ \text{keV}\cdot\text{nm}}{10.86\times10^{-3}\ \text{nm}}$$
$$= 207\ \text{keV} - 114\ \text{keV} = \boxed{93\ \text{keV}}$$

TAKING IT FURTHER The kinetic energy of the scattered electron is 93 keV and the rest energy of an electron is 511 keV, so the kinetic energy is 18 percent of the rest energy. Thus, the nonrelativistic formula for the kinetic energy $(\frac{1}{2}m_e v^2)$ is not valid.

PRACTICE PROBLEM 34-4 What is the speed of the scattered electron given by the nonrelativistic formula for the kinetic energy $(\frac{1}{2}m_e v^2)$?

34-4 ENERGY QUANTIZATION IN ATOMS

Ordinary white light has a continuous spectrum; that is, it contains *all* the wavelengths in the visible spectrum. But if atoms in a gas at low pressure are excited by an electric discharge, they emit light of specific wavelengths that are characteristic of the element or the compound. Because the energy of a photon is related to its wavelength by $E = hf = hc/\lambda$, a discrete set of wavelengths implies a discrete set of energies. Conservation of energy then implies that if an atom absorbs a photon, its internal energy increases by a discrete amount, an amount equal to the energy of the photon. (It also implies that if an atom emits a photon, its internal energy decreases by a discrete amount that is equal to the energy of the photon.) In 1913, this led Niels Bohr to postulate that the internal energy of an atom can have only a discrete set of values. That is, the internal energy of an atom is quantized. If an excited atom radiates light of frequency f, the atom makes a transition from one allowed level to another level that has less energy by $|\Delta E| = hf$. Bohr was able to construct a semiclassical model of the hydrogen atom that had a discrete set of energy levels consistent with the observed spectrum of emitted light.* However, the *reason* for the quantization of energy levels in atoms and other systems remained a mystery until the wave nature of electrons was discovered a decade later.

34-5 ELECTRONS AND MATTER WAVES

In 1897, J. J. Thomson showed that the rays of a cathode-ray tube (Figure 34-6) can be deflected by electric and magnetic fields and therefore must consist of electrically charged particles. By measuring the deflections of these particles, Thomson showed that all the particles have the same charge-to-mass ratio q/m. He also showed that particles with this charge-to-mass ratio can be obtained using any material for the cathode, which means that these particles, now called electrons, are a fundamental constituent of all matter.

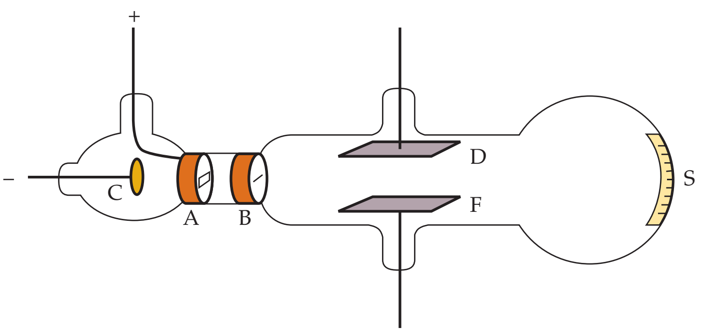

FIGURE 34-6 Schematic diagram of the cathode-ray tube Thomson used to measure q/m for the particles that comprise cathode rays (electrons). Electrons from the cathode C pass through the slits at A and B and strike a phosphorescent screen S. The beam can be deflected by an electric field between plates D and F or by a magnetic field (not shown).

THE DE BROGLIE HYPOTHESIS

Because light seems to have both wave and particle properties, it is natural to ask whether matter (for example, electrons and protons) might also have both wave and particle characteristics. In 1924, a French physics student, Louis de Broglie, suggested this idea in his doctoral dissertation. de Broglie's work was highly speculative, because no evidence existed at that time of any wave aspects of matter.

For the wavelength of electron waves, de Broglie chose

$$\lambda = \frac{h}{p} \qquad 34\text{-}13$$

DE BROGLIE RELATION FOR THE WAVELENGTH OF ELECTRON WAVES

where p is the momentum of the electron. Note that this is the same as Equation 34-7 for a photon. For the frequency of electron waves, de Broglie chose the Einstein equation relating the frequency and energy of a photon.

$$f = \frac{E}{h} \qquad 34\text{-}14$$

DE BROGLIE RELATION FOR THE FREQUENCY OF ELECTRON WAVES

* The Bohr model is reviewed in Chapter 36.

These equations are thought to apply to all matter. However, for macroscopic objects, the wavelengths calculated from Equation 34-13 are so small that it is impossible to observe the usual wave properties of interference or diffraction. Even a dust particle that has a mass as small as 1 μg is much too massive for any wave characteristics to be noticed, as we see in the following example.

Example 34-4 The de Broglie Wavelength

Try It Yourself

Find the de Broglie wavelength of a 1.00×10^{-6} g particle moving with a speed of 1.00×10^{-6} m/s.

PICTURE The wavelength λ and the momentum p of a particle are related by $\lambda = h/p$.

SOLVE

Cover the column to the right and try this on your own before looking at the answers.

Steps	Answers
Write the definition of the de Broglie wavelength and substitute the given data.	$\lambda = \frac{h}{p} = \frac{h}{mv} = \frac{6.63 \times 10^{-34}\,\mathrm{J \cdot s}}{(1.00 \times 10^{-9}\,\mathrm{kg})(1.00 \times 10^{-6}\,\mathrm{m/s})} = \boxed{6.63 \times 10^{-19}\,\mathrm{m}}$

CHECK As expected, this wavelength, which is four or five orders of magnitude smaller than the diameter of an atomic nucleus, is too small to be observed.

Because the wavelength found in Example 34-4 is so small, much smaller than any possible apertures or obstacles, diffraction or interference of such waves cannot be observed. In fact, the propagation of waves of very small wavelengths is indistinguishable from the propagation of particles. The momentum of the particle in Example 34-4 is only 10^{-15} kg·m/s. A macroscopic particle that has a greater momentum would have an even smaller de Broglie wavelength. We therefore do not observe the wave properties of such macroscopic objects as baseballs and billiard balls.

PRACTICE PROBLEM 34-5

Find the de Broglie wavelength of a baseball of mass 0.17 kg moving at 100 km/h.

The situation is different for low-energy electrons and other subatomic particles. Consider a particle with kinetic energy K. Its momentum is found from

$$K = \frac{p^2}{2m}$$

or

$$p = \sqrt{2mK}$$

Its wavelength is then

$$\lambda = \frac{h}{p} = \frac{h}{\sqrt{2mK}}$$

If we multiply the numerator and the denominator by c, we obtain

$$\lambda = \frac{hc}{\sqrt{2mc^2K}} = \frac{1240\ \mathrm{eV \cdot nm}}{\sqrt{2mc^2K}} \qquad 34\text{-}15$$

WAVELENGTH ASSOCIATED WITH A PARTICLE OF MASS m

where we have used $hc = 1240$ eV·nm. For electrons, $mc^2 = 0.5110$ MeV. Then,

$$\lambda = \frac{1240 \text{ eV} \cdot \text{nm}}{\sqrt{2mc^2K}} = \frac{1240 \text{ eV} \cdot \text{nm}}{\sqrt{2(0.5110 \times 10^6 \text{ eV})K}}$$

or

$$\lambda = \frac{1.226}{\sqrt{K}} \text{ nm} \qquad (K \text{ in electron volts}) \qquad 34\text{-}16$$

ELECTRON WAVELENGTH

Equation 34-15 and Equation 34-16 do not hold for relativistic particles whose kinetic energies are a significant fraction of their rest energies mc^2. (Rest energies are discussed in Chapter 7 and in Chapter R.)

PRACTICE PROBLEM 34-6
Find the wavelength of an electron whose kinetic energy is 10.0 eV.

ELECTRON INTERFERENCE AND DIFFRACTION

The observation of diffraction and interference of electron waves would provide the crucial test of the existence of wave properties of electrons. This observation was first seen serendipitously in 1927 by C. J. Davisson and L. H. Germer as they were studying electron scattering from a nickel target at the Bell Telephone Laboratories. After heating the target to remove an oxide coating that had accumulated during an accidental break in the vacuum system, they found that the scattered electron intensity as a function of the scattering angle showed maxima and minima. Their target had crystallized, and they had observed electron diffraction by accident. Davisson and Germer then prepared a target consisting of a single crystal of nickel and investigated this phenomenon extensively. Figure 34-7*a* illustrates their experiment. Electrons from an electron gun are directed at a crystal and detected at some angle ϕ that can be varied. Figure 34-7*b* shows a typical pattern observed. There is a strong scattering maximum at an angle of 50°. The angle for maximum scattering of waves from a crystal depends on the wavelength of the waves and the spacing of the atoms in the crystal. Using the known spacing of atoms in their crystal, Davisson and Germer calculated the wavelength that could

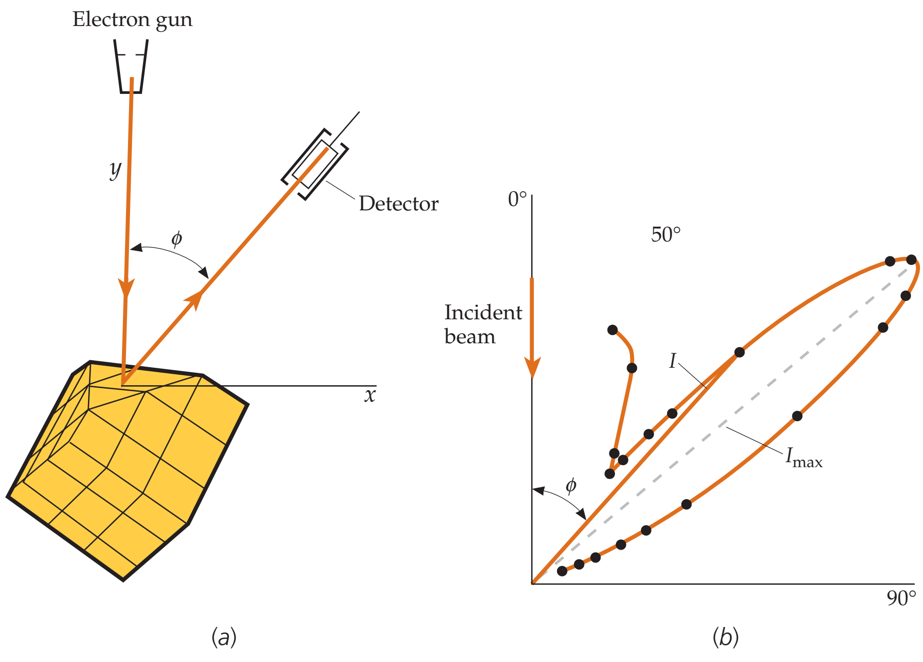

FIGURE 34-7 The Davisson–Germer experiment. (*a*) Electrons are scattered from a nickel crystal into a detector. (*b*) A polar plot of the intensity I of scattered electrons versus scattering angle. The maximum intensity I_{max} is at the angle predicted by the diffraction of waves of wavelength λ given by the de Broglie formula.

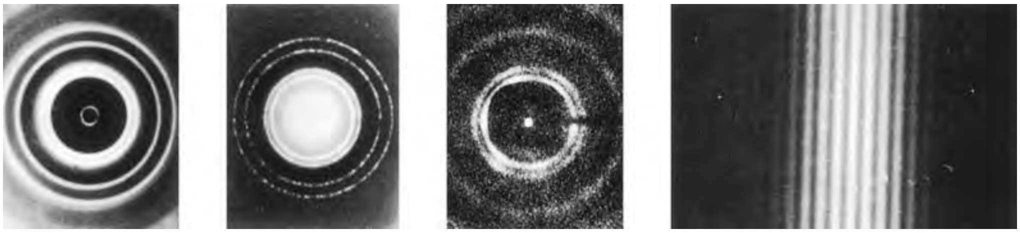

(a) (b) (c) (d)

FIGURE 34-8 (*a*) The diffraction pattern produced by X rays of wavelength 0.071 nm on an aluminum foil target. (*b*) The diffraction pattern produced by 600-eV electrons (λ = 0.050 nm) on an aluminum foil target. (*c*) The diffraction of 0.0568 eV neutrons (λ = 0.12 nm) incident on a copper foil. (*d*) A two-slit electron diffraction–interference pattern. (*(a) and (b) PSSC Physics, 2nd ed., 1965. D.C. Heath & Co., and Education Development Center, Inc., Newton, MA, (c) C.G. Shull, (d) Claus Jönsson.*)

produce such a maximum and found that it agreed with the de Broglie equation (Equation 34-16) for the electron energy they were using. By varying the energy of the incident electrons, they could vary the electron wavelengths and produce maxima and minima at different locations in the diffraction patterns. In all cases, the measured wavelengths agreed with de Broglie's hypothesis.

Another demonstration of the wave nature of electrons was provided in the same year by G. P. Thomson (son of J. J. Thomson) who observed electron diffraction in the transmission of electrons through thin metal foils. A metal foil consists of tiny, randomly oriented crystals. The diffraction pattern resulting from such a foil is a set of concentric circles. Figure 34-8*a* and Figure 34-8*b* show the diffraction pattern observed using X rays and electrons on an aluminum foil target. Figure 34-8*c* shows the diffraction patterns of neutrons on a copper foil target. Note the similarity of the patterns. The diffraction of hydrogen and helium atoms was observed in 1930. In all cases, the measured wavelengths agree with the de Broglie predictions. Figure 34-8*d* shows a diffraction pattern produced by electrons incident on two narrow slits. This experiment is equivalent to Young's famous double-slit experiment with light. The pattern is identical to the pattern observed with photons of the same wavelength. (Compare with Figure 34-1.)

Shortly after the wave properties of the electron were demonstrated, it was suggested that electrons rather than light might be used to *see* small objects. As discussed in Chapter 33, reflected waves or transmitted waves can resolve details of objects only if the details are larger than the wavelength of the reflected wave. Beams of electrons, which can be focused by electric and magnetic fields, can have very small wavelengths—much shorter than visible light. Today, the electron microscope (Figure 34-9) is an important research tool used to visualize specimens at scales far smaller than those possible with a light microscope.

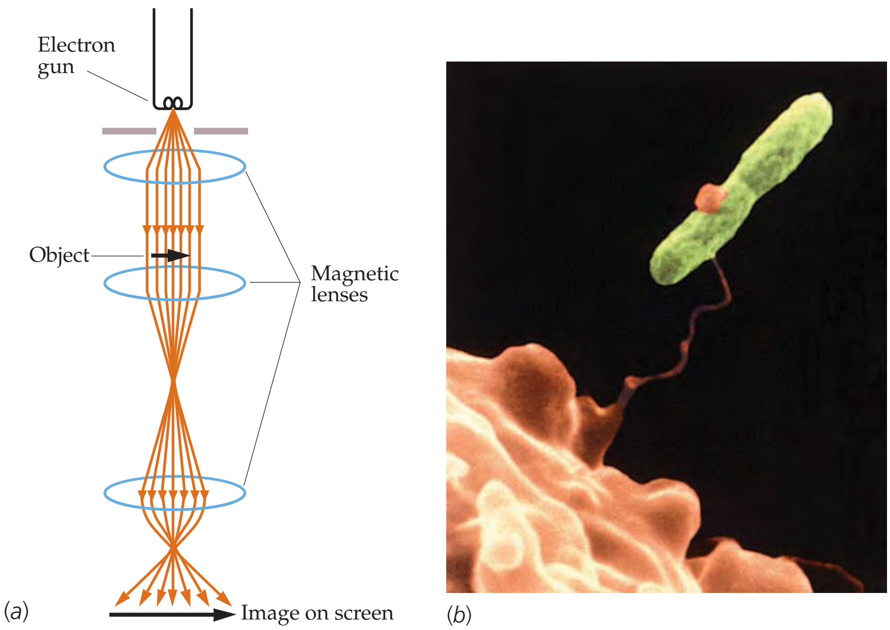

FIGURE 34-9 (*a*) An electron microscope. Electrons from a heated filament (the electron gun) are accelerated by a large potential difference. The electron beam is made parallel by a magnetic focusing lens. The electrons strike a thin target and are then focused by a second magnetic lens. The third magnetic lens projects the electron beam onto a fluorescent screen to produce the image. STANDING WAVES AND ENERGY QUANTIZATION

Given that electrons have wavelike properties, it should be possible to produce standing electron waves. If energy is associated with the frequency of a standing wave, as in $E = hf$ (Equation 34-14), then standing waves imply quantized energies.

The idea that the discrete energy states in atoms could be explained by standing waves led to the development of a detailed mathematical theory known as quantum theory, quantum mechanics, or wave mechanics by Erwin Schrödinger and others in 1926. In this theory, the electron is described by a wave function ψ that obeys a wave equation called the **Schrödinger equation.** The form of the Schrödinger equation of a particular system depends on the forces acting on the particle, which are described by the potential energy functions associated with those forces. In Chapter 35, we discuss this equation, which is somewhat similar to the classical wave equations for sound or for light. Schrödinger solved the standing wave problem for the hydrogen atom, the simple harmonic oscillator, and other systems of interest. He found that the allowed frequencies, combined with $E = hf$, resulted in the set of energy levels found experimentally for the hydrogen atom, thereby demonstrating that quantum theory provides a general method of finding the quantized energy levels for a given system. Quantum theory is the basis for our modern understanding of the world—from the inner workings of the atomic nucleus to the radiation spectra of distant galaxies.

! Do not think energy is always quantized. It is not unless the system is bound. The energy of a system consisting of a proton and an electron is quantized only if the electron is bound to the proton—as it is in the hydrogen atom. If the electron is not bound to the proton, then the energy of the system is not quantized.

34-6 THE INTERPRETATION OF THE WAVE FUNCTION

The wave function for waves on a string is the string displacement y. The wave function for sound waves can be either the displacement of the air molecules s, or the pressure P. The wave function for electromagnetic waves is the electric field $\vec{E}$ and the magnetic field $\vec{B}$. What is the wave function for electron waves? The symbol we use for this wave function is ψ (the Greek letter psi). When Schrödinger published his wave equation, neither he nor anyone else knew just how to interpret the wave function ψ. We can get a hint about how to interpret ψ by considering the quantization of light waves. For classical waves, such as sound or light, the energy per unit volume in the wave is proportional to the square of the wave function. Because the energy of a light wave is quantized, the energy per unit volume is proportional to the number of photons per unit volume. We might therefore expect the square of the photon's wave function to be proportional to the number of photons per unit volume in a light wave. But suppose we have a very low-energy source of light that emits just one photon at a time. In any unit volume, there is either one photon or none. The square of the wave function must then describe the *probability* of finding a photon in some unit volume.

The Schrödinger equation describes a single particle. The square of the wave function for a particle must then describe the *probability density*, which is the probability per unit volume, of finding the particle at a location. The probability of finding the particle in some volume element must also be proportional to the size of the volume element dV. Thus, in one dimension, the probability of finding a particle in a region of length dx at the position x is $\psi^2(x)\,dx$. If we call this probability $P(x)\,dx$, where $P(x)$ is the **probability density,** we have

$$P(x) = \psi^2(x) \qquad 34\text{-}17$$

PROBABILITY DENSITY

Generally the wave function depends on time as well as position, and is written $\psi(x,t)$. However, for standing waves, the probability density is independent of time. Because we will be concerned mostly with standing waves in this chapter, we omit the time dependence of the wave function and write it $\psi(x)$ or just ψ.

The probability of finding the particle either in the region between x_1 and $x_1 + dx$ or in the region between x_2 and $x_2 + dx$ is the sum of the separate probabilities $P(x_1)\,dx + P(x_2)\,dx$. If we have a particle at all, the probability of finding the particle somewhere must be 1. Then the sum of the probabilities over all the possible values of x must equal 1. That is,

$$\int_{-\infty}^{\infty} \psi^2\,dx = 1 \qquad 34\text{-}18$$

NORMALIZATION CONDITION

Equation 34-18 is called the **normalization condition.** If ψ is to satisfy the normalization condition, it must approach zero as $|x|$ approaches infinity. This condition places restrictions on the possible solutions of the Schrödinger equation. There are mathematical solutions to the Schrödinger equation that do not approach zero as $|x|$ approaches infinity. However, these solutions are not acceptable as wave functions.

Example 34-5 Probability Calculation for a Classical Particle

It is known that a classical point particle moves back and forth with constant speed between two walls at $x = 0$ and $x = 8.0$ cm (Figure 34-10). No additional information about the location of the particle is known. (*a*) What is the probability density $P(x)$? (*b*) What is the probability of finding the particle at the point where x equals exactly 2 cm? (*c*) What is the probability of finding the particle between $x = 3.0$ cm and $x = 3.4$ cm?

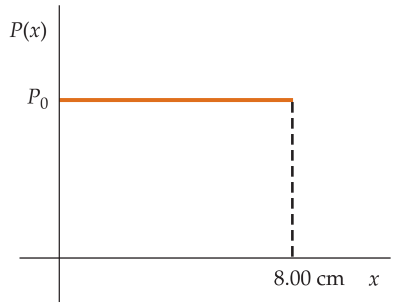

FIGURE 34-10 The probability function $P(x)$.

PICTURE We do not know the initial position of the particle. Because the particle moves with constant speed, it is equally likely to be anywhere in the region $0 < x < 8.0$ cm. The probability density $P(x)$ is therefore independent of x, for $0 < x < 8.0$ cm, and zero outside of this range. We can find $P(x)$, for $0 < x < 8.0$ cm, by normalization, that is, by requiring that the probability that the particle is somewhere between $x = 0$ and $x = 8.0$ cm is 1.

SOLVE

(*a*) 1. The probability density $P(x)$ is uniform between the walls and zero elsewhere:

$$P(x) = \begin{cases} 0 & x < 0 \\ P_0 & 0 < x < 8.0\text{ cm} \\ 0 & x > 8.0\text{ cm} \end{cases}$$

2. Apply the normalization condition:

$$\int_{-\infty}^{+\infty} P(x)\,dx = \int_{-\infty}^{0} P(x)\,dx + \int_{0}^{8.0\text{ cm}} P(x)\,dx + \int_{8.0\text{ cm}}^{\infty} P(x)\,dx$$

$$= 0 + \int_{0}^{8.0\text{ cm}} P_0\,dx + 0 = P_0\,(8.0\text{ cm}) = 1$$

3. Solve for P_0:

$$P_0 = \boxed{\frac{1}{8.0\text{ cm}}}$$

(*b*) On the interval $0 < x < 8.0$ cm, the probability of finding the particle in some range Δx is proportional to $P_0\Delta x = \Delta x/(8\text{ cm})$. The probability of finding the particle at the point $x = 2$ cm is zero because Δx is zero (no range exists). Alternatively, because an infinite number of points exists between $x = 0$ and $x = 8$ cm, and the particle is equally likely to be at any point, the chance that the particle will be at any one particular point must be zero.

$\boxed{\text{The probability of finding the particle at the point where } x \text{ equals exactly 2 cm is 0.}}$

(*c*) Because the probability density is uniform, the probability of a particle being in some range Δx in the region $0 < x < 8.0$ cm is $P_0\Delta x$. The probability of the particle being in the region $3.0\text{ cm} < x < 3.4\text{ cm}$ is thus:

$$P_0\Delta x = \left(\frac{1}{8.0\text{ cm}}\right)0.4\text{ cm} = \boxed{0.05}$$

CHECK The length of the interval $3.0\text{ cm} < x < 3.4\text{ cm}$ is 0.4 cm, which is 5 percent of $L = 8.0$ cm. Because the particle is moving at constant speed v, we expect it to be in the interval $3.0\text{ cm} < x < 3.4\text{ cm}$ during 5 percent of the time, provided the total time is much much longer than the time L/v (the time required for the particle to travel 8.0 cm). Our Part (*c*) result meets this expectation.

34-7 WAVE–PARTICLE DUALITY

We have seen that light, which we ordinarily think of as a wave, exhibits particle properties when it interacts with matter, as in the photoelectric effect or in Compton scattering. Electrons, which we usually think of as particles, exhibit the wave properties of interference and diffraction when they pass near the edges of obstacles. All carriers of momentum and energy (for example, electrons, atoms, or photons) exhibit both wave and particle characteristics. It might be tempting to say that an electron, for example, is both a wave and a particle, but what does this mean? In classical physics, the concepts of waves and particles are mutually exclusive. A **classical particle** behaves like a piece of shot; it can be localized and scattered, it exchanges energy suddenly at a point in space, and it obeys the laws of conservation of energy and momentum in collisions. It does *not* exhibit interference or diffraction. A **classical wave,** on the other hand, behaves like a sound or light wave; it exhibits diffraction and interference, and its energy is spread out continuously in space and time. A classical wave and a classical particle are mutually exclusive. Nothing can be both a classical particle and a classical wave at the same time.

After Thomas Young observed the two-slit interference pattern by using light in 1801, light was thought to be a classical wave. On the other hand, the electrons discovered by J. J. Thomson were thought to be classical particles. We now know that these classical concepts of waves and particles do not adequately describe the complete behavior of any phenomenon.

Everything propagates like a wave and exchanges energy like a particle.

Often the concepts of the classical particle and the classical wave give the same results. If the wavelength is very small, diffraction effects are negligible, so the waves travel in straight lines like classical particles. Also, interference is not seen for waves of very short wavelength, because the interference fringes are too closely spaced to be observed. It then makes no difference which concept we use. If diffraction is negligible, we can think of light as a wave propagating along rays, as in geometrical optics, or as a beam of photon particles. Similarly, we can think of an electron as a wave propagating in straight lines along rays or, more commonly, as a particle.

We can also use either the wave or particle concept to describe exchanges of energy if we have a large number of particles and we are interested only in the average values of energy and momentum exchanges.

THE TWO-SLIT EXPERIMENT REVISITED

The wave–particle duality of nature is illustrated by the analysis of the experiment in which a single electron is incident on a barrier that has two slits. The analysis is virtually the same whether we use an electron or a photon (light). To describe the propagation of an electron, we must use wave theory. Let us assume the source is a point source, such as a needle point, so we have spherical waves spreading out from the source. After passing through the two slits, the wavefronts spread out—as if each slit were a source of wavefronts. The wave function ψ at a point on a screen or film far from the slits depends on the difference in path lengths from the source to the point, one path through one slit, and the other path through the other slit. At points on the screen for which the difference in path lengths is either zero or an integral number of wavelengths, the amplitude of the wave function is a maximum. Because the probability of detecting the electron is proportional to ψ^2, the electron is very likely to arrive near these points. At points for which the path difference is an odd number of half wavelengths, the wave function ψ is zero, so the electron is very unlikely to arrive near these points. The chapter opening photos show the interference pattern produced by 10 electrons, 100 electrons, 3000 electrons, and 70,000 electrons. Note that, although the electron propagates through the slits like a wave, the electron interacts with the screen at a single point—like a particle.

THE UNCERTAINTY PRINCIPLE

An important principle consistent with the wave–particle duality of nature is the **uncertainty principle.** It states that, in principle, it is impossible to simultaneously measure both the position and the momentum of a particle with unlimited precision. A common way to measure the position of an object is to look at the object by using light. If we do this, we scatter light from the object and determine the position by the direction of the scattered light. If we use light of wavelength λ, we can measure the position x only to an uncertainty Δx of the order of λ because of diffraction effects.

$$\Delta x \sim \lambda$$

To reduce the uncertainty in position, we therefore use light of very short wavelength, perhaps even X rays. In principle, there is no limit to the accuracy of such a position measurement, because there is no limit on how small the wavelength λ can be.

We can determine the momentum p_x of the object if we know the mass and can determine its velocity. The momentum of the object can be found by measuring the object's position at two nearby times and computing its velocity. If we use light of wavelength λ, the photons carry momentum h/λ. If these photons are scattered by the object we are looking at, the scattering changes the momentum of the object in an uncontrollable way. Each photon carries momentum h/λ, so the uncertainty in the momentum Δp_x of the object is of the order of h/λ:

$$\Delta p_x \sim \frac{h}{\lambda}$$

If the wavelength of the radiation is small, the momentum of each photon will be large and the momentum measurement will have a large uncertainty. Reducing the intensity of light cannot eliminate this uncertainty; such a reduction merely reduces the number of photons in the beam. To see the object, we must scatter at least one photon. Therefore, the uncertainty in the momentum measurement of the object will be large if λ is small, and the uncertainty in the position measurement of the object will be large if λ is large.

Of course, we could always look at the objects by scattering electrons instead of photons, but the same difficulty remains. If we use low-momentum electrons to reduce the uncertainty in the momentum measurement, we have a large uncertainty in the position measurement because of diffraction of the electrons. The relation between the wavelength and momentum $\lambda = h/p_x$ is the same for electrons as it is for photons.

The product of the intrinsic uncertainties in position and momentum is

$$\Delta x\,\Delta p_x \sim \lambda \times \frac{h}{\lambda} = h$$

This relation between the uncertainties in position and momentum is called the uncertainty principle. If we define precisely what we mean by uncertainties in measurement, we can give a precise statement of the uncertainty principle. If Δx and Δp are defined to be the standard deviations in the measurements of position and momentum, it can be shown that their product must be greater than or equal to $\hbar/2$.

$$\Delta x\,\Delta p_x \geq \tfrac{1}{2}\hbar \qquad 34\text{-}19$$

where $\hbar = h/2\pi$.*

Equation 34-19 provides a statement of the uncertainty principle first given by Werner Heisenberg in 1927. In practice, the experimental uncertainties are usually much greater than the intrinsic lower limit that results from wave–particle duality.

34-8 A PARTICLE IN A BOX

We can illustrate many of the important features of quantum physics without solving the Schrödinger equation by considering a simple problem of a particle of mass m confined to a one-dimensional box of length L, like the particle in Example 34-5. This can be considered a crude description of an electron that is constrained to be within an atom or a proton that is constrained to be within a nucleus. If a classical particle bounces back and forth between the walls of the box, the particle's energy and momentum can have any values. However, according to quantum theory, the particle is described by a wave function ψ, whose square describes the probability of finding the particle in some region. Because we are assuming that the particle is indeed inside the box, the wave function must be zero everywhere outside the box. If the box is between $x = 0$ and $x = L$, we have

$$\psi = 0 \qquad \text{for } x \leq 0 \text{ and for } x \geq L$$

In particular, if we assume the wave function to be continuous everywhere, it must be zero at the end points of the box $x = 0$ and $x = L$. This is the same condition as the condition for standing waves on a string fixed at $x = 0$ and $x = L$, and the results are the same. The allowed wavelengths for a particle in the box are those where the length L equals an integral number of half wavelengths (Figure 34-11).

$$L = n\frac{\lambda_n}{2} \qquad n = 1, 2, 3, \ldots \qquad 34\text{-}20$$

STANDING-WAVE CONDITION FOR A PARTICLE IN A BOX OF LENGTH L

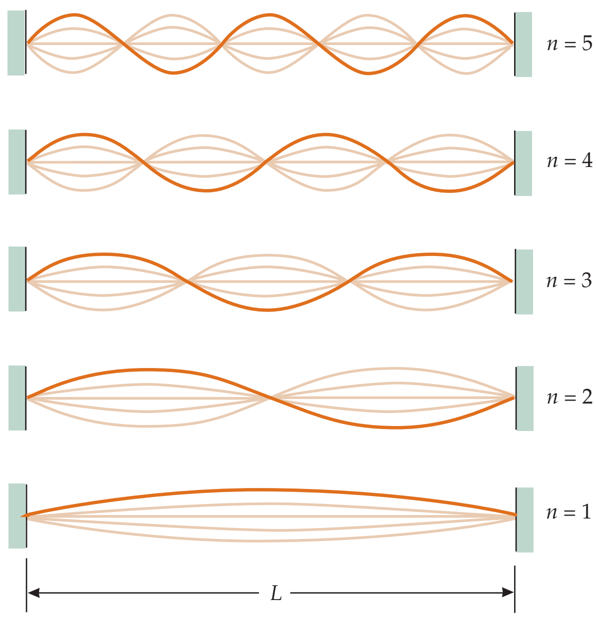

FIGURE 34-11 Standing waves on a string fixed at both ends. The standing-wave condition is the same as for standing electron waves in a box.

The total energy E of the particle is its kinetic energy

$$E = \frac{1}{2}mv^2 = \frac{p^2}{2m}$$

Substituting the de Broglie relation $p_n = h/\lambda_n$,

$$E_n = \frac{p_n^2}{2m} = \frac{(h/\lambda_n)^2}{2m} = \frac{h^2}{2m\lambda_n^2}$$

* The combination $h/2\pi$ occurs so often it is given a special symbol, somewhat analogous to giving the special symbol ω for $2\pi f$, which occurs often in oscillations.

Then the standing-wave condition $\lambda_n = 2L/n$ gives the allowed energies.

$$E_n = n^2 \frac{h^2}{8mL^2} = n^2 E_1 \qquad 34\text{-}21$$

ALLOWED ENERGIES FOR A PARTICLE IN A BOX

where

$$E_1 = \frac{h^2}{8mL^2} \qquad 34\text{-}22$$

GROUND-STATE ENERGY FOR A PARTICLE IN A BOX

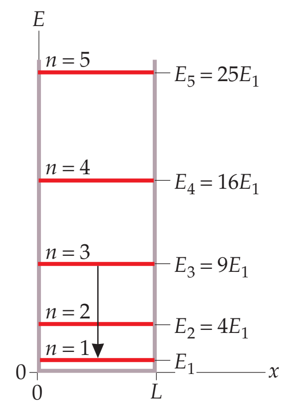

FIGURE 34-12 Energy-level diagram for a particle in a box. Classically, a particle can have any energy value. Quantum mechanically, only those energy values given by Equation 34-21 are allowed. A transition between the state $n = 3$ and the ground state $n = 1$ is indicated by the vertical arrow.

is the energy of the lowest state, which is the ground state.

The condition $\psi = 0$ at $x = 0$ and $x = L$ is called a **boundary condition.** Boundary conditions in quantum theory lead to energy quantization. Figure 34-12 shows the energy-level diagram for a particle in a box. Note that the lowest energy is not zero. This result is a general feature of quantum theory. If a particle is confined to some region of space, the particle has a minimum kinetic energy, called the **zero-point energy** that is greater than zero. The smaller the region of space the particle is confined to, the greater its zero-point energy. In Equation 34-22, this is indicated by the fact that E_1 varies as $1/L^2$.

If an electron is confined (bound to an atom) in some energy state E_i, the electron can make a transition to another energy state E_f by the emission of a photon if E_f is less than E_i. (If E_f is greater than E_i, the system absorbs a photon.) The transition from state 3 to the ground state is indicated in Figure 34-12 by the vertical arrow. The frequency of the emitted photon is found from the conservation of energy*

$$hf = E_i - E_f \qquad 34\text{-}23$$

The wavelength of the photon is then

$$\lambda = \frac{c}{f} = \frac{hc}{E_i - E_f} \qquad 34\text{-}24$$

STANDING-WAVE FUNCTIONS

The amplitude of a vibrating string that is fixed at $x = 0$ and $x = L$ is given by Equation 16-15:

$$A_n(x) = A_n \sin k_n x \qquad n = 1, 2, 3, \ldots$$

where A_n is a constant, $k_n = 2\pi/\lambda_n$ is the wave number, and $\lambda_n = 2L/n$. The wave functions for a particle in a box (which can be obtained by solving the Schrödinger equation, as we will see in Chapter 35) are the same:

$$\psi_n(x) = A_n \sin k_n x \qquad n = 1, 2, 3, \ldots$$

where $k_n = 2\pi/\lambda_n$. Using $\lambda_n = 2L/n$, we have

$$k_n = \frac{2\pi}{\lambda_n} = \frac{2\pi}{2L/n} = \frac{n\pi}{L}$$

The wave functions can thus be written

$$\psi_n(x) = A_n \sin\left(n\pi \frac{x}{L}\right)$$

* This equation was first proposed by Niels Bohr in his semiclassical model of the hydrogen atom in 1913, about 10 years before de Broglie's suggestion that electrons have wave properties. The Bohr model is presented in Chapter 36.

The constant A_n is determined by the normalization condition (Equation 34-18):

$$\int_{-\infty}^{\infty} \psi^2\, dx = \int_0^L A_n^2 \sin^2\left(n\pi \frac{x}{L}\right) dx = 1$$

Note that we need integrate only from $x = 0$ to $x = L$ because $\psi(x)$ is zero everywhere else. The result of evaluating the integral and solving for A_n is

$$A_n = \sqrt{\frac{2}{L}}$$

which is independent of n. The normalized standing-wave functions for a particle in a box are thus

$$\psi_n(x) = \sqrt{\frac{2}{L}} \sin\left(n\pi \frac{x}{L}\right) \qquad n = 1, 2, 3, \ldots \qquad 34\text{-}25$$

STANDING-WAVE FUNCTIONS FOR A PARTICLE IN A BOX

The standing-wave functions for $n = 1$, $n = 2$, and $n = 3$ are shown in Figure 34-13.

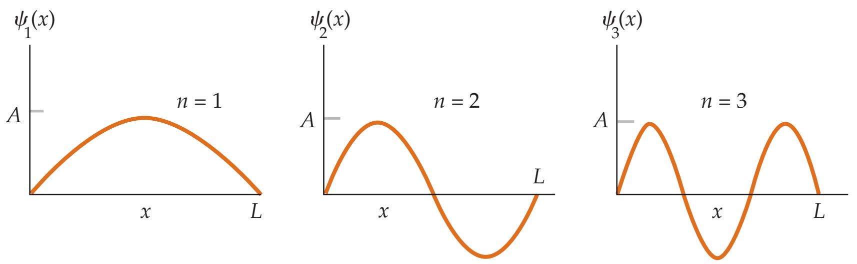

FIGURE 34-13 Standing-wave functions for $n = 1$, $n = 2$, and $n = 3$.

The number n is called a **quantum number.** It characterizes the wave function for a particular state and for the energy of that state. In our one-dimensional problem, a quantum number arises from the boundary condition on the wave function that it must be zero at $x = 0$ and $x = L$. In three-dimensional problems, three quantum numbers arise, one associated with a boundary condition in each dimension.

Figure 34-14 shows plots of ψ^2 for the ground state $n = 1$, the first excited state $n = 2$, the second excited state $n = 3$, and the state $n = 10$. In the ground state, the particle is most likely to be found near the center of the box, as indicated by

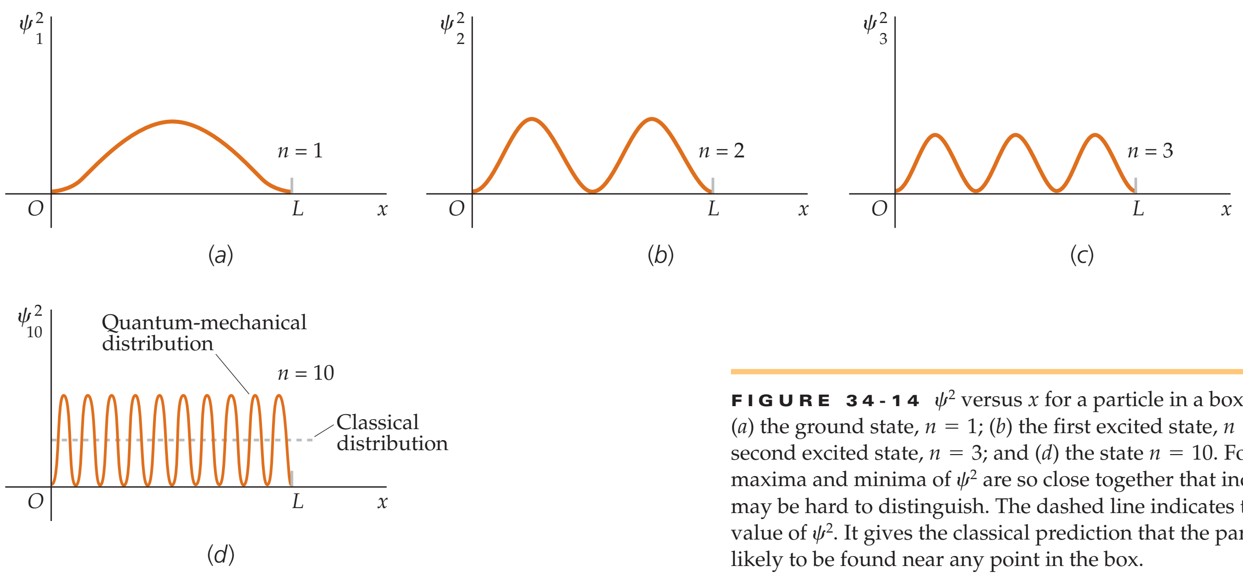

FIGURE 34-14 ψ^2 versus x for a particle in a box of length L for (*a*) the ground state, $n = 1$; (*b*) the first excited state, $n = 2$; (*c*) the second excited state, $n = 3$; and (*d*) the state $n = 10$. For $n = 10$, the maxima and minima of ψ^2 are so close together that individual maxima may be hard to distinguish. The dashed line indicates the average value of ψ^2. It gives the classical prediction that the particle is equally likely to be found near any point in the box.

the maximum value of ψ^2 at $x = L/2$. In the first excited state, the particle is least likely to be found near the center of the box because ψ^2 is small near $x = L/2$. For very large values of n, the maxima and minima of ψ^2 are very close together, as illustrated for $n = 10$. The average value of ψ^2 is indicated in this figure by the dashed line. For very large values of n, the maxima and minima are so closely spaced that ψ^2 cannot be distinguished from its average value. The fact that $(\psi^2)_{\text{av}}$ is constant across the whole box means that the particle is equally likely to be found anywhere in the box—the same as in the classical result. This is an example of **Bohr's correspondence principle:**

> In the limit of very large quantum numbers, the classical calculation and the quantum calculation must yield the same results.
>
> BOHR'S CORRESPONDENCE PRINCIPLE

The region of very large quantum numbers is also the region of very large energies. For large energies, the percentage change in energy between adjacent quantum states is very small, so energy quantization is not important (see Problem 71).

We are so accustomed to thinking of the electron as a classical particle that we tend to think of an electron in a box as a particle bouncing back and forth between the walls. But the probability distributions shown in Figure 34-14 are stationary; that is, they do not depend on time. A better picture for an electron in a bound state is a cloud of charge that has the charge density proportional to ψ^2. Figure 34-14 can then be thought of as plots of the charge density versus x for the various states. In the ground state, $n = 1$, the electron cloud is centered in the middle of the box and is spread out over most of the box, as indicated in Figure 34-14*a*. In the first excited state, $n = 2$, the charge density of the electron cloud has two maxima, as indicated in Figure 34-14*b*. For very large values of n, there are many closely spaced maxima and minima in the charge density resulting in an average charge density that is approximately uniform throughout the box. This electron-cloud picture of an electron is very useful in understanding the structure of atoms and molecules. However, it should be noted that whenever an electron is observed to interact with matter or radiation, it is always observed as a whole unit charge.

Example 34-6 Photon Emission by a Particle in a Box

An electron is in a one-dimensional box of length 0.100 nm. (*a*) Find the ground-state energy. (*b*) Find the energies of the four lowest-energy states that have energies above the ground-state energy, and then sketch an energy-level diagram. (*c*) Find the wavelength of the photon emitted for each transition from the state $n = 3$ to a lower-energy state.

PICTURE For Part (*a*) the ground state is the $n = 1$ state, and $E_1 = h^2/8mL^2$ (Equation 34-22). For Part (*b*), the energies are given by $E_n = n^2E_1$ (Equation 34-21), where, $n = 2, 3, 4$, and 5. For Part (*c*), the photon wavelengths are given by $\lambda = hc/(E_\text{i} - E_\text{f})$ (Equation 34-24).

SOLVE

(*a*) Use $hc = 1240\ \text{eV}\cdot\text{nm}$ and $mc^2 = 0.5110$ MeV to calculate E_1:

$$E_1 = \frac{h^2}{8mL^2} = \frac{(hc)^2}{8(mc^2)L^2} = \frac{(1240\ \text{eV}\cdot\text{nm})^2}{8(5.110 \times 10^5\ \text{eV})(0.100\ \text{nm})^2} = \boxed{37.6\ \text{eV}}$$

(*b*) 1. Calculate $E_n = n^2E_1$ for $n = 2, 3, 4$, and 5:

$$E_2 = (2)^2(37.6\ \text{eV}) = \boxed{150\ \text{eV}}$$

$$E_3 = (3)^2(37.6\ \text{eV}) = \boxed{338\ \text{eV}}$$

$$E_4 = (4)^2(37.6\ \text{eV}) = \boxed{602\ \text{eV}}$$

$$E_5 = (5)^2(37.6\ \text{eV}) = \boxed{940\ \text{eV}}$$

2. Sketch an energy-level diagram using the values for the five energy states (Figure 34-15).

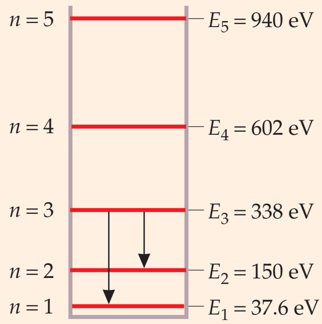

FIGURE 34-15

(*c*) 1. Use the energies found in Part (*b*) to calculate the wavelength for a transition from state 3 to state 2:

$$\lambda = \frac{hc}{E_3 - E_2} = \frac{1240\ \text{eV}\cdot\text{nm}}{338\ \text{eV} - 150\ \text{eV}} = \boxed{6.60\ \text{nm}}$$

2. Then use the energies in Part (*a*) and Part (*b*) to calculate the wavelength for a transition from state 3 to state 1:

$$\lambda = \frac{hc}{E_3 - E_1} = \frac{1240\ \text{eV}\cdot\text{nm}}{338\ \text{eV} - 37.6\ \text{eV}} = \boxed{4.13\ \text{nm}}$$

CHECK The wavelength of the photon emitted during the transition from the $n = 3$ to the $n = 1$ state is shorter than the wavelength of the photon emitted during the transition from the $n = 3$ to the $n = 2$ state. This result is expected—the greater the energy of the photon the shorter its wavelength.

TAKING IT FURTHER The energy-level diagram is shown in Figure 34-15. The transitions from $n = 3$ to $n = 2$ and from $n = 3$ to $n = 1$ are indicated by the vertical arrows. The ground-state energy of 37.6 eV is on the same order of magnitude as the kinetic energy of the electron in the ground state of the hydrogen atom, which is 13.6 eV. In the hydrogen atom, the electron has potential energy of -27.2 eV in the ground state, giving it a total ground-state energy (potential energy plus kinetic energy) of -13.6 eV.

PRACTICE PROBLEM 34-7 Calculate the wavelength of the photon emitted if the electron in the box makes a transition from $n = 4$ to $n = 3$.

34-9 EXPECTATION VALUES

The solution of a classical mechanics problem is typically specified by giving the position of a particle as a function of time. But the wave nature of matter prevents us from doing this for microscopic systems. The most that we can know is the relative probability of measuring a certain value of the position x. If we measure the position for a large number of identical systems, we get a range of values corresponding to the probability distribution. The average value of x obtained from such measurements is called the **expectation value** and is written $\langle x \rangle$. The expectation value of x is the same as the average value of x that we would expect to obtain from a measurement of the positions of a large number of particles that have the same wave function $\psi(x)$.

Because $\psi^2(x)\,dx$ is the probability of finding a particle in the region dx, the expectation value of x is

$$\langle x \rangle = \int_{-\infty}^{+\infty} x\psi^2(x)\,dx \qquad 34\text{-}26$$

EXPECTATION VALUE OF x DEFINED

See **Math Tutorial** *for more information on* **Integrals**

The expectation value of any function $F(x)$ is given by

$$\langle F(x) \rangle = \int_{-\infty}^{+\infty} F(x)\psi^2(x)\,dx \qquad 34\text{-}27$$

EXPECTATION VALUE OF $F(x)$ DEFINED

CALCULATING PROBABILITIES AND EXPECTATION VALUES

PROBLEM-SOLVING STRATEGY

Probabilities and Expectations

SOLVE

1. To calculate the probability P of finding a particle in the region of infinitesimal length between x and $x + dx$, we multiply the length dx by the probability per unit length at x, where the probability per unit length (called the probability density function) is given by ψ^2.
2. To calculate the probability P of finding a particle in the region $x_1 < x < x_2$, we, in principle, divide the region into an infinite number of regions of infinitesimal length dx, calculate the probability P of finding the particle in each infinitesimal length, and then sum the probabilities. That is, we evaluate the integral $\int_{x_1}^{x_2} \psi^2\,dx$.
3. To calculate the expected value of a function $F(x)$, we evaluate the integral $\int_{-\infty}^{+\infty} F(x)\psi^2(x)\,dx$. The result of this calculation is called the expected value of $F(x)$.

The problem of a particle in a box allows us to illustrate the calculation of the probability of finding the particle in various regions of the box and the expectation values for various energy states. We give two examples, using the wave functions given by Equation 34-25.

Example 34-7 The Probability of the Particle Being Found in a Specified Region of a Box

A particle in a one-dimensional box of length L is in the ground state. Find the probability of finding the particle (*a*) in the region that has a length $\Delta x = 0.01L$ and is centered at $x = \frac{1}{2}L$ and (*b*) in the region $0 < x < \frac{1}{4}L$.

PICTURE The probability P of finding the particle in some infinitesimal range dx is $\psi^2\,dx$. For a particle in the nth state, the wave function is given by $\psi_n = \sqrt{2/L}\,\sin(n\pi x/L)$ (Equation34-25). For a particle in the ground state, $n = 1$; and ψ_1^2 is illustrated in Figure 34-14. The probability of finding x in some region is just the area under this curve for the region. For Part (*a*) , the region is $\Delta x = 0.01L$, centered at $x = L/2$, and the area under the ψ_1^2 versus x curve is shown in Figure 34-16*a*. This area is $\sim\psi_1^2\Delta x$. For Part (*b*) , the region is $0 < x < L/4$, and the area under the curve is shown in Figure 34-16*b*. To calculate this area, we must integrate ψ_1^2 from $x = 0$ to $x = L/4$.

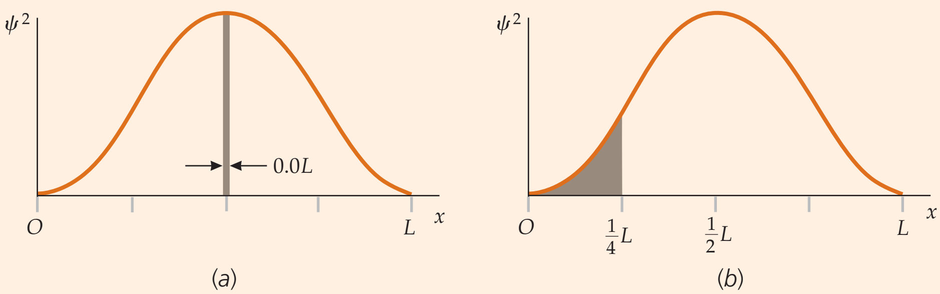

FIGURE 34-16

SOLVE

(*a*) 1. The probability of finding the particle is the area under the curve shown in Figure 34-16*a*. To calculate this area, we need to calculate the height of curve at $x = \frac{1}{2}L$:

$$\psi(x) = \psi_1(x) = \sqrt{\frac{2}{L}}\sin\left(\pi\frac{x}{L}\right)$$

so

$$\psi^2(\tfrac{1}{2}L) = \frac{2}{L}\sin^2\frac{\pi}{2} = \frac{2}{L}$$

2. The area is the height multiplied by the width, and the width is $\Delta x = 0.01L$:

$$P = \psi^2\left(\tfrac{1}{2}L\right)\Delta x = \frac{2}{L} \times 0.01L = \boxed{0.02}$$

(*b*) 1. The probability of finding the particle is the area under the curve shown in Figure 34-16*b*. To calculate this area, we need to integrate from $x = 0$ to $x = L/4$:

$$P = \int_0^{L/4}\psi^2(x)\,dx = \int_0^{L/4}\frac{2}{L}\sin^2\frac{\pi x}{L}\,dx$$

2. The integral can be evaluated a number of ways. If a table of integrals is used, a change in the integration variable in required. Changing the integration variable to $\theta = \pi x/L$ gives:

$$P = \frac{2}{\pi}\int_0^{\pi/4}\sin^2\theta\,d\theta$$

3. The integral can be found in tables:

$$\int_0^{\pi/4}\sin^2\theta\,d\theta = \left(\frac{\theta}{2} - \frac{\sin 2\theta}{4}\right)\Bigg|_0^{\pi/4} = \left(\frac{\pi}{8} - \frac{1}{4}\right)$$

4. Use the result from Part (*b*), step 3 to calculate the probability:

$$P = \frac{2}{\pi}\left(\frac{\pi}{8} - \frac{1}{4}\right) = \boxed{0.091}$$

CHECK If ψ_1^2 were uniformly distributed on the interval $0 < x < L$, the step-4 result would be 0.25. However, instead of ψ_1^2 being uniformly distributed, it is relatively small on the interval $0 < x < \frac{1}{4}L$, so a step-4 result that is less than 0.25 is expected.

TAKING IT FURTHER An integral was not necessary for Part (*a*) because the area of interest could be well approximated by a rectangle of height ψ^2 and width Δx. The chance of finding the particle in the region $\Delta x = 0.01L$ at $x = \frac{1}{2}L$ is approximately 2 percent. The chance of finding the particle in the region $0 < x < \frac{1}{4}L$ is about 9.1 percent.

CONCEPT CHECK 34-1

A fair six-sided die has the number 1 printed on four faces and the number 6 printed on the other two faces. What is the probability that a 1 comes up when the die is thrown? *Hint: The probability that a specific value comes up for one throw is the fraction of the throws that that value comes up after a large number of throws.*

Example 34-8 Calculating Expectation Values

Find (*a*) $\langle x\rangle$ and (*b*) $\langle x^2\rangle$ for a particle in its ground state in a box of length L.

PICTURE We use $\langle F(x)\rangle = \int F(x)\psi^2(x)\,dx$, with $\psi_n(x) = \sqrt{\frac{2}{L}}\sin\frac{n\pi x}{L}$.

SOLVE

(*a*) 1. Write $\langle x\rangle$ using the ground-state wave function given by Equation 34-25, with $n = 1$:

$$\langle x\rangle = \int_{-\infty}^{+\infty}x\psi^2(x)\,dx = \frac{2}{L}\int_0^L x\sin^2\left(\frac{\pi x}{L}\right)dx$$

2. To evaluate this integral by using a table of integrals, first change the integration variable to $\theta = \pi x/L$:

$$\langle x\rangle = \frac{2}{L}\left(\frac{L}{\pi}\right)^2\int_0^{\pi}\theta\sin^2\theta\,d\theta$$

$$= \frac{2L}{\pi^2}\int_0^{\pi}\theta\sin^2\theta\,d\theta$$

3. The table of integrals gives:

$$\int_0^{\pi}\theta\sin^2\theta\,d\theta = \left[\frac{\theta^2}{4} - \frac{\theta\sin 2\theta}{4} - \frac{\cos 2\theta}{8}\right]_0^{\pi} = \frac{\pi^2}{4}$$

4. Substitute this value into the expression in step 2:

$$\langle x\rangle = \frac{2L}{\pi^2}\int_0^{\pi}\theta\sin^2\theta\,d\theta = \frac{2L}{\pi^2}\frac{\pi^2}{4} = \boxed{\frac{L}{2}}$$

(*b*) 1. Repeat step 1 and step 2 of Part (*a*) for $\langle x^2\rangle$:

$$\langle x^2\rangle = \int_{-\infty}^{+\infty} x^2\psi^2(x)\,dx = \int_0^L x^2\frac{2}{L}\sin^2(\pi x/L)\,dx$$
$$= \frac{2}{L}\left(\frac{L}{\pi}\right)^3\int_0^\pi \theta^2\sin^2\theta\,d\theta = \frac{2L^2}{\pi^3}\int_0^\pi \theta^2\sin^2\theta\,d\theta$$

2. Evaluating the integral using a table of integrals gives:

$$\int_0^\pi \theta^2\sin^2\theta\,d\theta = \left[\frac{\theta^3}{6} - \left(\frac{\theta^2}{4} - \frac{1}{8}\right)\sin 2\theta - \frac{\theta\cos 2\theta}{4}\right]\Bigg|_0^\pi$$
$$= \frac{\pi^3}{6} - \frac{\pi}{4}$$

3. Substitute this value into the expression in step 1 of Part (*b*):

$$\langle x^2\rangle = \frac{2L^2}{\pi^3}\left(\frac{\pi^3}{6} - \frac{\pi}{4}\right) = \left(\frac{1}{3} - \frac{1}{2\pi^2}\right)L^2 = \boxed{0.283L^2}$$

CHECK The expectation value of x is $L/2$, as we would expect, because the probability distribution is symmetric about the midpoint of the box.

TAKING IT FURTHER Note that $\langle x^2\rangle$ is greater than $\langle x\rangle^2$.

CONCEPT CHECK 34-2

A fair six-sided die has the number 1 printed on four faces and the number 6 printed on the other two faces. Let N be the number that comes up when the die is thrown. What is the expectation value of N? What is the expectation value of N^2? *Hint: The expectation value of a quantity is the average value of that quantity after a large number of throws.*

34-10 ENERGY QUANTIZATION IN OTHER SYSTEMS

The quantized energies of a system are generally determined by solving the Schrödinger equation for that system. The form of the Schrödinger equation depends on the potential energy of the particle. The potential energy for a one-dimensional box from $x = 0$ to $x = L$ is shown in Figure 34-17. This potential energy function is called an **infinite square-well potential,** and it is described mathematically by

$$U(x) = \begin{cases} \infty & x < 0 \\ 0 & 0 < x < L \\ \infty & x > L \end{cases} \qquad 34\text{-}28$$

The particle moves freely inside the box, so the potential energy is uniform. For convenience, we choose the value of this potential energy to be zero. Outside the box the potential energy is infinite, so the particle cannot exist outside the box no matter what its energy. We did not need to solve the Schrödinger equation for this potential because the wave functions and quantized frequencies are the same as for a string fixed at both ends, which we studied in Chapter 16. Although this problem seems artificial, actually it is useful for some physical problems, such as a neutron that is constrained to a nucleus that has a large number of protons and neutrons.

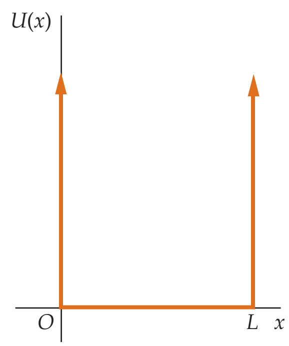

FIGURE 34-17 The infinite square-well potential energy. For $x < 0$ and $x > L$, the potential energy $U(x)$ is infinite. The particle is confined to the region in the well ($0 < x < L$).

THE HARMONIC OSCILLATOR

More realistic than the particle in a box is the harmonic oscillator, which applies to an object of mass m on a spring that has a force constant k or to any system undergoing small oscillations about a stable equilibrium. Figure 34-18 shows the potential energy function

$$U(x) = \tfrac{1}{2}kx^2 = \tfrac{1}{2}m\omega_0^2x^2$$

where $\omega_0 = \sqrt{k/m}$ is the natural frequency of the oscillator. Classically, the object oscillates between $x = +A$ and $x = -A$. Its total energy is $E = \frac{1}{2}m\omega_0^2A^2$, which can have any nonnegative value, including zero.

In quantum theory, the particle is represented by the wave function $\psi(x)$, which is determined by solving the Schrödinger equation for this potential. Normalizable wave functions $\psi_n(x)$ occur only for discrete values of the energy E_n given by

$$E_n = (n + \tfrac{1}{2})hf_0 \qquad n = 0, 1, 2, 3, \ldots \qquad 34\text{-}29$$

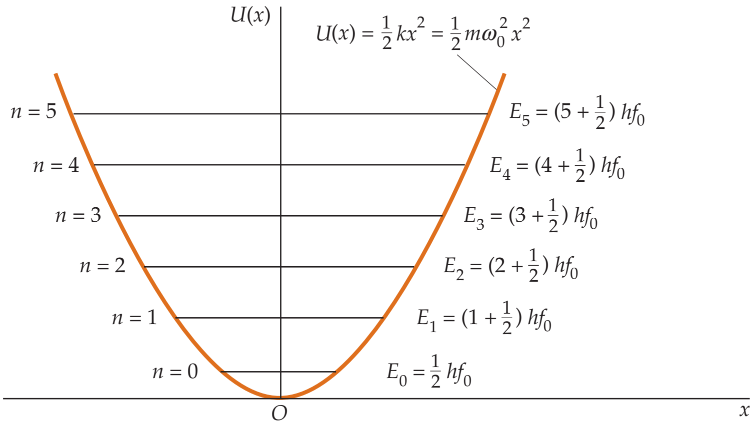

FIGURE 34-18 Harmonic oscillator potential energy function. The allowed energy levels are indicated by the equally spaced horizontal lines. Also, $\omega_0 = 2\pi f_0$.

where $f_0 = \omega_0/2\pi$ is the classical frequency of the oscillator. Note that the energy levels of a harmonic oscillator are evenly spaced with separation hf_0, as indicated in Figure 34-18. Compare this with the uneven spacing of the energy levels for the particle in a box, as shown in Figure 34-12. If a harmonic oscillator makes a transition from energy level n to the next lowest energy level $n - 1$, the frequency f of the photon emitted is given by $hf = E_i - E_f$ (Equation 34-23). Applying this equation gives

$$hf = E_n - E_{n-1} = (n + \tfrac{1}{2})hf_0 - (n - 1 + \tfrac{1}{2})hf_0 = hf_0$$

The frequency f of the emitted photon is therefore equal to the classical frequency f_0 of the oscillator.

THE HYDROGEN ATOM

In the hydrogen atom, an electron is bound to a proton by the electrostatic force of attraction (discussed in Chapter 21). This force varies inversely as the square of the separation distance (exactly like the gravitational attraction of Earth and the Sun). The potential energy of the electron–proton system therefore varies inversely with separation distance (Equation 23-9). As in the case of gravitational potential energy, the potential energy of the electron–proton system is chosen to be zero if the electron is an infinite distance from the proton. Then for all finite distances, the potential energy is negative. Like the case of an object orbiting Earth, the electron–proton system is a bound system if its total energy is negative. Like the energies of a particle in a box and of a harmonic oscillator, the energies are described by a quantum number n. As we will see in Chapter 36, the allowed energies of the hydrogen atom are given by

$$E_n = -\frac{13.6\text{ eV}}{n^2} \qquad n = 1, 2, 3, \ldots \tag{34-30}$$

The lowest energy corresponds to $n = 1$. The ground-state energy is thus -13.6 eV. The energy of the first excited state is $-(13.6\text{ eV})/2^2 = -3.40$ eV. Figure 34-19 shows the energy-level diagram for the hydrogen atom. The vertical arrows indicate transitions from a higher state to a lower state that accompany the emission of electromagnetic radiation. Only those transitions ending at the first excited state ($n = 2$) involve energy differences in the range of visible light of 1.77 eV to 3.10 eV, as calculated in Example 34-1.

Other atoms are more complicated than the hydrogen atom, but their energy levels are similar in many ways to those of hydrogen. Their ground-state energies are of the order of -1 eV to -10 eV, and many transitions involve energies corresponding to photons in the visible range.

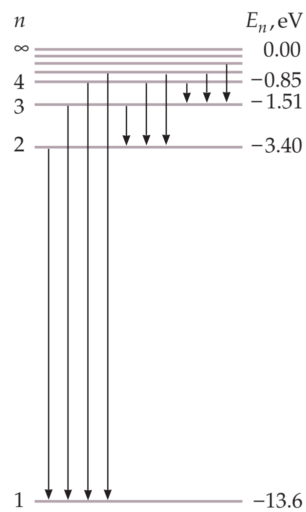

FIGURE 34-19 Energy-level diagram for the hydrogen atom. The energy of the ground state is -13.6 eV. As n approaches infinity, the energy approaches 0, which is the highest energy state for which an electron is bound to the nucleus.

! Do not think an electron orbits a proton in a classical orbit like Earth's orbit around the Sun. It doesn't.

Summary

1. All phenomena propagate like waves and interact like particles.
2. The quantum of light is called a photon and has energy $E = hf$, where h is Planck's constant.
3. The relation between wavelength and momentum of electrons, photons, and other particles is given by the de Broglie relation $\lambda = h/p$.
4. Energy quantization in bound systems arises from standing-wave conditions, which are equivalent to boundary conditions on the wave function.
5. The uncertainty principle is a fundamental law of nature that places theoretical restrictions on the precision of a simultaneous measurement of the position and momentum of a particle. It follows from the general properties of waves.

TOPIC	RELEVANT EQUATIONS AND REMARKS	
1. Constants and Values		
Planck's constant	$h = 6.626 \times 10^{-34}\ \mathrm{J \cdot s} = 4.136 \times 10^{-15}\ \mathrm{eV \cdot s}$	34-2
hc	$hc = 1240\ \mathrm{eV \cdot nm}$	34-5
2. The Particle Nature of Light: Photons	Energy is quantized.	
Photon energy and momentum	$E = hf \quad \text{and} \quad E = pc$	34-1 and 34-6
3. Frequency–Wavelength (Energy–Momentum) Relations		
Photons and material particles (de Broglie relations)	$E = hf \quad \text{and} \quad p = \dfrac{h}{\lambda}$	34-14 and 34-13
Nonrelativistic particles	$K = \dfrac{p^2}{2m} \quad \text{so} \quad \lambda = \dfrac{hc}{\sqrt{2mc^2 K}}$	34-15
Photoelectric effect	$K_{\max} = \left(\tfrac{1}{2}mv^2\right)_{\max} = hf - \phi$ where ϕ is the work function of the cathode.	34-3
Compton scattering	$\lambda_s - \lambda_i = \dfrac{h}{m_e c}(1 - \cos\theta) = \lambda_C(1 - \cos\theta) = 2.426\ \mathrm{pm}\,(1 - \cos\theta)$	34-11
4. Quantum Mechanics	The state of a particle, such as an electron, is described by its wave function ψ, which is the solution of the Schrödinger wave equation.	
Probability density	The probability of finding the particle in some region of space dx is given by $P(x) = \psi^2(x)\, dx$	34-17
Normalization condition	$\int_{-\infty}^{\infty} \psi^2\, dx = 1$	34-18
Quantum number	The wave function for a particular energy state is characterized by a quantum number n. In three dimensions there are three quantum numbers—one associated with a boundary condition in each dimension.	
Expectation value	The expectation value of x is the same as the average value of x that we would expect to obtain from a measurement of the positions of a large number of particles with the same wave function $\psi(x)$. $\langle x \rangle = \int_{-\infty}^{+\infty} x\psi^2(x)\, dx$ $\langle F(x) \rangle = \int_{-\infty}^{+\infty} F(x)\psi^2(x)\, dx$	34-26 34-27

TOPIC	RELEVANT EQUATIONS AND REMARKS
5. Wave–Particle Duality	Photons, electrons, neutrons, and all other carriers of momentum and energy exhibit both wave and particle properties. Everything propagates like a classical wave, exhibiting diffraction and interference, but exchanges energy in discrete lumps like a classical particle. Because the wavelength of macroscopic objects is so small, diffraction and interference are not observed. Also, if a macroscopic amount of energy is exchanged, so many quanta are involved that the particle nature of the energy is not evident.
6. Uncertainty Principle	The wave–particle duality of nature leads to the uncertainty principle, which states that the product of the uncertainty in a measurement of position and the uncertainty in a measurement of momentum must be greater than or equal to $\frac{1}{2}\hbar$, where $\hbar$ is Planck's constant divided by 2π. $\Delta x\, \Delta p_x \geq \frac{1}{2}\hbar$ 34-19

Answers to Concept Checks

34-1 2/3

34-2 $\langle N \rangle = 8/3$ $\langle N^2 \rangle = 38/3$

Answers to Practice Problems

34-1 4.13×10^{-7} eV

34-2 (*a*) 12.4 μm, (*b*) 1.24 nm, (*c*) 1.24 pm

34-3 $1.46 \times 10^{7}\ \text{cm}^{-3}$

34-4 $0.6c$

34-5 1.4×10^{-34} m

34-6 0.388 nm. From this result, we see that a 10-eV electron has a de Broglie wavelength of about 0.4 nm. This quantity is of the same order of magnitude as the size of the atom and the spacing of atoms in a crystal.

34-7 4.70 nm

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • The quantized character of electromagnetic radiation is observed by (*a*) the Young double-slit experiment, (*b*) diffraction of light by a small aperture, (*c*) the photoelectric effect, (*d*) the J. J. Thomson cathode-ray experiment. SSM

2 •• Two monochromatic light sources, A and B, emit the same number of photons per second. The wavelength of A is $\lambda_A = 400$ nm and the wavelength of B is $\lambda_B = 600$ nm. The power radiated by source B (*a*) is equal to the power of source A, (*b*) is less than the power of source A, (*c*) is greater than the power of source A, (*d*) cannot be compared to the power from source A using the available data.

3 • The work function of a surface is ϕ. The threshold wavelength for emission of photoelectrons from the surface is equal to (*a*) hc/ϕ, (*b*) ϕ/hf, (*c*) hf/ϕ, (*d*) none of the above. SSM

4 •• When light of wavelength λ_1 is incident on a certain photoelectric cathode, no electrons are emitted, no matter how intense the incident light is. Yet, when light of wavelength $\lambda_2 < \lambda_1$ is incident, electrons are emitted, even when the incident light has low intensity. Explain this observation.

5 • True or false: (*a*) The wavelength of an electron's matter wave varies inversely with the momentum of the electron. (*b*) Electrons can undergo diffraction. (*c*) Neutrons can undergo diffraction.

6 • If the wavelength of an electron is equal to the wavelength of a proton, then (*a*) the speed of the proton is greater than the speed of the electron, (*b*) the speeds of the proton and the electron are equal, (*c*) the speed of the proton is less than the speed of the electron, (*d*) the energy of the proton is greater than the energy of the electron, (*e*) both (*a*) and (*d*) are correct.

7 • A proton and an electron have equal kinetic energies. It follows that the wavelength of the proton is (*a*) greater than the wavelength of the electron, (*b*) equal to the wavelength of the electron, (*c*) less than the wavelength of the electron.

8 • The parameter x represents the position of a particle. Can the expectation value of x ever have a value such that the probability density function $P(x)$ is zero? Give a specific example.

9 •• It was once believed that if two identical experiments are done on identical systems under the same conditions, the results must be identical. Explain how this statement can be modified so that it is consistent with quantum physics.

10 •• A six-sided die has the numeral 1 painted on three sides and the numeral 2 painted on the other three sides. (*a*) What is the probability of a 1 coming up when the die is thrown? (*b*) What is the expectation value of the numeral that comes up when the die is thrown? (*c*) What is the expectation value of the cube of the numeral that comes up when the die is thrown?

ESTIMATION AND APPROXIMATION

11 •• During an advanced physics lab, students measure the Compton wavelength, λ_C. The students obtain the following wavelength shifts $\lambda_s - \lambda_i$ as a function of scattering angle θ.

θ	45°	75°	90°	135°	180°
$\lambda_s - \lambda_i$	0.647 pm	1.67 pm	2.45 pm	3.98 pm	4.95 pm

Use their data to estimate the value for the Compton wavelength. Compare this number with the accepted value. SSM

12 •• **SPREADSHEET** Students in a physics lab are trying to determine the value of Planck's constant h, using a photoelectric apparatus similar to the one shown in Figure 34-2. The students are using a helium–neon laser that has a tunable wavelength as the light source. The data that the students obtain for the maximum electron kinetic energies are

λ	544 nm	594 nm	604 mn	612 nm	633 mn
K_{max}	0.360 eV	0.199 eV	0.156 eV	0.117 eV	0.062 eV

(*a*) Using a spreadsheet program or graphing calculator, plot K_{max} versus light frequency. (*b*) Use the graph to estimate the value of Planck's constant. (*Note:* You may wish to use a feature of your spreadsheet program or graphing calculator to obtain the best straight-line fit to the data.) (*c*) Compare your result with the accepted value for Planck's constant.

13 •• **SPREADSHEET** The cathode that was used by the students in the experiment described in Problem 12 is constructed from one of the following metals:

Metal	Tungsten	Silver	Potassium	Cesium
Work function	4.58 eV	2.4 eV	2.1 eV	1.9 eV

Determine which metal composes the cathode by using the same data given in Problem 12. (*a*) Using a spreadsheet program or graphing calculator, plot K_{max} versus frequency. (*b*) Use the graph to estimate the value of the work function based on the students' data. (*Note:* You may wish to use a feature of your spreadsheet program or graphing calculator to obtain the best straight-line fit to the data.) (*c*) Which metal was most likely used for the cathode in their experiment?

THE PARTICLE NATURE OF LIGHT: PHOTONS

14 • Find the photon energy in electron volts for light of wavelength (*a*) 450 nm, (*b*) 550 nm, and (*c*) 650 nm.

15 • Find the photon energy in electron volts for an electromagnetic wave of frequency (*a*) 100 MHz in the FM radio band and (*b*) 900 kHz in the AM radio band.

16 • What are the frequencies of photons that have the following energies: (*a*) 1.00 eV, (*b*) 1.00 keV, and (*c*) 1.00 MeV?

17 • Find the photon energy in electron volts if the wavelength is (*a*) 0.100 nm (about 1 atomic diameter) and (*b*) 1.00 fm (1 fm = 10^{-15} m, about 1 nuclear diameter).

18 •• The wavelength of red light emitted by a 3.00-mW helium–neon laser is 633 nm. If the diameter of the laser beam is 1.00 mm, what is the density of photons in the beam? Assume that the intensity is uniformly distributed across the beam.

19 • **ENGINEERING APPLICATION** Lasers used in a telecommunications network typically produce light that has a wavelength near 1.55 μm. How many photons per second are being transmitted if such a laser has an output power of 2.50 mW? SSM

THE PHOTOELECTRIC EFFECT

20 • The work function for tungsten is 4.58 eV. (*a*) Find the threshold frequency and wavelength for the photoelectric effect to occur when monochromatic electromagnetic radiation is incident on the surface of a sample of tungsten. Find the maximum kinetic energy of the electrons if the wavelength of the incident light is (*b*) 200 nm and (*c*) 250 nm.

21 • When monochromatic ultraviolet light that has a wavelength equal to 300 nm is incident on a sample of potassium, the emitted electrons have maximum kinetic energy of 2.03 eV. (*a*) What is the energy of an incident photon? (*b*) What is the work function for potassium? (*c*) What would be the maximum kinetic energy of the electrons if the incident electromagnetic radiation had a wavelength of 430 nm? (*d*) What is the maximum wavelength of incident electromagnetic radiation that will result in the photoelectric emission of electrons by a sample of potassium?

22 • The maximum wavelength of electromagnetic radiation that will result in the photoelectric emission of electrons from a sample of silver is 262 nm. (*a*) Find the work function for silver. (*b*) Find the maximum kinetic energy of the electrons if the incident radiation has a wavelength of 175 nm.

23 • The work function for cesium is 1.90 eV. (*a*) Find the minimum frequency and maximum wavelength of electromagnetic radiation that will result in the photoelectric emission of electrons from a sample of cesium. Find the maximum kinetic energy of the electrons if the wavelength of the incident radiation is (*b*) 250 nm and (*c*) 350 nm.

24 •• When a surface is illuminated with electromagnetic radiation of wavelength 780 nm, the maximum kinetic energy of the emitted electrons is 0.37 eV. What is the maximum kinetic energy if the surface is illuminated using radiation of wavelength 410 nm?

COMPTON SCATTERING

25 • Find the shift in wavelength of photons scattered by free stationary electrons at $\theta = 60°$. (Assume that the electrons are initially moving with negligible speed and are virtually free of (unattached to) any atoms or molecules.)

26 • When photons are scattered by electrons in a carbon sample, the shift in wavelength is 0.33 pm. Find the scattering angle. (Assume that the electrons are initially moving with negligible speed and are virtually free of (unattached to) any atoms or molecules.)

27 • The photons in a monochromatic beam are scattered by electrons. The wavelength of the photons that are scattered at an angle of 135° with the direction of the incident photon beam is 2.3 percent less than the wavelength of the incident photons. What is the wavelength of the incident photons?

28 • Compton used photons of wavelength 0.0711 nm. (*a*) What is the energy of one of those photons? (*b*) What is the wavelength of the photons scattered in the direction opposite to the direction of the incident photons? (*c*) What is the energy of the photon scattered in that direction?

29 • For the photons used by Compton (see Problem 28), find the momentum of the incident photon and the momentum of the photon scattered in the direction opposite to the direction of the incident photons. Use the conservation of momentum to find the momentum of the recoil electron in this case.

30 •• A beam of photons that have a wavelength equal to 6.00 pm is scattered by electrons initially at rest. A photon in the beam is scattered in a direction perpendicular to the direction of the incident beam. (*a*) What is the change in wavelength of the photon? (*b*) What is the kinetic energy of the electron?

ELECTRONS AND MATTER WAVES

31 • An electron is moving at 2.5×10^5 m/s. Find the electron's wavelength.

32 • An electron has a wavelength of 200 nm. Find (*a*) the magnitude of its momentum and (*b*) its kinetic energy.

33 •• An electron, a proton, and an alpha particle each have a kinetic energy of 150 keV. Find (*a*) the magnitudes of their momenta and (*b*) their de Broglie wavelengths.

34 • A neutron in a reactor has a kinetic energy of approximately 0.020 eV. Calculate the wavelength of the neutron.

35 • Find the wavelength of a proton that has a kinetic energy of 2.00 MeV.

36 • What is the kinetic energy of a proton whose wavelength is (*a*) 1.00 nm and (*b*) 1.00 fm?

37 • The kinetic energy of the electrons in the electron beam in a run of Davisson and Germer's experiment was 54 eV. Calculate the wavelength of the electrons in the beam.

38 • The distance between Li^+ and Cl^- ions in a LiCl crystal is 0.257 nm. Find the energy of electrons that have a wavelength equal to that spacing.

39 • An electron microscope uses electrons that have energies equal to 70 keV. Find the wavelength of the electrons. SSM

40 • What is the wavelength of a neutron that has a speed of 1.00×10^6 m/s?

A PARTICLE IN A BOX

41 •• (*a*) Find the energy of the ground state ($n = 1$) and the first two excited states of a neutron in a one-dimensional box of length $L = 1.00 \times 10^{-15}$ m = 1.00 fm (about the diameter of an atomic nucleus). Make an energy-level diagram for the system. Calculate the wavelength of electromagnetic radiation emitted when the neutron makes a transition from (*b*) $n = 2$ to $n = 1$, (*c*) $n = 3$ to $n = 2$, and (*d*) $n = 3$ to $n = 1$.

42 •• (*a*) Find the energy of the ground state ($n = 1$) and the first two excited states of a neutron in a one-dimensional box of length 0.200 nm (about the diameter of a H_2 molecule). Calculate the wavelength of electromagnetic radiation emitted when the neutron makes a transition from (*b*) $n = 2$ to $n = 1$, (*c*) $n = 3$ to $n = 2$, and (*d*) $n = 3$ to $n = 1$.

CALCULATING PROBABILITIES AND EXPECTATION VALUES

43 •• A particle is in the ground state of a one-dimensional box that has length L. (The box has one end at the origin and the other end on the positive x axis.) Determine the probability of finding the particle in the interval of length $\Delta x = 0.002L$ and centered at (*a*) $\frac{1}{4}x = L$, (*b*) $x = \frac{1}{2}L$, and (*c*) $x = \frac{3}{4}L$. (Because Δx is very small you need not do any integration.)

44 •• A particle is in the second excited state ($n = 3$) of a one-dimensional box that has length L. (The box has one end at the origin and the other end on the positive x axis.) Determine the probability of finding the particle in the interval of length $\Delta x = 0.002L$ and centered at (*a*) $x = \frac{1}{3}L$, (*b*) $x = \frac{1}{2}L$, and (*c*) $x = \frac{2}{3}L$. (Because Δx is very small you need not do any integration.)

45 •• A particle is in the first excited ($n = 2$) state of a one-dimensional box that has length L. (The box has one end at the origin and the other end on the positive x axis.) Find (*a*) $\langle x \rangle$ and (*b*) $\langle x^2 \rangle$.

46 •• A particle in a one-dimensional box that has length L is in the first excited state ($n = 2$). (The box has one end at the origin and the other end on the positive x axis.) (*a*) Sketch $\psi^2(x)$ versus x for this state. (*b*) What is the expectation value $\langle x \rangle$ for this state? (*c*) What is the probability of finding the particle in some small region dx centered at $x = L/2$? (*d*) Are your answers for Part (*b*) and Part (*c*) contradictory? If not, explain why your answers are not contradictory.

47 •• A particle of mass m has a wave function given by $\psi(x) = Ae^{-|x|/a}$, where A and a are positive constants. (*a*) Find the normalization constant A. (*b*) Calculate the probability of finding the particle in the region $-a \le x \le a$.

48 •• A one-dimensional box is on the x axis in the region of $0 \le x \le L$. A particle in this box is in its ground state. Calculate the probability that the particle will be found in the region (*a*) $0 < x < \frac{1}{2}L$, (*b*) $0 < x < \frac{1}{3}L$, and (*c*) $0 < x < \frac{3}{4}L$.

49 •• A one-dimensional box is on the x axis in the region of $0 \le x \le L$. A particle in this box is in its first excited state. Calculate the probability that the particle will be found in the region (*a*) $0 < x < \frac{1}{2}L$, (*b*) $0 < x < \frac{1}{3}L$, and (*c*) $0 < x < \frac{3}{4}L$.

50 •• The classical probability distribution function for a particle in a one-dimensional box on the x axis in the region of $0 < x < L$ is given by $P(x) = 1/L$. Use this expression to show that $\langle x \rangle = \frac{1}{2}L$ and $\langle x^2 \rangle = \frac{1}{3}L^2$ for a classical particle in the box.

51 •• A one-dimensional box is on the x axis in the region of $0 \le x \le L$. (*a*) The wave functions for a particle in the box are given by

$$\psi_n(x) = \sqrt{\frac{2}{L}} \sin \frac{n\pi x}{L} \qquad n = 1, 2, 3, \ldots$$

For a particle in the nth state, show that $\langle x \rangle = \frac{1}{2}L$ and $\langle x^2 \rangle = L^2/3 - L^2/(2n^2\pi^2)$. (*b*) Compare these expressions for $\langle x \rangle$ and $\langle x^2 \rangle$, for $n \gg 1$, with the expressions for $\langle x \rangle$ and $\langle x^2 \rangle$ for the classical distribution of Problem 50.

52 •• **SPREADSHEET** (*a*) Use a spreadsheet program or graphing calculator to plot $\langle x^2 \rangle$ as a function of the quantum number n for the particle in the box described in Problem 48 and for values of n from 1 to 100. Assume $L = 1.00$ m for your graph. Refer to Problem 51. (*b*) Comment on the significance of any asymptotic limits that your graph shows.

53 •• The wave functions for a particle of mass m in a one-dimensional box of length L *centered at the origin* (so that the ends are at $x = \pm\frac{1}{2}L$) are given by

$$\psi(x) = \sqrt{\frac{2}{L}} \cos \frac{n\pi x}{L} \qquad n = 1, 3, 5, 7, \ldots$$

and

$$\psi(x) = \sqrt{\frac{2}{L}} \sin \frac{n\pi x}{L} \qquad n = 2, 4, 6, 8, \ldots$$

Calculate $\langle x \rangle$ and $\langle x^2 \rangle$ for the ground state ($n = 1$).

54 •• Calculate $\langle x \rangle$ and $\langle x^2 \rangle$ for the first excited state ($n = 2$) of the box described in Problem 53.

GENERAL PROBLEMS

55 • Photons in a uniform 4.00-cm-diameter light beam have wavelengths equal to 400 nm and the beam has an intensity of 100 W/m^2. (*a*) What is the energy of each photon in the beam? (*b*) How much energy strikes an area of 1.00 cm^2 perpendicular to the beam in 1.00 s? (*c*) How many photons strike this area in 1.00 s? SSM

56 • A 1-μg particle is moving with a speed of approximately 1 mm/s in a one-dimensional box that has a length equal to 1 cm. Calculate the approximate value of the quantum number n of the state occupied by the particle.

57 • (*a*) For the particle and box of Problem 56, find Δx and Δp_x, assuming that these uncertainties are given by $\Delta x/L = 0.01$ percent and $\Delta p_x/p_x = 0.01$ percent. (*b*) What is $(\Delta x\, \Delta p_x)/\hbar$?

58 • In 1987, a laser at Los Alamos National Laboratory produced a flash that lasted 1×10^{-12} s and had a power of 5×10^{15} W. Estimate the number of emitted photons, assuming they all had wavelengths equal to 400 nm.

59 • **ENGINEERING APPLICATION** You cannot "see" anything smaller than the wavelength of the wave used to make the observation. What is the minimum energy of an electron needed in an electron microscope to "see" an atom that has a diameter of about 0.1 nm?

60 • A common flea that has a mass of 0.008 g can jump vertically as high as 20 cm. Estimate the wavelength for the flea immediately after takeoff.

61 •• **BIOLOGICAL APPLICATION** A 100-W source radiates light of wavelength 600 nm uniformly in all directions. An eye that has been adapted to the dark has a 7-mm-diameter pupil and can detect the light if at least 20 photons per second enter the pupil. How far from the source can the light be detected under these rather extreme conditions? SSM

62 •• **BIOLOGICAL APPLICATION** The diameter of the pupil of an eye under room-light conditions is approximately 5 mm. Find the intensity of light that has a wavelength equal to 600 nm so that 1 photon per second passes through the pupil.

63 •• A 100-W incandescent lightbulb radiates 2.6 W of visible light uniformly in all directions. (*a*) Find the intensity of the light from the bulb at a distance of 1.5 m. (*b*) If the average wavelength of the visible light is 650 nm, and counting only those photons in the visible spectrum, find the number of photons per second that strike a surface that has an area equal to 1.0 cm^2, is oriented so that the line to the bulb is perpendicular to the surface, and is a distance of 1.5 m from the bulb.

64 •• When light of wavelength λ_1 is incident on the cathode of a photoelectric tube, the maximum kinetic energy of the emitted electrons is 1.8 eV. If the wavelength is reduced to $\frac{1}{2}\lambda_1$, the maximum kinetic energy of the emitted electrons is 5.5 eV. Find the work function ϕ of the cathode material.

65 •• An incident photon of energy E_i undergoes Compton scattering at an angle of θ. Show that the energy E_s of the scattered photon is given by

$$E_\text{s} = \frac{E_\text{i}}{1 + (E_\text{i}/m_\text{e}c^2)(1 - \cos\theta)}$$

66 •• A particle is confined to a one-dimensional box. While the particle makes a transition from the state n to the state $n - 1$, radiation of 114.8 nm is emitted. While the particle makes the transition from the state $n - 1$ to the state $n - 2$, radiation of wavelength 147 nm is emitted. The ground-state energy of the particle is 1.2 eV. Determine n.

67 •• The Pauli exclusion principle states that no more than one electron may occupy a particular quantum state at a time. Electrons intrinsically occupy two spin states. Therefore, if we wish to model an atom as a collection of electrons trapped in a one-dimensional box, no more than two electrons in the box can have the same value of the quantum number n. Calculate the energy that the most energetic electron(s) would have for the uranium atom that has an atomic number 92. Assume the box has a length of 0.050 nm and the electrons are in the lowest possible energy states. How does this energy compare to the rest energy of the electron? SSM

68 •• A beam of electrons that each have the same kinetic energy illuminates a pair of slits separated by a distance 54 nm. The beam forms bright and dark fringes on a screen located a distance 1.5 m beyond the two slits. The arrangement is otherwise identical to that used in the optical two-slit interference experiment described in Chapter 33 and in Figure 33-7 and the fringes have the appearance shown in Figure 34-8*d*. The bright fringes are found to be separated by a distance of 0.68 mm. What is the kinetic energy of the electrons in the beam?

69 •• When a surface is illuminated by light of wavelength λ, the maximum kinetic energy of the emitted electrons is 1.20 eV. If the wavelength $\lambda' = 0.800\lambda$ is used, the maximum kinetic energy increases to 1.76 eV. For wavelength $\lambda' = 0.600\lambda$, the maximum kinetic energy of the emitted electrons is 2.676 eV. Determine the work function of the surface and the wavelength λ.

70 •• A simple pendulum has a length equal to 1.0 m and has a bob that has a mass equal to 0.30 kg. The energy of this oscillator is quantized, and the allowed values of the energy are given by $E_n = \left(n + \frac{1}{2}\right)hf_0$, where n is an integer and f_0 is the frequency of the pendulum. (*a*) Find n if the angular amplitude is 1.0°. (*b*) Find n such that E_{n+1} exceeds E_n by 0.010 percent.

71 •• (*a*) Show that for large n, the fractional difference in energy between state n and state $n + 1$ for a particle in a one-dimensional box is given approximately by

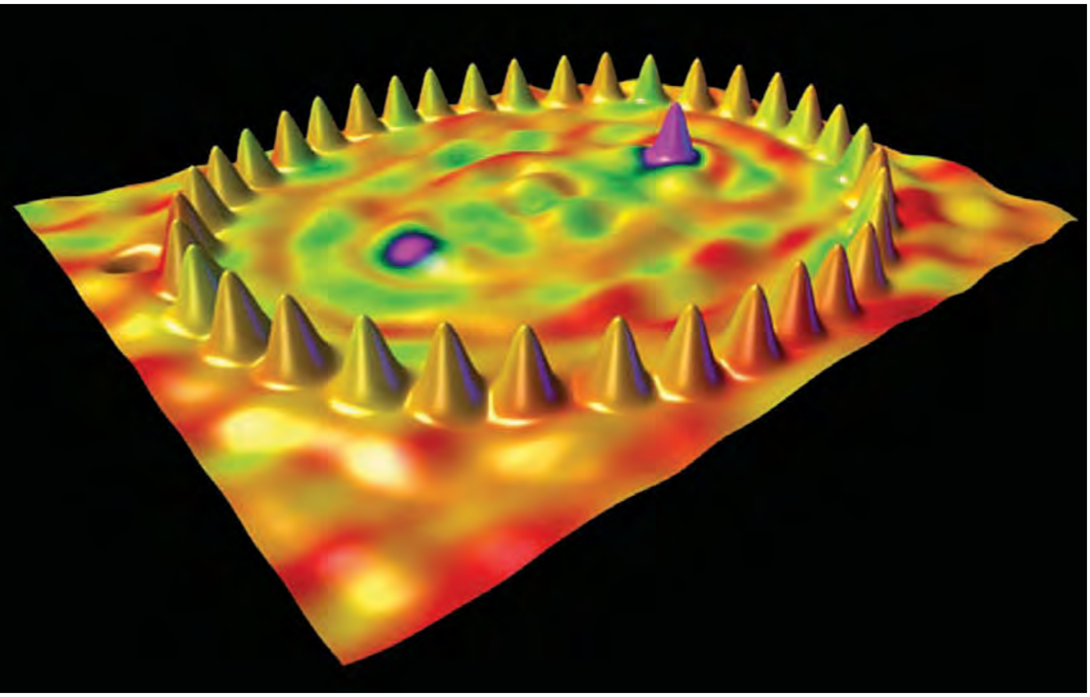
$$(E_{n+1} - E_n)/E_n \approx 2/n$$

(*b*) What is the approximate percentage energy difference between the states $n_1 = 1000$ and $n_2 = 1001$? (*c*) Comment on how this result is related to Bohr's correspondence principle. SSM

72 •• A mode-locked, titanium–sapphire laser has a wavelength of 850 nm and produces 100 million pulses of light each second. Each pulse has a duration of 125 femtoseconds ($1 \text{ fs} = 10^{-15}$ s) and consists of 5×10^9 photons. What is the average power produced by the laser?

73 •• This problem estimates the time lag in the photoelectric effect that is expected classically but not observed. Let the intensity of the incident radiation falling on an atom be 0.010 W/m^2. (*a*) If the area presented by an atom is 0.010 nm^2, find the energy per second falling on an atom. (*b*) If the work function is 2.0 eV, how long would it take for this much energy to fall on the atom if the radiation energy was distributed uniformly rather than in compact packets (photons)?

CHAPTER 35



A QUANTUM MIRAGE. THE SCANNING TUNNELING MICROSCOPE (STM) ALLOWS ONE TO PUSH INDIVIDUAL ATOMS AROUND ON A SURFACE AND TO IMAGE THEM. ESPECIALLY INTRIGUING ARE IMAGES OF QUANTUM CORRALS, WHICH ARE CIRCULAR OR ELLIPTICAL ARRANGEMENTS ON A SURFACE INSIDE OF WHICH THE WAVES CORRESPONDING TO ELECTRONS NEAR THE SUBSTRATE SURFACE CAN BE REVEALED. THIS IMAGE COMES FROM IBM, WHERE PHYSICISTS PLACED THIRTY-SIX COBALT ATOMS IN AN ELLIPTICAL “STONEHENGE” PATTERN ON A COPPER SURFACE. AN EXTRA MAGNETIC COBALT ATOM WAS PLACED AT ONE OF THE TWO FOCI OF THE ELLIPSE, CAUSING VISIBLE INTERACTIONS WITH THE SURFACE ELECTRON WAVES. BUT THE WAVES ALSO SEEM TO BE INTERACTING WITH A PHANTOM COBALT ATOM AT THE OTHER FOCUS, AN ATOM THAT IS NOT REALLY THERE. *(Courtesy of IBM and the IBM Almadin Laboratories.)*

Applications of the Schrödinger Equation

? Could the phantom cobalt atom described above be caused by reflections of waves from the corral of cobalt atoms? (See Section 35-4).

In Chapter 34, we found that electrons and other particles have wave properties and are described by wave functions in the form $\Psi(x, t)$. We also mentioned that the wave function is a solution of the Schrödinger equation, and we discussed some solutions qualitatively without reference to the equation itself. In particular, we showed how the standing-wave conditions lead to quantization of energy for a particle confined to a one-dimensional box.

In this chapter we continue our discussion of the material introduced in Chapter 34. We discuss the Schrödinger equation and apply the equation to the particle-in-the-box problem and to several other situations in which a particle is confined to a region of space to illustrate how boundary conditions lead to energy quantization. We then show how the Schrödinger equation leads to barrier penetration and discuss the extension of the Schrödinger equation to more than one dimension and to more than one particle.

35-1 THE SCHRÖDINGER EQUATION

Like the classical wave equation (Equation 15-10*b*), the Schrödinger equation is a partial differential equation in space and time. Like Newton's laws of motion, the Schrödinger equation cannot be derived. Its validity, like that of Newton's laws, lies in its agreement with experiment. In one dimension, the Schrödinger equation is*

$$-\frac{\hbar^2}{2m}\frac{\partial^2\Psi(x,t)}{\partial x^2} + U\Psi(x,t) = i\hbar\frac{\partial\Psi(x,t)}{\partial t} \qquad 35\text{-}1$$

TIME-DEPENDENT SCHRÖDINGER EQUATION

where U is the potential energy function and $\Psi(x, t)$ is a wave function. Equation 35-1 is called the **time-dependent Schrödinger equation.** Unlike the classical wave equation, it relates the *second* space derivative of the wave function to the *first* time derivative of the wave function, and it contains the imaginary number $i = \sqrt{-1}$. The wave functions that are solutions of this equation are not necessarily real. $\Psi(x, t)$ is not a measurable function like the classical wave functions for sound or electromagnetic waves. The probability of finding a particle in some region of space dx certainly has a real value, though. We can modify slightly the equation for probability density given in Chapter 34 (Equation 34-17) to determine the probability of finding a particle in some region dx

$$P(x,t)\,dx = |\Psi(x,t)|^2\,dx = \Psi^*\Psi\,dx \qquad 35\text{-}2$$

where Ψ^*, the complex conjugate of Ψ, is identical to Ψ, except that $-i$ is substituted for i wherever i appears in the expression for Ψ.†

See **Math Tutorial** *for more information on*
Complex Numbers

In classical mechanics, the standing-wave solutions to the wave equation (Equation 16-16) are of great interest and value. Not surprisingly, standing-wave solutions to the Schrödinger wave equation are also of great interest and value. The wave function for the standing-wave motion of a uniform taut string is $A\sin(kx)\cos(\omega t + \delta)$, which is representative of all standing waves. A standing wave function can always be expressed as a function of position multiplied by a function of time, where the function of time is one that varies sinusoidally with time. Standing-wave solutions to the one-dimensional Schrödinger wave equation are thus expressed

$$\Psi(x,t) = \psi(x)e^{-i\omega t} \qquad 35\text{-}3$$

where $e^{-i\omega t} = \cos(\omega t) - i\sin(\omega t)$. The right side of Equation 35-1 is then

$$i\hbar\frac{\partial\Psi(x,t)}{\partial t} = i\hbar(-i\omega)\psi(x)e^{-i\omega t} = \hbar\omega\psi(x)e^{-i\omega t} = E\psi(x)e^{-i\omega t}$$

where $E = \hbar\omega$ is the energy of the particle.

The Schrödinger wave equation has standing-wave solutions only if the potential energy function U depends on position x alone. Substituting $\psi(x)e^{-i\omega t}$ into Equation 35-1 and canceling the common factor $e^{-i\omega t}$, we obtain an equation for $\psi(x)$, called the **time-independent Schrödinger equation:**

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = E\psi(x) \qquad 35\text{-}4$$

TIME-INDEPENDENT SCHRÖDINGER EQUATION

* Although we simply state the Schrödinger equation, Schrödinger himself had a vast knowledge of classical wave theory that led him to this equation.

† Every complex number can be written in the form $z = a + bi$, where a and b are real numbers and $i = \sqrt{-1}$. The complex conjugate of z is $z^* = a - bi$, so $z^*z = (a + bi)(a - bi) = a^2 + b^2 = |z|^2$.

where we have written U as $U(x)$ to emphasize that while U may depend on position, U does not depend on time. The function $U(x)$ represents the interaction between the environment and the particle being observed. Different environments require different expressions for the potential energy function U in the Schrödinger equation.

The calculation of the allowed energy levels in a system involves only the time-independent Schrödinger equation, whereas finding the probabilities of transition between these levels requires the solution of the time-dependent equation. In this book, we will be concerned only with the time-independent Schrödinger equation (Equation 35-4).

The solution of Equation 35-4 depends on the form of the potential energy function $U(x)$. When $U(x)$ is such that the particle is confined to some region of space, only certain discrete energies E_n give solutions ψ_n that can satisfy the normalization condition (Equation 34-18):

$$\int_{-\infty}^{\infty} |\psi_n|^2 dx = 1$$

The complete time-dependent wave functions are then given, from Equation 35-3, by

$$\Psi_n(x, t) = \psi_n(x)e^{-i\omega_n t} = \psi_n(x)e^{-i(E_n/\text{h})t} \qquad 35\text{-}5$$

A PARTICLE IN AN INFINITE SQUARE-WELL POTENTIAL

We will illustrate the use of the time-independent Schrödinger equation by solving it for the problem of a particle in a box. The potential energy for a one-dimensional box from $x = 0$ to $x = L$ is shown in Figure 35-1. It is called an **infinite square-well potential** and is described mathematically by

$$U(x) = \begin{cases} \infty & x < 0 \\ 0 & 0 < x < L \\ \infty & x > L \end{cases} \qquad 35\text{-}6$$

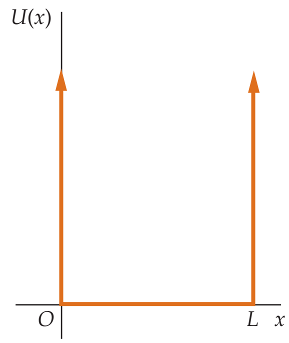


FIGURE 35-1 The infinite square-well potential energy function. For both $x < 0$ and $x > L$, the potential energy $U(x)$ is infinite. The particle is confined to the region in the well $0 < x < L$.

Inside the box, the potential energy is zero, whereas outside the box it is infinite. Because we require the particle to be in the box, we have $\psi(x) = 0$ everywhere outside the box. We then need to solve the Schrödinger equation inside the box for wave functions $\psi(x)$ that must be zero at $x = 0$ and at $x = L$.

Inside the box $U(x) = 0$, so the Schrödinger equation is written

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} = E\psi(x)$$

or

$$\frac{d^2\psi(x)}{dx^2} + k^2\psi(x) = 0 \qquad 35\text{-}7$$

where

$$k^2 = \frac{2mE}{\hbar^2} \qquad 35\text{-}8$$

The general solution of Equation 35-7 can be written as

$$\psi(x) = A \sin kx + B \cos kx \qquad 35\text{-}9$$

where A and B are constants. At $x = 0$, we have

$$\psi(0) = A \sin(0) + B \cos(0) = 0 + B$$

The boundary condition $\psi(x) = 0$ at $x = 0$ thus gives $B = 0$, and Equation 35-9 becomes

$$\psi(x) = A \sin kx \qquad 35\text{-}10$$

The wave function is thus a sine wave where the wavelength λ is related to the wave number k in the usual way, $\lambda = 2\pi/k$. The boundary condition $\psi(x) = 0$ at $x = L$ restricts the possible values of k and therefore the values of the wavelength λ, and (from Equation 35-8) the energy $E = \frac{1}{2}\hbar^2k^2/m$. We have

$$\psi(L) = A \sin kL = 0 \qquad 35\text{-}11$$

This condition is satisfied if kL is π or any integer multiplied by π, that is, if k is restricted to the values k_n given by

$$k_n = n\frac{\pi}{L} \qquad n = 1, 2, 3, \ldots \qquad 35\text{-}12$$

The condition (Equation 35-11) is also satisfied for $n = 0$. The function $\psi(x) = A \sin 0 = 0$ for all values of x, in the interval $0 < x < L$, is also a solution to the wave equation. However, if the wave function has a value of zero everywhere inside the box, then the box is empty. Furthermore, the wave function cannot be normalized and cannot be a wave function for a particle. Substituting $n\pi/L$ for k_n into Equation 35-8 and solving for E gives us the allowed energy values:

$$E_n = \frac{\hbar^2k_n^2}{2m} = \frac{\hbar^2}{2m}\left(n\frac{\pi}{L}\right)^2 = n^2\left(\frac{h^2}{8mL^2}\right) = n^2E_1 \qquad 35\text{-}13$$

where

$$E_1 = \frac{h^2}{8mL^2} \qquad 35\text{-}14$$

Equation 35-14 is the same as Equation 34-22, which we obtained by fitting an integral number of half-wavelengths into the box.

For each value of n, there is wave function $\psi_n(x)$ given by

$$\psi_n(x) = \begin{cases} 0 & x < 0 \\ A_n \sin\dfrac{n\pi x}{L} & 0 < x < L \\ 0 & x > L \end{cases} \qquad 35\text{-}15$$

which is the same as Equation 34-25, where the constant $A_n = \sqrt{2/L}$ is determined by normalization.*

35-2 A PARTICLE IN A FINITE SQUARE WELL

The quantization of energy that we found for a particle in an infinite square well is a result that follows from the general solution of the Schrödinger equation for any particle confined to some region of space. We will illustrate this by considering the qualitative behavior of the wave function for a slightly more general potential energy function, the finite square well, which is shown in Figure 35-2. This potential energy function is described mathematically by

$$U(x) = \begin{cases} U_0 & x < 0 \\ 0 & 0 < x < L \\ U_0 & x > L \end{cases} \qquad 35\text{-}16$$

* See Equation 34-18.

CONCEPT CHECK 35-1

The function below is not an acceptable wave function. What makes the function unacceptable?

$$\psi_n(x) = A_n \sin\frac{n\pi x}{L} \qquad -\infty < x < \infty$$

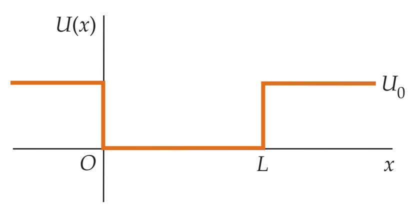

FIGURE 35-2 The finite square-well potential energy function.

This potential energy function is discontinuous at $x = 0$ and $x = L$, but it is finite everywhere. The solutions of the Schrödinger equation for this type of potential energy function depend on whether the total energy E is greater or less than U_0. We will not discuss the case of $E > U_0$, except to remark that in that case the particle is not confined and any value of the energy is allowed. That is, there is no energy quantization when $E > U_0$. Here, we assume that $0 \le E < U_0$.

Inside the well, $U(x) = 0$, and the time-independent Schrödinger equation is the same as for the infinite well (Equation 35-7):

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} = E\psi(x) \qquad 0 \le x \le L$$

or

$$\frac{d^2\psi(x)}{dx^2} + k^2\psi(x) = 0$$

where $k^2 = 2mE/\hbar^2$. The general solution is of the form

$$\psi(x) = A\sin kx + B\cos kx$$

In this case, $\psi(x)$ is not required to be zero at $x = 0$ (the particle is not required to be inside the box), so B is not zero. Outside the well, the time-independent Schrödinger equation is

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U_0\psi(x) = E\psi(x) \qquad x < 0 \text{ and } x > L$$

or

$$\frac{d^2\psi(x)}{dx^2} - \alpha^2\psi(x) = 0 \qquad \text{35-17}$$

where

$$\alpha^2 = \frac{2m}{\hbar^2}(U_0 - E) \qquad U_0 > E \qquad \text{35-18}$$

The wave functions and allowed energies for the particle can be found by solving Equation 35-17 for $\psi(x)$ outside the well and then requiring that both $\psi(x)$ and $d\psi(x)/dx$ be continuous at the boundaries $x = 0$ and $x = L$. The solution of Equation 35-17 is not difficult [in the region $x > L$, it is of the form $\psi(x) = Ce^{-\alpha x}$ and in the region $x < L$ it is of the form $\psi(x) = Ce^{+\alpha x}$], but applying the boundary conditions involves much tedious algebra and is not important for our purpose. The important feature of Equation 35-17 is that $d^2\psi/dx^2$ has the same sign as ψ. Thus, if ψ is positive, $d^2\psi/dx^2$ is also positive and the wave function curves away from the axis as x approaches either $+\infty$ or $-\infty$, as shown in Figure 35-3*a*. Similarly, if ψ is negative, $d^2\psi/dx^2$ is negative and ψ again curves away from the axis as x approaches either $+\infty$ or $-\infty$, as shown in Figure 35-3*b*. This behavior is very different from the behavior inside the well, where ψ and $d^2\psi/dx^2$ have opposite signs so that ψ always curves toward the axis like a sine or cosine function. Because of this behavior outside the well, for most values of the energy E in Equation 35-17, $\psi(x)$ becomes infinite as x approaches $\pm\infty$; that is, most wave functions $\psi(x)$ are not well behaved outside the well. Though they satisfy the Schrödinger equation, such functions are not proper wave functions because they cannot be normalized. The solutions of the Schrödinger equation are well behaved (that is, they approach 0 as $|x|$ becomes very large) only for certain values of the energy. These energy values are the allowed energies for the finite square well.

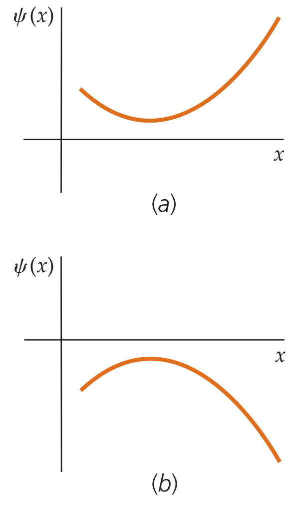

FIGURE 35-3 (*a*) A function ψ that has both a positive value and a positive concavity throughout the region shown. (Concavity is the sign of $d\psi/dx$.) (*b*) A function ψ that has both a negative value and a negative concavity throughout the region shown.

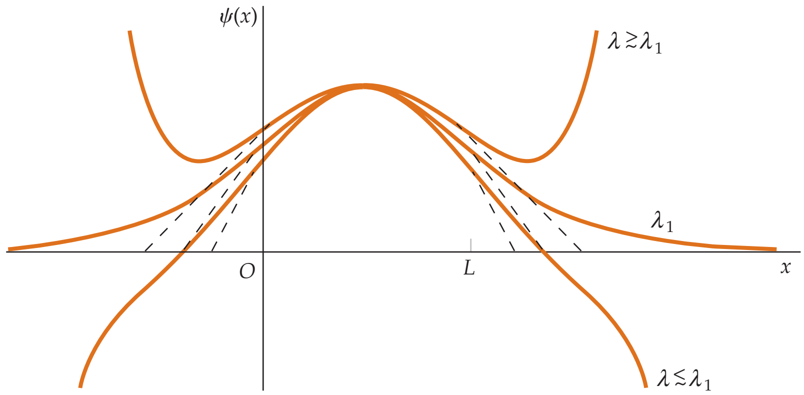

FIGURE 35-4 Functions satisfying the Schrödinger equation that have a wavelength λ that is almost equal to the wavelength λ_1, which is the wavelength that corresponds to the ground-state energy $E_1 = \hbar^2/2m\lambda_1^2$ in the finite well. If λ is slightly greater than λ_1, the function approaches plus infinity as $|x|$ approaches infinity, like the function in Figure 35-3*a*. At the critical wavelength λ_1, the function and its slope approach zero together as $|x|$ approaches infinity. If λ is slightly less than λ_1, the function crosses the x axis while the slope is still negative. The slope then becomes more negative because its rate of change $d^2\psi/dx^2$ is now negative. This function approaches negative infinity as $|x|$ approaches infinity.

Figure 35-4 shows a well-behaved wave function, a wave function that has a wavelength λ_1 inside the well that corresponds to the ground-state energy. The behavior of the wave functions corresponding to nearby wavelengths and energies is also shown. Figure 35-5 shows the wave functions and probability distributions for the ground state and first two excited states. From this figure, we can see that the wavelengths inside the well are slightly longer than the corresponding wavelengths for the infinite well (Figure 34-14), so the corresponding energies are slightly less than those for the infinite well. Another feature of the finite-well problem is that there are only a finite number of allowed energies. For very small values of U_0, there is only one allowed energy.

Note that the wave function penetrates beyond the edges of the well at $x = L$ and $x = 0$, indicating that there is some small probability of finding the particle in the region in which its total energy E is less than its potential energy U_0. This region is called the *classically forbidden region* because the kinetic energy, $E - U_0$, would be negative when $U_0 > E$. Because negative kinetic energy has no meaning in classical physics, it is interesting to speculate on the result of an attempt to observe the particle in the classically forbidden region. It can be shown from the uncertainty principle that if an attempt is made to localize the particle in the classically forbidden region, such a measurement introduces an uncertainty in the momentum of the particle corresponding to a minimum kinetic energy that is greater than $U_0 - E$. This is just great enough to prevent us from measuring a negative kinetic energy. The penetration of the wave function into a classically forbidden region does have important consequences in barrier penetration, which will be discussed in Section 35-4.

Much of our discussion of the finite-well problem applies to any problem in which $E > U(x)$ in some region and $E < U(x)$ outside that region, as we see in the next section.

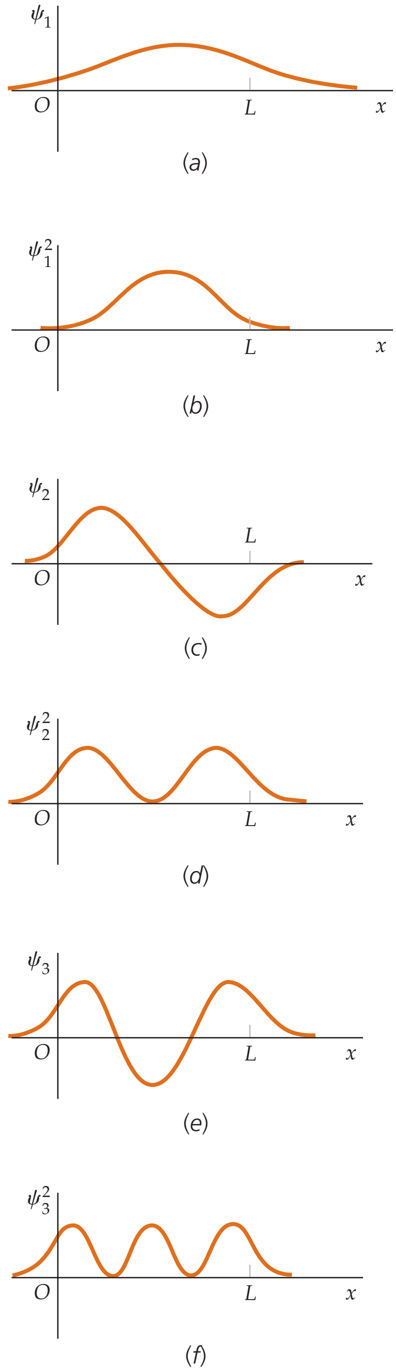

FIGURE 35-5 Graphs of the wave functions $\psi_n(x)$ and probability distributions $\psi^2(x)$ for $n = 1$, $n = 2$, and $n = 3$ for the finite square well. Compare these graphs with those of Figure 34-14 for the infinite square well, where the wave functions are zero at $x = 0$ and $x = L$. The wavelengths here are slightly longer than the corresponding wavelengths for the infinite well, so the allowed energies are somewhat smaller.

35-3 THE HARMONIC OSCILLATOR

The potential energy for a particle that has mass m and is attached to a spring that has force constant k is

$$U(x) = \tfrac{1}{2}kx^2 = \tfrac{1}{2}m\omega_0^2x^2 \qquad 35\text{-}19$$

where $\omega_0 = \sqrt{k/m}$ is the natural frequency of the oscillator. Classically, the object oscillates between $x = +A$ and $x = -A$. The object's total energy is $E = \frac{1}{2}m\omega_0^2A^2$, which can have any positive value or zero.

This potential energy function, shown in Figure 35-6, applies to virtually any system undergoing small oscillations about a position of stable equilibrium. For example, it could apply to the oscillations of the atoms of a diatomic molecule (such as H_2 or HCl) in which the atoms are oscillating about their equilibrium positions. Between the classical turning points $(-A < x < A)$, the total energy is greater than the potential energy, and the Schrödinger equation can be written

$$\frac{d^2\psi(x)}{dx^2} = -k^2\psi(x) \qquad -A < x < A \tag{35-20}$$

where $k^2 = (2m/\hbar^2)[E - U(x)]$ now depends on x. The solutions of this equation are no longer simple sine or cosine functions because the wave number $k = 2\pi/\lambda$ now varies with x; but because $d^2\psi/dx^2$ and ψ have opposite signs throughout the region $-A < x < A$, ψ will always curve toward the axis and the solutions will oscillate.

Outside the classical turning points $(|x| > A)$, the potential energy is greater than the total energy and the Schrödinger equation is similar to Equation 35-17:

$$\frac{d^2\psi(x)}{dx^2} - \alpha^2\psi(x) = 0 \qquad |x| > A \tag{35-21}$$

except that here $\alpha^2 = (2m/\hbar^2)[U(x) - E] > 0$, where $U(x) > E$, depends on x. For $|x| > A$, $d^2\psi/dx^2$ and ψ have the same sign, so ψ will curve away from the axis and there will be only certain values of E for which solutions exist that approach zero as x approaches infinity.

For the harmonic oscillator potential energy function, the Schrödinger equation is

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + \tfrac{1}{2}m\omega_0^2x^2\psi(x) = E\psi(x) \tag{35-22}$$

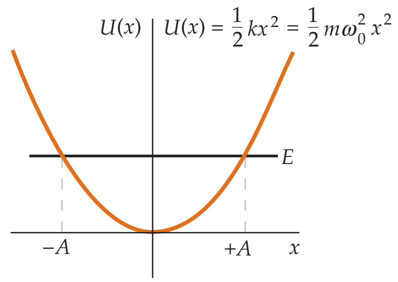

FIGURE 35-6 Harmonic oscillator potential.

WAVE FUNCTIONS AND ENERGY LEVELS

Rather than pursue a general solution to the Schrödinger equation for this system, we simply present the solution for the ground state and the first excited state.

The ground-state wave function $\psi_0(x)$ is found to be a Gaussian function centered at the origin:

$$\psi_0(x) = A_0e^{-ax^2} \tag{35-23}$$

where A_0 and a are positive constants. This wave function and the wave function for the first excited state are shown in Figure 35-7.

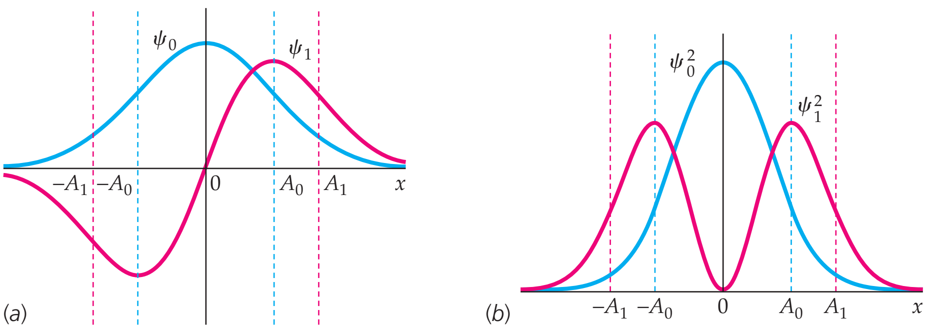

FIGURE 35-7 (*a*) The ground-state ψ_0 and first excited state ψ_1 wave functions for the harmonic oscillator potential. Classically, the motion of a harmonic oscillator with the ground-state energy E_0 would be restricted to the region $-A_0 \le x \le +A_0$ and the motion of a harmonic oscillator with the first excited state energy E_1 would be restricted to the region $-A_1 \le x \le +A_1$. (*b*) The ground-state ψ_0^2 and first excited state ψ_1^2 probability density functions for the harmonic oscillator potential.

Example 35-1 Verifying the Ground-State Wave Function

Verify that $\psi_0(x) = A_0 e^{-ax^2}$, where A_0 and a are positive constants, is a solution of the Schrödinger equation for the harmonic oscillator.

PICTURE We calculate the second derivative of ψ_0 with respect to x and substitute into Equation 35-22. Because this expression is the ground-state wave function, we write E_0 for the energy E.

SOLVE

1. Compute $d\psi_0/dx$:

$$\frac{d\psi_0(x)}{dx} = \frac{d}{dx}(A_0 e^{-ax^2}) = -2axA_0 e^{-ax^2}$$

2. Compute $d^2\psi_0/dx^2$:

$$\frac{d^2\psi_0(x)}{dx^2} = -2aA_0 e^{-ax^2} + 4a^2x^2 A_0 e^{-ax^2}$$
$$= (4a^2x^2 - 2a)A_0 e^{-ax^2}$$

3. Substitute into the Schrödinger equation (Equation 35-22):

$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + \frac{1}{2}m\omega_0^2 x^2\psi(x) = E\psi(x)$$
$$-\frac{\hbar^2}{2m}(4a^2x^2 - 2a)A_0 e^{-ax^2} + \frac{1}{2}m\omega_0^2 x^2 A_0 e^{-ax^2} = E_0 A_0 e^{-ax^2}$$

4. Cancel the common factor $A_0 e^{-ax^2}$ and show the result in standard polynomial form:

$$-\frac{\hbar^2}{2m}(4a^2x^2 - 2a) + \frac{1}{2}m\omega_0^2 x^2 = E_0$$

so

$$\left(\frac{1}{2}m\omega_0^2 - \frac{2\hbar^2 a^2}{m}\right)x^2 + \left(\frac{\hbar^2 a}{m} - E_0\right) = 0$$

5. The equation in step 4 must hold for all x. Set $x = 0$ and solve for E_0:

$$0 + \left(\frac{\hbar^2 a}{m} - E_0\right) = 0$$

so

$$E_0 = \frac{\hbar^2 a}{m}$$

6. Substitute this result for E_0 into the equation in step 4 and simplify:

$$\left(-\frac{2\hbar^2 a^2}{m} + \frac{1}{2}m\omega_0^2\right)x^2 + 0 = 0$$

7. It follows that the coefficient of x^2 must equal zero:

$$-\frac{2\hbar^2 a^2}{m} + \frac{1}{2}m\omega_0^2 = 0$$

8. Solve for a:

$$a = \frac{m\omega_0}{2\hbar}$$

9. Substitute this result into the equation for E_0 in step 5:

$$E_0 = \frac{\hbar^2 a}{m} = \frac{1}{2}\hbar\omega_0$$

> We have shown that the given function, $\psi_0(x) = A_0 e^{-ax^2}$, satisfies the Schrödinger equation for any value of A_0, as long as the energy is given by $E_0 = \frac{1}{2}\hbar\omega_0$.

CHECK Planck's constant has units of joules multiplied by seconds, and angular frequency has units of reciprocal seconds, so the step-9 expression $\frac{1}{2}\hbar\omega_0$ has the dimensions of energy, as expected.

TAKING IT FURTHER The step-4 equation is a polynomial that is equal to zero. A theorem that would have simplified the solution is "If a polynomial is equal to zero over a continuous range of values of x, then each of the polynomial coefficients is equal to zero. For example, if $Ax^3 + Bx^2 + Cx + D = 0$ on the interval $1 < x < 2$, then $A = B = C = D = 0$."

We see from this example that the ground-state energy is given by

$$E_0 = \frac{\hbar^2 a}{m} = \frac{1}{2}\hbar\omega_0 \qquad 35\text{-}24$$

The first excited state has a node in the center of the potential well, just as with the particle in a box.* The wave function $\psi_1(x)$ is

$$\psi_1(x) = A_1 x e^{-ax^2} \qquad 35\text{-}25$$

where $a = \frac{1}{2}m\omega_0/\hbar$, as in Example 35-1. This function is also shown in Figure 35-7. Substituting $\psi_1(x)$ into the Schrödinger equation, as was done for $\psi_0(x)$ in Example 35-1, yields the energy of the first excited state,

$$E_1 = \tfrac{3}{2}\hbar\omega_0$$

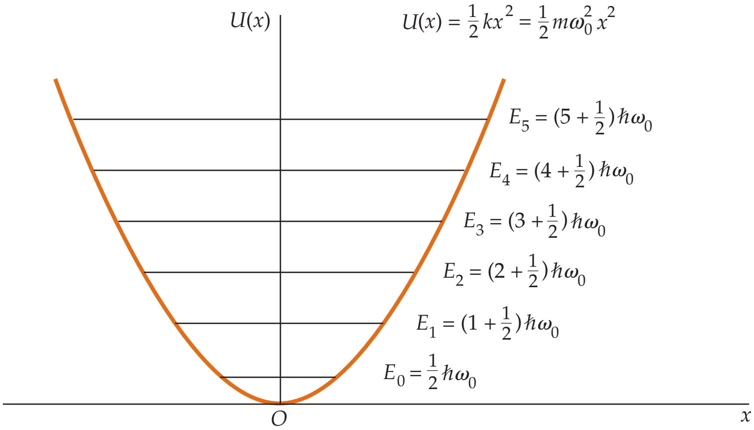

FIGURE 35-8 Energy levels in the harmonic oscillator potential.

In general, the energy of the nth excited state of the harmonic oscillator is

$$E_n = \left(n + \tfrac{1}{2}\right)\hbar\omega_0 \qquad n = 0, 1, 2, \ldots \qquad 35\text{-}26$$

as indicated in Figure 35-8. The fact that the energy levels are evenly spaced by the amount $\hbar\omega_0$ is a peculiarity of the harmonic oscillator potential. As we saw in Chapter 34, the energy levels for a particle in a box, or for the hydrogen atom, are not evenly spaced. The precise spacing of energy levels is closely tied to the particular form of the potential energy function.

35-4 REFLECTION AND TRANSMISSION OF ELECTRON WAVES: BARRIER PENETRATION

In Sections 35-2 and 35-3, we were concerned with bound-state problems in which the potential energy is larger than the total energy for large values of $|x|$. In this section, we consider some simple examples of unbound states for which E is greater than $U(x)$. For these problems, $d^2\psi/dx^2$ and ψ have opposite signs, so $\psi(x)$ curves toward the axis and does not become infinite as x approaches either $+\infty$ or $-\infty$.

STEP POTENTIAL

Consider a particle of energy E moving in a region in which the potential energy is the step function

$$U(x) = \begin{cases} 0 & x < 0 \\ U_0 & x > 0 \end{cases}$$

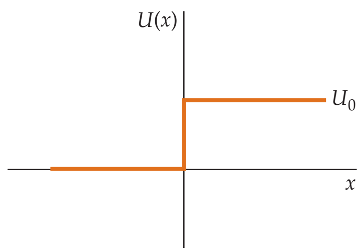

FIGURE 35-9 Step potential. A classical particle that is incident from the left and has total energy $E > U_0$ is always transmitted. The change in potential energy at $x = 0$ merely provides an impulsive force that reduces the speed of the particle. A wave incident from the left is partially transmitted and partially reflected because the wavelength changes abruptly at $x = 0$.

as shown in Figure 35-9. We are interested in what happens when a particle moving from left to right encounters the step.

The classical answer is simple. To the left of the step, the particle moves with a speed $v = \sqrt{2E/m}$. At $x = 0$, an impulsive force acts on the particle. If the initial energy E is less than U_0, the particle will be turned around and will then move to the left at its original speed; that is, the particle will be reflected by the step.

* Each higher-energy state has one additional node in the wave function.

If E is greater than U_0, the particle will continue to move to the right but with reduced speed given by $v = \sqrt{2(E - U_0)/m}$. We can picture this classical problem as a ball rolling along a level surface and coming to a steep hill of height h given by $mgh = U_0$. If the initial kinetic energy of the ball is less than mgh, the ball will roll part way up the hill and then back down and to the left along the lower surface at its original speed. If E is greater than mgh, the ball will roll up the hill and proceed to the right at a lesser speed.

The quantum-mechanical result is similar when E is less than U_0. Figure 35-10 shows the wave function for the case $E < U_0$. The wave function does not go to zero at $x = 0$ but rather decays exponentially, like the wave function for the bound state in a finite square-well problem. The wave penetrates slightly into the classically forbidden region $x > 0$, but it is eventually completely reflected. This problem is somewhat similar to that of total internal reflection in optics.

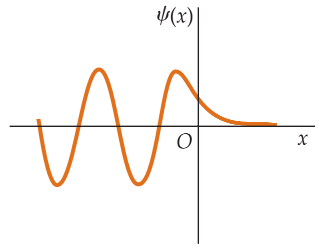

FIGURE 35-10 When the total energy E is less than U_0, the wave function penetrates slightly into the region $x > 0$. However, the probability of reflection for this case is 1, so no energy is transmitted.

For $E > U_0$, the quantum-mechanical result differs markedly from the classical result. At $x = 0$, the wavelength changes abruptly from $\lambda_1 = h/p_1 = h/\sqrt{2mE}$ to $\lambda_2 = h/p_2 = h/\sqrt{2m(E - U_0)}$. We know from our study of waves that when the wavelength changes suddenly, part of the wave is reflected and part of the wave is transmitted. Because the motion of an electron (or other particle) is governed by a wave equation, the electron sometimes will be transmitted and sometimes will be reflected. The probabilities of reflection and transmission can be calculated by solving the Schrödinger equation in each region of space and comparing the amplitudes of the transmitted waves and reflected waves with the amplitudes of the incident wave. These calculations and their results are similar to finding the fraction of light reflected from an air–glass interface. If R is the probability of reflection, called the reflection coefficient, this calculation gives

$$R = \frac{(k_1 - k_2)^2}{(k_1 + k_2)^2} \qquad 35\text{-}27$$

where k_1 is the wave number for the incident wave and k_2 is the wave number for the transmitted wave. This result is the same as the result in optics for the reflection of light at normal incidence from the boundary between two media having different indexes of refraction n (Equation 31-17). The probability of transmission T, called the **transmission coefficient,** can be calculated from the reflection coefficient, because the probability of transmission plus the probability of reflection must equal 1:

$$T + R = 1 \qquad 35\text{-}28$$

Example 35-2 Reflection and Transmission at a Step Barrier

A particle that has kinetic energy E_0 and is traveling in a region in which the potential energy is zero is incident on a potential-energy barrier of height $U_0 = 0.20E_0$. Find the probability that the particle will be reflected.

PICTURE We need to calculate the wave numbers k_1 and k_2 and use them to calculate the reflection coefficient R from Equation 35-27. The wave numbers are related to the momentum by the de Broglie relation $p = h/\lambda$ (Equation 34-13), where $k = 2\pi/\lambda$. Combining these two equations gives $p = \hbar k$. Thus, the kinetic energy K is related to the wave number by $K = \frac{1}{2}p^2/m = \frac{1}{2}\hbar^2k^2/m$.

SOLVE

1. The probability of reflection is the reflection coefficient: $$R = \frac{(k_2 - k_1)^2}{(k_1 + k_2)^2}$$

2. Calculate k_1 from the initial kinetic energy E_0: $$E_0 = \frac{\hbar^2 k_1^2}{2m}$$ $$k_1 = \sqrt{2mE_0/\hbar^2}$$

3. Relate the final kinetic energy K_2 to the initial kinetic energy E_0 and the potential energy U_0 in the region $x > 0$:

$$K_2 = E_0 - U_0 = E_0 - 0.2E_0 = 0.8E_0$$

4. Relate k_2 to the final kinetic energy K_2 and solve for k_2:

$$K_2 = \frac{\hbar k_2^2}{2m}$$

so

$$k_2 = \sqrt{2mK_2/\hbar^2} = \sqrt{2m(0.8E_0)/\hbar^2}$$
$$= \sqrt{0.80}\sqrt{2mE_0/\hbar^2}$$

5. Substitute these values into Equation 35-27 to calculate R:

$$R = \frac{(k_1 - k_2)^2}{(k_1 + k_2)^2} = \left(\frac{1 - \sqrt{0.80}}{1 + \sqrt{0.80}}\right)^2 = \boxed{0.0031}$$

CHECK Classically, the particle would not be reflected by such a low barrier. The step-5 result gives a probability of 0.31 percent that the particle will be reflected. Such a low probability approaches being in agreement with our classical expectations.

TAKING IT FURTHER The probability of reflection is only 0.31 percent. This probability is small because the barrier height reduces the kinetic energy by only 20 percent. Because k is proportional to the square root of the kinetic energy, the wave number and therefore the wavelength is changed by only 10 percent.

PRACTICE PROBLEM 35-1 Express the index of refraction n of light in terms of the wave number k and the frequency ω, and show that the expression $(n_1 - n_2)^2/(n_1 + n_2)^2$ (Equation 31-7) for the reflection coefficient of light at normal incidence is the same as Equation 35-27. *Hint: Express the index of refraction n of light in terms of the wave number k and the angular frequency ω.*

In quantum mechanics, a localized particle is represented by a wave packet, which has a maximum at the most probable position of the particle. Figure 35-11 shows a wave packet representing a particle of energy E incident on a step potential of height U_0, which is less than E. After the encounter, there are two wave packets. The relative heights of the transmitted packet and reflected packet indicate the relative probabilities of transmission and reflection. For the situation shown here, E is much greater than U_0, and the probability of transmission is much greater than that of reflection.

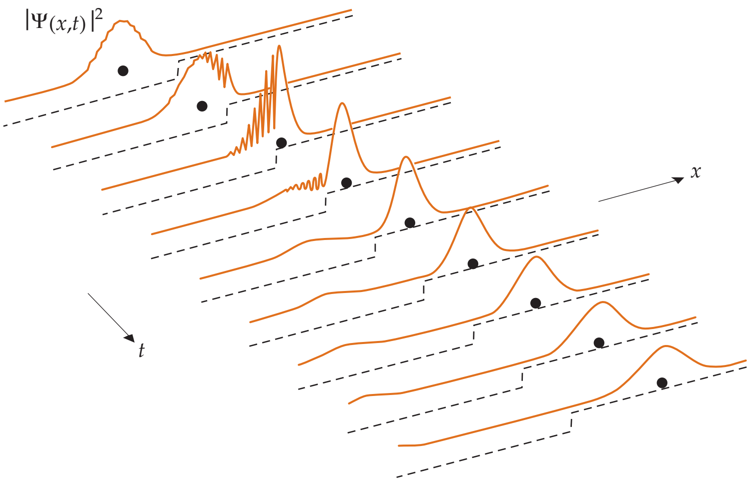

FIGURE 35-11 Time development of a one-dimensional wave packet representing a particle incident on a step potential for $E > U_0$. The position of a classical particle is indicated by the dot. Note that part of the packet is transmitted and part is reflected.

BARRIER PENETRATION

Figure 35-12*a* shows a rectangular potential-energy barrier of height U_0 and width a given by

$$U(x) = \begin{cases} 0 & x < 0 \\ U_0 & 0 < x < a \\ 0 & x > a \end{cases}$$

We consider a particle of energy E, which is slightly less than U_0, that is incident on the barrier from the left. Classically, the particle would always be reflected. However, a wave incident from the left does not decrease immediately to zero at the barrier, but it will instead decay exponentially in the classically forbidden region $0 < x < a$. On reaching the far wall of the barrier ($x = a$), the wave function must join smoothly to a sinusoidal wave function to the right of the barrier, as shown in Figure 35-12*b* This implies that there is some probability of the particle (which is represented by the wave function) being found on the far side of the barrier even though, classically, it should never pass through the barrier. For the case in which the quantity αa [where $\alpha^2 = 2m(U_0 - E)/\hbar^2$] is much greater than 1 the transmission coefficient T is equal to $e^{-2\alpha a}$:

! Do not think it might be possible to detect a particle in the classically forbidden region. It cannot. A proof shows this claim to be a consequence of the uncertainty principle.

$$T = e^{-2\alpha a} \qquad \alpha a \gg 1 \tag{35-29}$$

TRANSMISSION THROUGH A BARRIER

The probability of penetration of the barrier thus decreases exponentially with both the barrier thickness a and the square root of the relative barrier height $(U_0 - E)$. This phenomenon, the penetrating of a classically forbidden region, is called **quantum tunneling.**

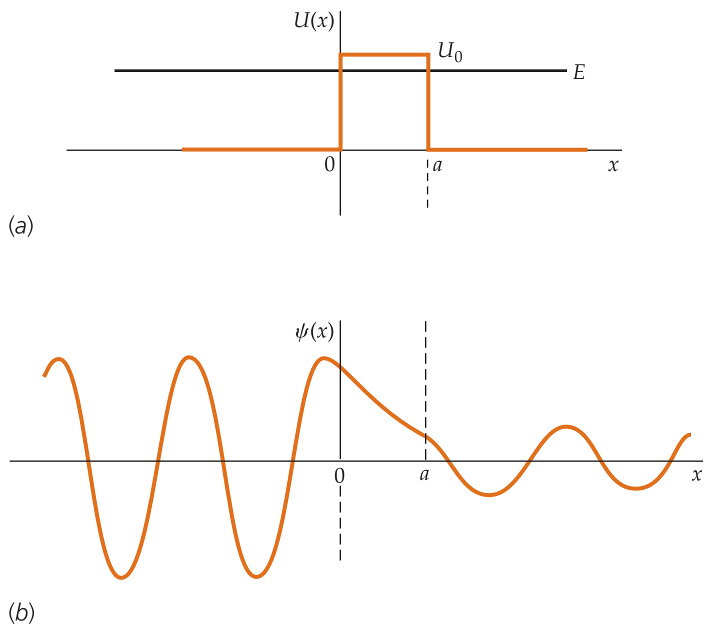

FIGURE 35-12 (*a*) A rectangular potential-energy barrier. (*b*) The penetration of the barrier by a wave that has a total energy less than the barrier energy. Part of the wave is transmitted by the barrier even though, classically, the particle cannot enter the region $0 < x < a$ in which the potential energy is greater than the total energy. To the left of the barrier, there is both an incident wave and a reflected wave. These waves form a resultant wave so that ψ is a superposition of a standing wave and a traveling wave (traveling toward the barrier). Only the transmitted wave exists in the region $x > a$, and it is traveling away from the barrier.

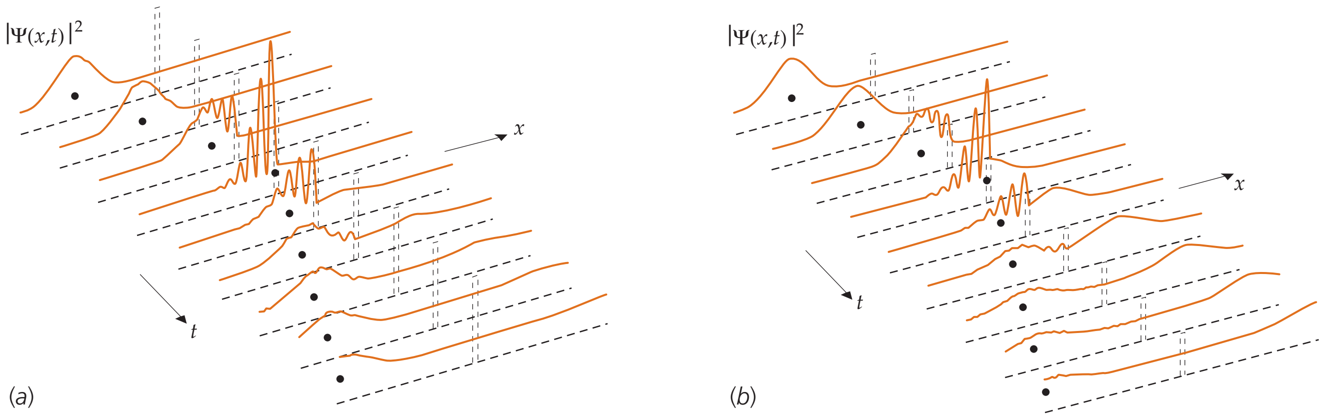

FIGURE 35-13 Barrier penetration. (*a*) The same particle incident on a barrier of height much greater than the energy of the particle. A very small part of the packet tunnels through the barrier. In both drawings, the position of a classical particle is indicated by a dot. (*b*) A wave packet representing a particle incident on a barrier of height just slightly greater than the energy of the particle. For this particular choice of energies, the probability of transmission is approximately equal to the probability of reflection, as indicated by the relative sizes of the transmitted and reflected packets.

Figure 35-13*a* shows a wave packet incident on a potential-energy barrier of height U_0 that is considerably greater than the energy of the particle. The probability of penetration is very small, as indicated by the relative sizes of the reflected and transmitted packets. In Figure 35-13*b*, the barrier is just slightly greater than the energy of the particle. In this case, the probability of penetration is about the same as the probability of reflection. Figure 35-14 shows a particle incident on two potential-energy barriers of height just slightly greater than the energy of the particle.

As we have mentioned, the penetration of a barrier is not unique to quantum mechanics. When light is totally reflected from a glass–air interface, the light wave can penetrate the air barrier if a second piece of glass is brought within a few

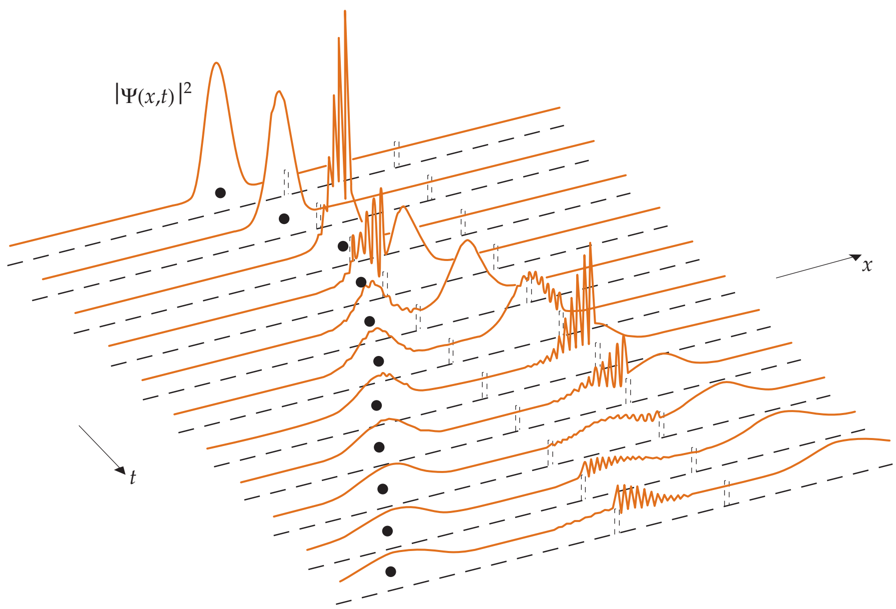

FIGURE 35-14 A wave packet representing a particle incident on two barriers. At each encounter, part of the packet is transmitted and part reflected, resulting in part of the packet being trapped between the barriers for some time.

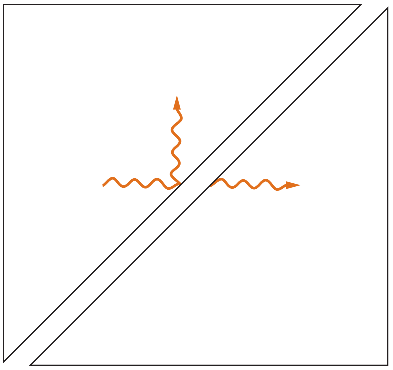

FIGURE 35-15 The penetration of an optical barrier. If the second prism is close enough to the first, part of the wave penetrates the air barrier even when the angle of incidence in the first prism is greater than the critical angle.

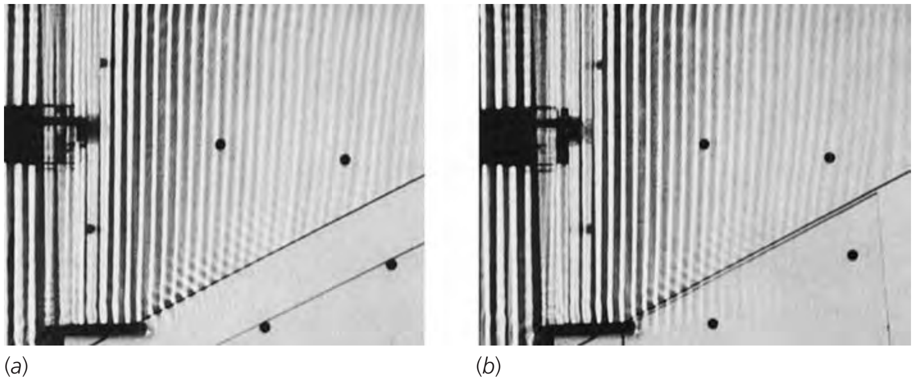

FIGURE 35-16 The penetration of a barrier by water waves in a ripple tank. In Figure 35-16*a*, the waves are totally reflected from a gap of deeper water. When the gap is very narrow, as in Figure 35-16*b*, a transmitted wave appears. The dark circles are spacers that are used to support the prisms from below. *(Education Development Center.)*

wavelengths of the first. This effect can be demonstrated with a laser beam and two 45° prisms (Figure 35-15). Similarly, water waves in a ripple tank can penetrate a gap of deep water (Figure 35-16).

The theory of barrier penetration was used by George Gamow in 1928 to explain the enormous variation in the half-lives for α decay of radioactive nuclei. (Alpha particles are emitted from atoms during radioactive decay and consist of two protons and two neutrons tightly bound together.) In general, the smaller the energy of the emitted α particle, the longer the half-life of the particle is. The energies of α particles from natural radioactive sources range from approximately 4 MeV to 7 MeV, whereas the half-lives range from approximately 10^{-5} seconds to 10^{10} years. Gamow represented a radioactive nucleus by a potential well of finite depth containing an α particle, as shown in Figure 35-17. Without knowing very much about the nuclear force that is exerted by the nucleus on the particle, Gamow represented it by a square well. Just outside the well, the α particle that has a charge of $+2e$ is repelled by the nucleus that has a charge $+Ze$, where Ze is the remaining nuclear charge. This force is represented by the Coulomb potential energy $+k(2e)(Ze)/r$. The energy E is the measured kinetic energy of the emitted α particle, because when it is far from the nucleus its potential energy is zero. After the α particle is formed from the radioactive nucleus, it bounces back and forth inside the nucleus, hitting the barrier at the nuclear radius R. Each time the α particle strikes the barrier, some small probability exists of the particle penetrating the barrier and appearing outside the nucleus. We can see from Figure 35-17 that a small increase in E reduces the relative height of the barrier $U - E$ and also the barrier's thickness. Because the probability of penetration is so sensitive to the barrier thickness and relative height, a small increase in E leads to a large increase in the probability of transmission and therefore to a shorter lifetime. Gamow was able to derive an expression for the half-life as a function of E that is in excellent agreement with experimental results.

In the **scanning tunneling microscope (STM),** developed in the 1980s, a thin space between the surface of a sample and the tip of a tiny needle-like probe (Figure 35-18) acts as a potential-energy barrier to electrons bound in the sample. (The height of the barrier is the work function of the surface.) A small voltage applied between the probe and the sample causes the electrons to *tunnel* through the vacuum separating the tip of the probe and the surface of the sample if the surfaces are close enough together. The tunneling current is extremely sensitive to the size of the gap between the probe and sample. A constant tunneling current is maintained as the probe scans (travels along) the surface by a feedback

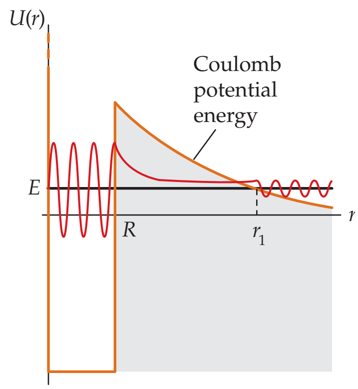

FIGURE 35-17 Model of a potential energy function for an α particle of a radioactive nucleus. The strong attractive nuclear force when r is approximately equal to the nuclear radius R can be approximately described by the potential well shown. The nuclear force is negligible outside the nucleus, and the potential there is given by Coulomb's law, $U(r) = +k(2e)(Ze)/r$, where Ze is the nuclear charge and $2e$ is the charge of the α particle. The wave function of the alpha particle, shown in red, is placed on the graph.

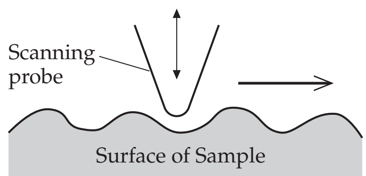

FIGURE 35-18 The tiny probe of a scanning tunneling microscope travels along the surface of a sample. A constant potential difference is maintained between the probe and the sample and electrons tunnel through the potential-energy barrier at the surface. A feedback mechanism maintains a constant tunneling current by moving the probe up and down as it travels along the surface.

mechanism that moves the probe up and down (farther from or closer to the surface). The surface of the sample is mapped out by the tracking of the motions of the probe. In this way, the surface features of the sample can be measured with a resolution of the order of the size of an atom.

35-5 THE SCHRÖDINGER EQUATION IN THREE DIMENSIONS

The one-dimensional time-independent Schrödinger equation is easily extended to three dimensions. In rectangular coordinates, it is

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}+\frac{\partial^2\psi}{\partial z^2}\right)+U\psi=E\psi \qquad \text{35-30}$$

where the wave function ψ and the potential energy U are generally functions of all three coordinates, x, y, and z. To illustrate some of the features of problems in three dimensions, we consider a particle in a three-dimensional infinite square well given by $U(x, y, z) = 0$ for $0 < x < L$, $0 < y < L$, and $0 < z < L$. Outside this cubical region, $U(x, y, z) = \infty$. For this problem, the wave function must be zero at the edges of the well.

There are standard methods in partial differential equations for solving Equation 35-30. We can guess the form of the solution from our knowledge of probability. For a one-dimensional box along the x axis, we have found the probability that a particle is in the region between x and $x + dx$ to be $A_1^2\sin^2(k_1x)\,dx$ (from Equation 35-10), where A_1 is a normalization constant and $k_1 = n\pi/L$ is the wave number. Similarly, for a box along the y axis, the probability of a particle being in a region between y and $y + dy$ is $A_2^2\sin^2(k_2y)dy$. The probability of two independent events occurring is the product of the probabilities of each event occurring.* So the probability of a particle being in region between x and $x + dx$ *and* in region between y and $y + dy$ is $A_1^2\sin^2(k_1x)\,dx\,A_2^2\sin^2(k_2y)\,dy = A_1^2\sin^2(k_1x)\,A_2^2\sin^2(k_2y)\,dx\,dy$. The probability of a particle being in the region between x and $x + dx$, y and $y + dy$, and z and $z + dz$ is $\psi^2(x, y, z)\,dx\,dy\,dz$, where $\psi(x, y, z)$ is the solution of Equation 35-30. This solution is of the form

$$\psi(x, y, z) = A\sin(k_1x)\sin(k_2y)\sin(k_3z) \qquad \text{35-31}$$

where the constant A is determined by normalization. Inserting this solution into Equation 35-30, we obtain for the energy

$$E=\frac{\hbar^2}{2m}(k_1^2+k_2^2+k_3^2)$$

which is equivalent to $E = \frac{1}{2}(p_x^2 + p_y^2 + p_z^2)/m$, where $p_x = \hbar k_1$, $p_y = \hbar k_2$, and $p_z = \hbar k_3$. The wave function (Equation 35-31) will be zero at $x = L$ if $k_1 = n_1\pi/L$, where n_1 is an integer. Similarly, the wave function will be zero at $y = L$ if $k_2 = n_2\pi/L$, and the wave function will be zero at $z = L$ if $k_3 = n_3\pi/L$. (It is also zero at $x = 0$, $y = 0$, and $z = 0$.) The energy is thus quantized to the values

$$E_{n_1n_2n_3}=\frac{\hbar^2\pi^2}{2mL^2}(n_1^2+n_2^2+n_3^2)=E_1(n_1^2+n_2^2+n_3^2) \qquad \text{35-32}$$

where n_1, n_2, and n_3 are positive integers and $E_1 = \hbar^2\pi^2/(2mL^2)$ is the ground-state energy of the one-dimensional well. Note that the energy and wave function are characterized by three quantum numbers, each arising from the boundary conditions for one of the coordinates x, y, and z.

---

* For example, if you throw two dice, the probability of the first die coming up 6 is 1/6 and the probability of the second die coming up an odd number is 1/2. The probability of the first die coming up 6 *and* the second die coming up an odd number is (1/6)(1/2) = 1/12.

The lowest energy state (the ground state) for the cubical well occurs when $n_1 = n_2 = n_3 = 1$ and has the value

$$E_{111} = \frac{3\hbar^2\pi^2}{2mL^2} = 3E_1$$

The first excited energy level can be obtained in three different ways: $n_1 = 2$, $n_2 = n_3 = 1$; $n_2 = 2$, $n_1 = n_3 = 1$; or $n_3 = 2$, $n_1 = n_2 = 1$. Each has a different wave function. For example, the wave function for $n_1 = 2$ and $n_2 = n_3 = 1$ is

$$\psi_{211} = A \sin\frac{2\pi x}{L} \sin\frac{\pi y}{L} \sin\frac{\pi z}{L} \qquad \text{35-33}$$

There are thus three different quantum states as described by the three different wave functions corresponding to the same energy level. An energy level with which more than one wave function is associated is said to be **degenerate.** In this case, there is threefold degeneracy. Degeneracy is related to the spatial symmetry of the system. If, for example, we consider a noncubic well, where $U = 0$ for $0 < x < L_1$, $0 < y < L_2$, and $0 < z < L_3$, the boundary conditions at the edges would lead to the quantum conditions $k_1L_1 = n_1\pi$, $k_2L_2 = n_2\pi$, and $k_3L_3 = n_3\pi$, and the total energy would be

$$E_{n_1n_2n_3} = \frac{\hbar^2\pi^2}{2m}\left(\frac{n_1^2}{L_1^2} + \frac{n_2^2}{L_2^2} + \frac{n_3^2}{L_3^2}\right) \qquad \text{35-34}$$

These energy levels are not degenerate if L_1, L_2, and L_3 are all different. Figure 35-19 shows the energy levels for the ground state and first two excited states for an infinite cubic well in which the excited states are degenerate and for a noncubic infinite well in which L_1, L_2, and L_3 are all slightly different so that the excited levels are slightly split apart and the degeneracy is removed. The ground state is the state where the quantum numbers n_1, n_2, and n_3 all equal 1. None of the three quantum numbers can be zero. If any one of n_1, n_2, and n_3 were zero, the corresponding wave number k would also equal zero and the corresponding wave function (Equation 35-31) would equal zero for all values of x, y, and z.

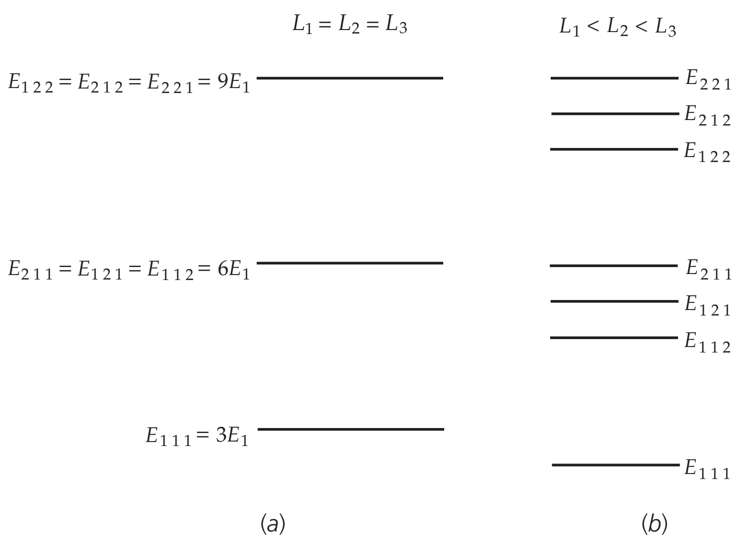

FIGURE 35-19 Energy-level diagrams for (*a*) a cubic infinite well and (*b*) a noncubic infinite well. In Figure 35-19*a* the energy levels are degenerate; that is, there are two or more wave functions having the same energy. The degeneracy is removed when the symmetry of the potential is removed, as in Figure 35-19*b*.

Example 35-3 Energy Levels for a Particle in a Three-Dimensional Box

A particle is in a three-dimensional box where $L_3 = L_2 = 2L_1$. Give the quantum numbers n_1, n_2, and n_3 that correspond to the state(s) in each of the seven lowest energy levels of this box.

PICTURE We can use Equation 35-34 to write the energy in terms of L_1 and the quantum numbers n_1, n_2, and n_3. Then we can find by inspection the values of the quantum numbers that give the lowest energies.

SOLVE

1. The energy of a level is given by Equation 35-34:
$$E_{n_1n_2n_3} = \frac{\hbar^2\pi^2}{2m}\left(\frac{n_1^2}{L_1^2} + \frac{n_2^2}{L_2^2} + \frac{n_3^2}{L_3^2}\right)$$

2. Factor out $1/L_1^2$:
$$E_{n_1n_2n_3} = \frac{\hbar^2\pi^2}{2m}\left(\frac{n_1^2}{L_1^2} + \frac{n_2^2}{4L_1^2} + \frac{n_3^2}{4L_1^2}\right) = \frac{\hbar^2\pi^2}{8mL_1^2}(4n_1^2 + n_2^2 + n_3^2)$$

3. The lowest energy is E_{111}:
$$E_{111} = E_1(4 \cdot 1^2 + 1^2 + 1^2) = \boxed{6E_1} \qquad \text{(1st)}$$
where $E_1 = \hbar^2\pi^2/8mL_1^2$.

4. The energy increases the least when we increase n_2 or n_3. Trying various values of the quantum numbers:
$$E_{121} = E_{112} = E_1(4 \cdot 1^2 + 2^2 + 1^2) = \boxed{9E_1} \qquad \text{(2nd)}$$
$$E_{122} = E_1(4 \cdot 1^2 + 2^2 + 2^2) = \boxed{12E_1} \qquad \text{(3rd)}$$
$$E_{131} = E_{113} = E_1(4 \cdot 1^2 + 3^2 + 1^2) = \boxed{14E_1} \qquad \text{(4th)}$$
$$E_{132} = E_{123} = E_1(4 \cdot 1^2 + 3^2 + 2^2) = \boxed{17E_1} \qquad \text{(5th)}$$
$$E_{211} = E_1(4 \cdot 2^2 + 1^2 + 1^2) = \boxed{18E_1} \qquad \text{(6th)}$$
$$\left.\begin{array}{l} E_{221} = E_{212} = E_1(4 \cdot 2^2 + 2^2 + 1^2) = \boxed{21E_1} \\ E_{141} = E_{114} = E_1(4 \cdot 1^2 + 4^2 + 1^2) = \boxed{21E_1} \end{array}\right\} \quad \text{(7th)}$$

CHECK Because two of the lengths are equal, degenerate energy levels are expected. Our results meet this expectation.

TAKING IT FURTHER Energies E_{221} and E_{212} are exactly equal because L_2 and L_3 are exactly equal. However, energies E_{221} and E_{141} are exactly equal because L_1 is exactly half of L_2.

PRACTICE PROBLEM 35-2 Find the quantum numbers and energies of the next two energy levels in step 4.

Example 35-4 Wave Functions for a Particle in a Three-Dimensional Box

Try It Yourself

Write the degenerate wave functions for the fourth and fifth excited states (the 5th and 6th levels) of the results in step 4 of Example 35-3.

PICTURE Use $\psi(x, y, z) = A\sin(k_1x)\sin(k_2y)\sin(k_3z)$ (a generalized version of Equation 35-31) with $k_i = n_i\pi/L_i$.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
Write the wave functions corresponding to the energies E_{131} and E_{113}	$\psi_{131} = A \sin\frac{\pi x}{L_1} \sin\frac{3\pi y}{2L_1} \sin\frac{\pi z}{2L_1}$ $\psi_{113} = A \sin\frac{\pi x}{L_1} \sin\frac{\pi y}{2L_1} \sin\frac{3\pi z}{2L_1}$

35-6 THE SCHRÖDINGER EQUATION FOR TWO IDENTICAL PARTICLES

Our discussion of quantum mechanics has thus far been limited to situations in which a single particle moves in some force field characterized by a potential energy function U. The most important physical problem of this type is the hydrogen atom, in which a single electron moves in the Coulomb potential of a proton. This problem is actually a two-body problem, because the proton also moves in the field of the electron. However, the motion of the much more massive proton requires only a very small correction to the energy of the atom that is easily made in both classical and quantum mechanics. When we consider more complicated problems, such as the helium atom, we must apply quantum mechanics to two or more electrons moving in an external field. Such problems are complicated, not only by the interaction of the electrons with each other, but also by the fact that the electrons are identical.

The interaction of two electrons with each other is electromagnetic and is essentially the same as the classical interaction of two charged particles. The Schrödinger equation for an atom that has two or more electrons cannot be solved exactly, so approximation methods must be used. This situation is not very different from the situation in which a classical expression describes three or more particles. However, the complications arising from the identity of electrons are purely quantum mechanical and have no classical counterpart. They are due to the fact that it is impossible to keep track of which electron is which. Classically, identical particles can be identified by their positions, which in principle can be determined with unlimited accuracy. This is impossible quantum mechanically because of the uncertainty principle. Figure 35-20 offers a schematic illustration of the problem.

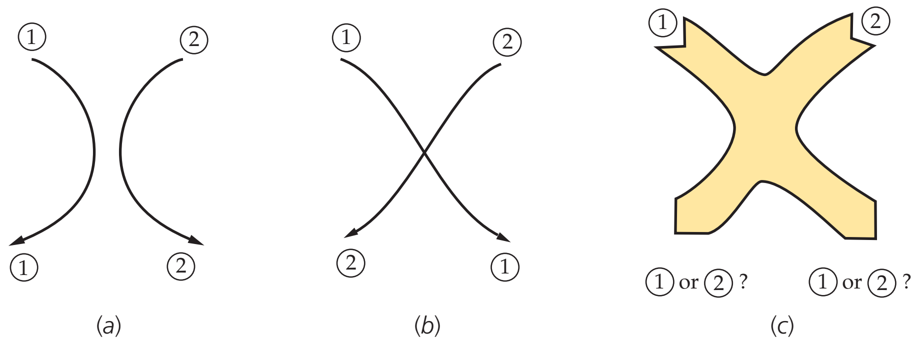

FIGURE 35-20 (*a*, *b*) Two possible classical electron paths. If electrons were classical particles, they could be distinguished by the paths followed. (*c*) However, because of the quantum-mechanical wave properties of electrons, the paths are spread out, as indicated by the shaded region. It is impossible to distinguish which electron is which after they separate.

The indistinguishability of identical particles has important consequences. For instance, consider the very simple case of two identical, noninteracting particles in a one-dimensional infinite square well. The time-independent Schrödinger equation for two particles, each of mass m, is

$$-\frac{\hbar^2}{2m}\frac{\partial^2\psi(x_1, x_2)}{\partial x_1^2} - \frac{\hbar^2}{2m}\frac{\partial^2\psi(x_1, x_2)}{\partial x_2^2} + U\psi(x_1, x_2) = E\psi(x_1, x_2) \qquad \text{35-35}$$

where x_1 and x_2 are the coordinates of the two particles. If the particles interact, the potential energy U is described by terms that have both x_1 and x_2 and cannot be separated into separate terms having only x_1 or x_2. For example, the electrostatic repulsion of two electrons in one dimension is represented by the potential energy function $ke^2/|x_2 - x_1|$. However, if the particles do not interact (as we are assuming here), we can write $U = U_1(x_1) + U_2(x_2)$. For the infinite square well, we need only solve the Schrödinger equation inside the well where $U = 0$ and require that the wave function be zero at the walls of the well. With $U = 0$, Equation 35-35 looks just like the expression for a particle in a two-dimensional well (Equation 35-30, but no z terms exist and y is replaced by x_2).

Solutions of this equation can be written in the form*

$$\psi_{nm} = \psi_n(x_1)\psi_m(x_2) \qquad \text{35-36}$$

where ψ_n and ψ_m are the single-particle wave functions for a particle in an infinite well and n and m are the quantum numbers of particles 1 and 2, respectively. For example, for $n = 1$ and $m = 2$, the wave function is

$$\psi_{12} = A\sin\frac{\pi x_1}{L}\sin\frac{2\pi x_2}{L} \qquad \text{35-37}$$

The probability of finding particle 1 in the region between $x = x_1$ and $x = x_1 + dx_1$ and particle 2 in the region between $x = x_2$ and $x = x_2 + dx_2$ is $\psi^2_{nm}(x_1, x_2)\,dx_1\,dx_2$, which is just the product of the separate probabilities $\psi^2_n(x_1)\,dx_1$ and $\psi^2_m(x_2)\,dx_2$. However, even though we have labeled the particles 1 and 2, we cannot distinguish which is between x_1 and $x_1 + dx_1$ and which is between x_2 and $x_2 + dx_2$ if they are identical. The mathematical descriptions of identical particles must be the same if we interchange the labels. The probability density $\psi^2(x_1, x_2)$ must therefore be the same as $\psi^2(x_2, x_1)$:

$$\psi^2(x_2, x_1) = \psi^2(x_1, x_2) \qquad \text{35-38}$$

Equation 35-38 is satisfied if $\psi(x_2, x_1)$ is either **symmetric** or **antisymmetric** on the exchange of particles—that is, if either

$$\psi(x_2, x_1) = \psi(x_1, x_2) \quad \text{symmetric} \qquad \text{35-39}$$

or

$$\psi(x_2, x_1) = -\psi(x_1, x_2) \quad \text{antisymmetric} \qquad \text{35-40}$$

Note that the wave functions given by Equations 35-36 and 35-37 are neither symmetric nor antisymmetric. If we interchange x_1 and x_2 in these wave functions, we get a different wave function, which implies that the particles can be distinguished.

* Again, this result can be obtained by solving Equation 35-35, but it also can be understood in terms of our knowledge of probability. The probability of electron 1 being between $x = x_1$ and $x = x_1 + dx_1$ and electron 2 being between $x = x_2$ and $x = x_2 + dx_2$ is the product of the individual probabilities.

We can find symmetric and antisymmetric wave functions that are solutions of the Schrödinger equation by adding or subtracting ψ_{nm} and ψ_{mn}. Adding them, we obtain

$$\psi_S = A'[\psi_n(x_1)\psi_m(x_2) + \psi_n(x_2)\psi_m(x_1)] \quad \text{symmetric} \qquad 35\text{-}41$$

and subtracting them, we obtain

$$\psi_A = A'[\psi_n(x_1)\psi_m(x_2) - \psi_n(x_2)\psi_m(x_1)] \quad \text{antisymmetric} \qquad 35\text{-}42$$

For example, the symmetric and antisymmetric wave functions for the first excited state of two identical particles in an infinite square well would be

$$\psi_S = A'\left(\sin\frac{\pi x_1}{L}\sin\frac{2\pi x_2}{L} + \sin\frac{\pi x_2}{L}\sin\frac{2\pi x_1}{L}\right) \qquad 35\text{-}43$$

and

$$\psi_A = A'\left(\sin\frac{\pi x_1}{L}\sin\frac{2\pi x_2}{L} - \sin\frac{\pi x_2}{L}\sin\frac{2\pi x_1}{L}\right) \qquad 35\text{-}44$$

There is an important difference between antisymmetric and symmetric wave functions. If $n = m$, the antisymmetric wave function is identically zero for all values of x_1 and x_2, whereas the symmetric wave function is not. Thus, if the wave function describing two identical particles is antisymmetric, the quantum numbers n and m of two particles cannot be the same. The idea that no two electrons in an atom can occupy the same quantum state, and thus have the same quantum numbers, was first stated by Wolfgang Pauli in 1925. This idea was soon generalized to include systems other than atoms and particles other than electrons. For example, no two protons of a nucleus can occupy the same quantum state, and no two neutrons of a nucleus can occupy the same quantum state. Electrons, protons, neutrons, neutrinos, and quarks all have a spin quantum number s equal to one-half, and all particles that have half-integer spin are called fermions. The two allowed values for the secondary spin quantum number m_s are plus and minus one half. Pauli's idea is called the **Pauli exclusion principle:**

No two identical fermions can simultaneously occupy the same quantum state.

PAULI EXCLUSION PRINCIPLE

The wave function for two or more identical fermions must be an antisymmetric wave function. Other particles (for example, α particles, deuterons, photons, and mesons) have integer spin and symmetric wave functions. These particles are called **bosons.**

A wave function that is a solution to the multiparticle time-independent wave equation (Equation 35-35) is called a spatial state. A bound system that contains fermions has either one or two identical fermions in each occupied spatial state. However, for a bound system that contain bosons there is no limit to the number of identical bosons in each spatial state.

Summary

1. The Schrödinger equation is a partial differential equation that relates the second space derivative of a wave function to its first time derivative. Wave functions that describe physical situations are solutions of this differential equation.
2. Because a wave function must satisfy the normalization condition, it must be well behaved; this means, among other things, that it must approach zero as $|x|$ approaches infinity. For bound systems such as a particle in a box, a simple harmonic oscillator, or an electron in an atom, this requirement leads to energy quantization.
3. The well-behaved wave functions for bound systems describe standing waves.

TOPIC	RELEVANT EQUATIONS AND REMARKS
1. Time-Independent Schrödinger Equation	$$-\frac{\hbar^2}{2m}\frac{d^2\psi(x)}{dx^2} + U(x)\psi(x) = E\psi(x) \qquad \text{35-4}$$
Allowable solutions	In addition to satisfying the Schrödinger equation, a wave function $\psi(x)$ must be continuous and must have a continuous first derivative $d\psi/dx$.* Because the probability of finding an electron somewhere must be 1, the wave function must obey the normalization condition $$\int_{-\infty}^{\infty} \lvert\psi\rvert^2\,dx = 1$$ This condition implies the boundary condition that ψ must approach 0 as $\lvert x\rvert$ approaches ∞. Such boundary conditions lead to the quantization of energy.
2. Confined Particles	When the total energy E is greater than the potential energy $U(x)$ in some region (the classically allowed region) and less than $U(x)$ outside that region, the wave function ψ oscillates within the classically allowed region and $\lvert\psi\rvert$ decreases exponentially outside that region. The wave function approaches zero as $\lvert x\rvert$ approaches ∞ only for certain values of the total energy E. The energy is thus quantized.
In a finite square well	In a finite well of height U_0, there are only a finite number of allowed energies, and these are slightly less than the corresponding energies in an infinite well.
In the simple harmonic oscillator	For the oscillator with potential energy function $U(x) = \frac{1}{2}m\omega_0^2 x^2$, the allowed energies are equally spaced and given by $$E_n = \left(n + \tfrac{1}{2}\right)\hbar\omega_0 \qquad n = 0, 1, 2, \ldots \qquad \text{35-26}$$ The ground-state wave function is given by $$\psi_0(x) = A_0 e^{-ax^2} \qquad \text{35-23}$$ where A_0 is the normalization constant and $$a = \tfrac{1}{2}m\omega_0/\hbar.$$
3. Reflection and Barrier Penetration	When the potential changes abruptly over a small distance, a particle may be reflected even though $E > U(x)$. A particle may penetrate a region in which $E < U(x)$. Reflection and penetration of matter waves are similar to those for other kinds of waves.
4. The Schrödinger Equation in Three Dimensions	The wave function for a particle in a three-dimensional box can be written $$\psi(x, y, z) = \psi_1(x)\psi_2(y)\psi_3(z)$$ where ψ_1, ψ_2, and ψ_3 are wave functions for a one-dimensional box.
Degeneracy	When more than one wave function is associated with the same energy level, the energy level is said to be degenerate. Energy-level degeneracy occurs because of spatial symmetry.

* An exception to this claim is for the infinite well potential (where U is equal to zero inside the well and to infinity outside the well). For this potential function $d\psi/dx$ is not continuous at the boundary of the well (see Figure 34-17).

TOPIC	RELEVANT EQUATIONS AND REMARKS
5. The Schrödinger Equation for Two Identical Particles	A wave function that describes two identical particles must be either symmetric or antisymmetric when the coordinates of the particles are exchanged. Fermions (which include electrons, protons, and neutrons) are described by antisymmetric wave functions and obey the Pauli exclusion principle, which states that no two identical particles can simultaneously have the same values for their quantum number. Bosons (which include α particles, deuterons, photons, and mesons) have symmetric wave functions and do not obey the Pauli exclusion principle.

Answers to Concept Checks

35-1 The wave function cannot be normalized.

Answers to Practice Problems

35-2 $E_{133} = 22E_1$, $E_{142} = E_{124} = E_{222} = 24E_1$

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • Sketch (*a*) the wave function and (*b*) the probability density function for the $n = 5$ state of the finite square-well potential.

2 • Sketch (*a*) the wave function and (*b*) the probability density function for the $n = 4$ state of the finite square-well potential.

THE SCHRÖDINGER EQUATION

3 •• Show that if $\psi_1(x)$ and $\psi_2(x)$ are each solutions to the time-independent Schrödinger equation (Equation 35-4), then $\psi_3(x) = \psi_1(x) + \psi_2(x)$ is also a solution. This result, known as the superposition principle, applies to the solutions of all linear equations.

THE HARMONIC OSCILLATOR

4 •• The harmonic oscillator problem may be used to describe the vibrations of molecules. For example, the hydrogen molecule H_2 is found to have equally spaced vibrational energy levels separated by 8.7×10^{-20} J. What value of the force constant of the spring would be needed to get this energy spacing, assuming that half the molecule can be modeled as a hydrogen atom attached to one end of a spring that has its other end fixed? *Hint: The spacing for the energy levels of this half-molecule would be half of the spacing for the energy levels of the complete molecule. In addition, the force constant of a spring is inversely proportional to its relaxed length, so if half of the spring has force constant k, the entire spring has a force constant that is equal to* $\frac{1}{2}k$.

5 •• Use the procedure of Example 35-1 to verify that the energy of the first excited state of the harmonic oscillator is $E_1 = \frac{3}{2}\hbar\omega_0$. (Note: *Rather than solve for a again, use the step-8 result* $a = \frac{1}{2}m\omega_0/\hbar$ *obtained in* Example 35-1) SSM

6 •• Show that the expectation value $\langle x \rangle = \int_{-\infty}^{\infty} x|\psi|^2\,dx$ is zero for both the ground state and the first excited state of the harmonic oscillator.

7 •• Verify that the normalization constant A_0 in the ground-state harmonic-oscillator wave function $\psi_0(x) = A_0 e^{-ax^2}$ (Equation 35-23) is given by $A_0 = (2m\omega_0/h)^{1/4}$.

8 •• Using the result of Problem 7, show that for the ground state of the harmonic oscillator $\langle x^2 \rangle = \int x^2|\psi|^2\,dx = \hbar/(2m\omega_0) = 1/(4a)$. Use this result to show that the average potential energy equals half the total energy.

9 •• The quantity $\sqrt{\langle x^2 \rangle - \langle x \rangle^2}$ is a measure of the average spread in the location of a particle. (*a*) Consider an electron trapped in a harmonic oscillator potential. Its lowest energy level is found to be 2.1×10^{-4} eV. Calculate $\sqrt{\langle x^2 \rangle - \langle x \rangle^2}$ for this electron. (See Problems 6 and 8.) (*b*) Now consider an electron trapped in an infinite square-well potential. If the width of the well is equal to $\sqrt{\langle x^2 \rangle - \langle x \rangle^2}$, what would be the lowest energy level for this electron?

10 ••• Classically, the average kinetic energy of the harmonic oscillator equals the average potential energy. Assume that this result is also true for the quantum-mechanical harmonic oscillator, and use this result, along with the result of Problem 8, to determine the expectation value of p_x^2 (where $p_x = mv_x$) for the ground state of the one-dimensional harmonic oscillator.

11 ••• We know that for the classical harmonic oscillator, $p_{x\,\mathrm{av}} = 0$. It can be shown that for the quantum-mechanical harmonic oscillator, $\langle p_x \rangle = 0$. Use the results of Problems 6, 8, and 10 to determine the uncertainty product $\Delta x\,\Delta p_x$ for the ground state of the harmonic oscillator. The uncertainties are defined by $(\Delta x)^2 = \langle (x - \langle x \rangle)^2 \rangle$ and $(\Delta p_x)^2 = \langle (p_x - \langle p_x \rangle)^2 \rangle$.

REFLECTION AND TRANSMISSION OF ELECTRON WAVES: BARRIER PENETRATION

12 •• A particle of energy E approaches a step barrier of height U_0. What should be the ratio E/U_0 so that the reflection coefficient is $\frac{1}{2}$?

13 •• **SPREADSHEET** A particle that has mass m is traveling in the direction of increasing x. The potential energy of the particle is equal to zero everywhere in the region $x < 0$ and is equal to U_0 everywhere in the region $x > 0$, where $U_0 > 0$. (*a*) Show that if the total energy is $E = \alpha U_0$, where $\alpha \geq 1$, then the wave number k_2 in the region $x > 0$ is given by $k_2 = k_1\sqrt{(\alpha - 1)/\alpha}$, where k_1 is the wave number in the region $x < 0$. (b) Using a spreadsheet program or graphing calculator, graph the reflection coefficient R and the transmission coefficient T as functions of α, for $1 \leq \alpha \leq 5$. SSM

14 •• Suppose that the potential energy in Problem 13 is equal to zero everywhere in the region $x < 0$ and is equal to $-U_0$ everywhere in the region $x > 0$, where $U_0 > 0$. The wave number for the incident particle is again k_1, and the total energy is $2U_0$. (*a*) What is the wave number for the particle in the region where $x > 0$? (*b*) What is the reflection coefficient R? (*c*) What is the transmission coefficient T? (*d*) If each of one million particles that are in the region $x < 0$ are traveling with wave number k_1 in the direction of increasing x and are incident upon the potential energy drop at $x = 0$, how many of these particles are expected to continue along in the direction of increasing x? How does this compare with the classical prediction?

15 •• A 10-eV electron (an electron with a kinetic energy of 10 eV) is incident on a potential-energy barrier that has a height equal to 25 eV and a width equal to 1.0 nm. (*a*) Use Equation 35-29 to calculate the order of magnitude of the probability that the electron will tunnel through the barrier. (*b*) Repeat your calculation for a width of 0.10 nm. SSM

16 •• Use Equation 35-29 to calculate the order of magnitude of the probability that a proton will tunnel out of a nucleus in one collision with the nuclear barrier if the proton has an energy 6.0 MeV below the top of the potential-energy barrier and the barrier thickness is 1.2×10^{-15} m.

17 ••• To understand how a small change in α-particle energy can dramatically change the probability of the α particle tunneling from a nucleus, consider an α particle emitted by a uranium nucleus ($Z = 92$). (*a*) Referring to Figure 35-17, calculate the center-to-center distance of closest approach r_1 that α particles that have kinetic energies of 4.0 MeV and 7.0 MeV could make to the uranium nucleus. (*b*) Use the result from Part (*a*) to calculate the relative transmission coefficient $e^{-2\alpha a}$ for the same α particles. (*Note:* The actual half-lives of uranium nuclei vary over nine orders of magnitude. Your calculation will show a smaller range than this; however, to find half-life, you must also include the frequency with which the α particle strikes the barrier.)

THE SCHRÖDINGER EQUATION IN THREE DIMENSIONS

18 •• (*a*) A particle is confined to a three-dimensional box that has sides L_1, $L_2 = 2L_1$, and $L_3 = 3L_1$. Give the quantum numbers n_1, n_2 and n_3 that correspond to the ten lowest-energy quantum states of this box. *Hint: A spreadsheet can be helpful.* (*b*) What quantum numbers, if any, correspond to degenerate energy levels? (*c*) Give a wave function for the fifth excited state. (There are only five states that have energy levels below the energy level of the fifth excited state.)

19 •• (*a*) A particle is confined to a three-dimensional box that has sides L_1, $L_2 = 2L_1$, and $L_3 = 4L_1$. Give the quantum numbers n_1, n_2 and n_3 that correspond to the ten lowest-energy quantum states of this box. *Hint: A spreadsheet can be helpful.* (*b*) What combinations of these quantum numbers, if any, correspond to degenerate energy levels? (*c*) Give the wave function for the fourth excited energy state. (There are only four states that have energy levels below the energy level of the fourth excited state.)

20 • A particle moves in a potential well given by $U(x, y, z) = 0$ for $-L/2 < x < L/2$, $0 < y < L$, and $0 < z < L$; $U = \infty$ outside these ranges. (*a*) Write an expression for the ground-state wave function for the particle. (*b*) How do the allowed energies compare with those for a well having $U = 0$ for $0 < x < L$, rather than for $-L/2 < x < L/2$? Explain your answer.

21 •• A particle is constrained to the two-dimensional region defined by $0 \leq x \leq L$ and $0 \leq y \leq L$ and moves freely throughout that region. (*a*) Find the wave functions that meet these conditions and are solutions of the Schrödinger equation. (*b*) Find the energies that correspond to the wave functions in part (*a*). (*c*) Find the quantum numbers of the two lowest states that have the same energy (that are degenerate). (*d*) Find the quantum numbers of the three lowest states that have the same energy.

THE SCHRÖDINGER EQUATION FOR TWO IDENTICAL PARTICLES

22 • Show that the two-particle wave function $\psi_{12} = A\sin(\pi x_1/L)\sin(2\pi x_2/L)$, $0 < x_1 < L$ and $0 < x_2 < L$, (Equation 35-37), is a solution of

$$-\frac{\hbar^2}{2m}\frac{\partial^2\psi(x_1, x_2)}{\partial x_1^2} - \frac{\hbar^2}{2m}\frac{\partial^2\psi(x_1, x_2)}{\partial x_2^2} + U\psi(x_1, x_2) = E\psi(x_1, x_2)$$

(Equation 35-35), if $U(x_1, x_2) = 0$, and find the energy of the state represented by this wave function.

23 • What is the ground-state energy of ten noninteracting bosons in a one-dimensional box of length L?

24 •• What is the ground-state energy of seven identical noninteracting fermions in a one-dimensional box of length L? (Because the quantum number associated with spin can have two values, each spatial state can be occupied by two fermions.)

ORTHOGONALITY OF WAVE FUNCTIONS

The integral of two functions over some space interval is somewhat analogous to the dot product of two vectors. If this integral is zero, the functions are said to be orthogonal, which is analogous to two vectors being perpendicular. The following problems illustrate the general principle that any two wave functions corresponding to different energy levels in the same potential are orthogonal. A general hint for all these problems is that the integral $\int_{x_1}^{x_2} f(x)\,dx$ *is equal to zero if* x_1 *is equal to* $-x_2$ *and if* $f(x)$ *is equal to* $-f(-x)$.

25 •• Show that the ground-state and the first excited state wave functions of the harmonic oscillator are orthogonal; that is, show that $\int_{-\infty}^{\infty}\psi_0(x)\psi_1(x)\,dx = 0$.

26 •• The wave function for the state $n = 2$ of the harmonic oscillator is $\psi_2(x) = A_2\left(2ax^2 - \frac{1}{2}\right)e^{-ax^2}$, where A_2 is the normalization constant and a is a positive constant. Show that the wave functions for the states $n = 1$ and $n = 2$ of the harmonic oscillator are orthogonal.

27 •• For the wave functions

$$\psi_n(x) = A\sin(n\pi x/L) \qquad n = 1, 2, 3, \ldots$$

corresponding to a particle in an infinite square-well potential from 0 to L, show that $\int_0^L \psi_m(x)\psi_n(x)\,dx = 0$ for all positive integers m and n, where $m \neq n$; that is, show that the wave functions are orthogonal.

GENERAL PROBLEMS

28 •• Consider a particle in an infinite one-dimensional box that has a length L and is centered at the origin. (*a*) What are the values of $\psi_1(0)$ and $\psi_2(0)$? (*b*) What are the values of $\langle x\rangle$ for the $n = 1$ and $n = 2$ states? (*c*) Evaluate $\langle x^2\rangle$ for the $n = 1$ and $n = 2$ states.

29 •• Eight identical noninteracting fermions are confined to an infinite two-dimensional square box of side length L. Determine the energies of the three lowest energy states. (See Problem 22.) SSM

30 •• A particle is confined to a two-dimensional box defined by the following boundary conditions: $U(x, y) = 0$ for $-L/2 \le x \le L/2$ and $-3L/2 \le y \le 3L/2$, and $U(x, y) = \infty$ outside these ranges. (*a*) Determine the energies of the three lowest energy states. Are any of these states degenerate? (*b*) Identify the quantum numbers of the two lowest energy degenerate states and determine the energy of these states.

31 ••• The classical probability distribution function for a particle in an infinite one-dimensional well of length L is $P = 1/L$. (See Example 34-5.) (*a*) Show that the classical expectation value of x^2 for a particle in an infinite one-dimensional well of length L that is centered at the origin is $L^2/12$. (*b*) Find the quantum expectation value of x^2 for the nth state of a particle in the one-dimensional box and show that it approaches the classical limit $L^2/12$ as n approaches infinity.

32 •• Show that Equations 35-27 and 35-28 imply that the transmission coefficient for particles of energy E incident on a step barrier $U_0 < E$ is given by

$$T = \frac{4k_1k_2}{(k_1 + k_2)^2} = \frac{4r}{(1 + r)^2}$$

where $r = k_2/k_1$.

33 •• (*a*) Show that for the case of a particle of energy E incident on a step barrier $U_0 < E$, the wave numbers k_1 and k_2 are related by

$$\frac{k_2}{k_1} = r = \sqrt{1 - \frac{U_0}{E}}$$

(*b*) Use this result to show that $R = (1 - r)^2/(1 + r)^2$.

34 •• **SPREADSHEET** (*a*) Using a spreadsheet program or graphing calculator and the results of Problem 32 and Problem 33, graph the transmission coefficient T and reflection coefficient R as a function of incident energy E for values of E ranging from $E = U_0$ to $E = 10.0U_0$. (*b*) What limiting values do your graphs indicate?

35 ••• The wave function for the state $n = 2$ of the harmonic oscillator is $\psi_2(x) = A_2(2ax^2 - \frac{1}{2})e^{-ax^2}$, where $a = \frac{1}{2}m\omega_0/\hbar$. Determine the normalization constant A_2.

36 ••• Consider the time-independent, one-dimensional Schrödinger equation when the potential function is symmetric about the origin, that is, when $U(x)$ is even.* (*a*) Show that if $\psi(x)$ is a solution of the Schrödinger equation and has energy E, then $\psi(-x)$ is also a solution that has the same energy E. Furthermore, $\psi(x)$ and $\psi(-x)$ can differ by only a multiplicative constant. (*b*) Write $\psi(x) = C\psi(-x)$, and show that $C = \pm 1$. Note that $C = +1$ means that $\psi(x)$ is an even function of x, and $C = -1$ means that $\psi(x)$ is an odd function of x.

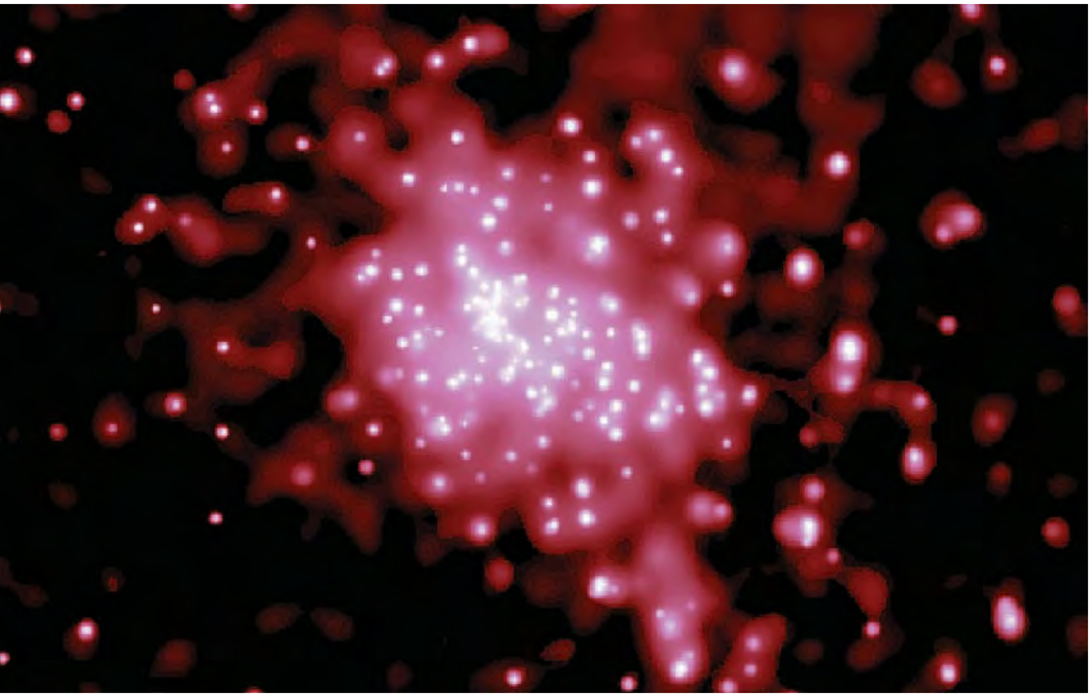
37 ••• In this problem, you will derive the ground-state energy of the harmonic oscillator using the precise form of the uncertainty principle, $\Delta x\,\Delta p_x \ge \hbar/2$, where Δx and Δp_x are defined to be the standard deviations $(\Delta x)^2 = \langle(x - \langle x\rangle)^2\rangle$ and $(\Delta p_x)^2 = \langle(p_x - \langle p_x\rangle)^2\rangle$.

Proceed as follows:

1. Write the total classical energy in terms of the position x and momentum p_x using $U(x) = \frac{1}{2}m\omega_0^2x^2$ and $K = \frac{1}{2}p_x^2/m$.
2. Show that $(\Delta x)^2 = \langle(x - \langle x\rangle)^2\rangle = \langle x^2\rangle - \langle x\rangle^2$ and $(\Delta p_x)^2 = \langle(p_x - \langle p_x\rangle)^2\rangle = \langle p_x^2\rangle - \langle p_x\rangle^2$. *Hint: See Equations 17-34a and 17-34b.*
3. Use the symmetry of the potential energy function to argue that $\langle x\rangle$ and $\langle p_x\rangle$ must be zero, so that $(\Delta x)^2 = \langle x^2\rangle$ and $(\Delta p_x)^2 = \langle p_x^2\rangle$.
4. Assume that $\Delta p_x \Delta x = \hbar/2$ to eliminate $\langle p_x^2\rangle$ from the average energy $\langle E\rangle = \langle \frac{1}{2}p_x^2/m + \frac{1}{2}m\omega_0^2x^2\rangle = \frac{1}{2}\langle p_x^2\rangle/m + \frac{1}{2}m\omega_0^2\langle x^2\rangle$ and write $\langle E\rangle$ as $\langle E\rangle = \hbar^2/(8mZ) + \frac{1}{2}m\omega^2Z$, where $Z = \langle x^2\rangle$.
5. Set $d\langle E\rangle/dZ = 0$ to find the value of Z for which $\langle E\rangle$ is a minimum.
6. Show that the minimum energy is given by $\langle E\rangle_{\min} = +\frac{1}{2}\hbar\omega_0$. SSM

38 ••• A particle that has mass m and is near Earth's surface, at which $z = 0$, can be described by the potential energy function $U = mgz$ in the region $z > 0$, and by $U = \infty$ in the region $z < 0$. Sketch a graph of $U(z)$ versus z. For some positive value of total energy E, indicate the classically allowed region on the graph and plot the classical kinetic energy versus z on the graph. The Schrödinger equation for this problem is quite difficult to solve. Using arguments similar to those in Section 35-2 about the concavity of the wave function as given by the Schrödinger equation, sketch the shape of the wave function for the ground state and for the first two excited states.

* A function $f(x)$ is even if $f(x) = f(-x)$ for all x, and a function $f(x)$ is odd if $f(x) = -f(-x)$ for all x.



CHAPTER 36

AT A DISTANCE OF 6,000 LIGHT YEARS FROM EARTH, THE STAR CLUSTER RCW 38 IS A RELATIVELY CLOSE STAR-FORMING REGION. THIS IMAGE COVERS AN AREA ABOUT 5 LIGHT YEARS ACROSS AND CONTAINS THOUSANDS OF HOT, VERY YOUNG STARS FORMED LESS THAN A MILLION YEARS AGO. X RAYS FROM THE HOT UPPER ATMOSPHERES OF 190 OF THESE STARS WERE DETECTED BY CHANDRA, AN X-RAY OBSERVATORY ORBITING EARTH. THE MECHANISMS GENERATING THESE X RAYS ARE NOT KNOWN. ON EARTH, X-RAY MACHINES PRODUCE X RAYS BY BOMBARDING A TARGET WITH HIGH-ENERGY ELECTRONS. THE ATOMIC NUMBER OF THE ATOMS THAT MAKE UP THE TARGET CAN BE DETERMINED BY ANALYZING THE RESULTING X-RAY SPECTRA. *(NASA/CXC/CfA/S.Wolk et al.)*

? How is the atomic number obtained from the spectral analysis? (See Example 36-8.)

Atoms

One hundred eleven chemical elements have been discovered, and several additional chemical elements recently have been reported but not authenticated. Each element is characterized by an atom that has a number of protons Z and an equal number of electrons. The number of protons Z is called the **atomic number.** The atom that has the fewest protons is called hydrogen (H) and has $Z = 1$. A helium (He) atom has two protons ($Z = 2$), a lithium (Li) atom has three protons ($Z = 3$), and so forth. Nearly all the mass of an atom is concentrated in its tiny nucleus, which is made up of protons and neutrons. An atom's nuclear radius is approximately 1 fm to 10 fm (1 fm $= 10^{-15}$ m) and the radius of an atom is approximately 0.1 nm $=$ 100 000 fm.

The chemical properties and physical properties of an element are determined by the number and arrangement of the electrons in an atom of the element. Because each proton has a positive charge $+e$, the nucleus has a total positive charge $+Ze$. The electrons are negatively charged ($-e$), so they are attracted to the nucleus and repelled by each other. Because electrons and protons have equal but opposite charges and an atom has equal numbers of electrons and protons, atoms are electrically neutral. Atoms that lose or gain one or more electrons are then electrically charged and are called *ions*.

We will begin our study of atoms by discussing the Bohr model, a semiclassical model developed by Niels Bohr in 1913 to explain the electromagnetic spectra produced by hydrogen atoms. Although this pre-quantum mechanics model has many shortcomings, it provides a useful framework for the discussion of atomic phenomena. After discussing the Bohr model, we will then apply our knowledge of quantum mechanics from Chapter 35 to give a much more productive model of the hydrogen atom. We will then discuss the structure of other atoms and the periodic table of the elements. Finally, we will discuss both optical and X-ray spectra.

36-1 THE ATOM

ATOMIC SPECTRA

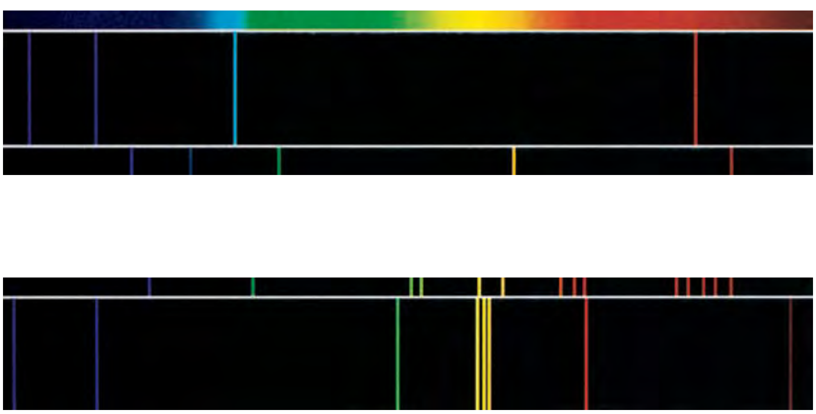
By the beginning of the twentieth century, a large body of data had been collected on the emission of light by atoms in a gas when the atoms are excited by an electric discharge. Viewed through a spectroscope that has a narrow-slit aperture, light that has been emitted by atoms of a particular element appears as a discrete set of lines of different colors or wavelengths. The spacing and relative intensities of the lines are characteristic of the element. The wavelengths of these spectral lines could be accurately determined, and much effort went into finding regularities in the spectra. Figure 36-1 shows line spectra for hydrogen and for mercury.

In 1885, Johann Balmer determined that the wavelengths of the lines in the visible spectrum of hydrogen can be represented by the formula

$$\lambda = (364.6\text{ nm})\frac{m^2}{m^2 - 4} \qquad m = 3, 4, 5, \ldots \qquad \text{36-1}$$

Balmer suggested that this expression might be a special case of a more general expression that would be applicable to the spectra of other elements. Such an expression, found by Johannes R. Rydberg and Walter Ritz and known as the **Rydberg–Ritz formula,** gives the reciprocal wavelength as

$$\frac{1}{\lambda} = R\left(\frac{1}{n_2^2} - \frac{1}{n_1^2}\right) \qquad \text{36-2}$$



(a)

(b)

FIGURE 36-1 (*a*) Line spectrum of hydrogen and (*b*) line spectrum of mercury. *((a) and (b) adapted from Eastern Kodak and Wabash Instrument Corporation.)*

where n_1 and n_2 are integers, $n_1 > n_2$, and R is the Rydberg constant. The Rydberg constant does vary slightly, and in a regular way, from element to element. For hydrogen, R has the value

$$R_H = 1.097776 \times 10^7\ m^{-1}$$

RYDBERG CONSTANT FOR HYDROGEN

The Rydberg–Ritz formula gives the wavelengths for all the lines in the spectra of hydrogen, as well as alkali elements such as lithium and sodium. The hydrogen Balmer series given by Equation 36-1 is also given by Equation 36-2, with $R = R_H$, $n_2 = 2$, and $n_1 = m$.

Many attempts were made to construct a model of the atom that would yield these formulas for an atom's radiation spectrum. The most popular model, created by J. J. Thomson, considered various arrangements of electrons embedded in some kind of fluid that had most of the mass of the atom and had enough positive charge to make the atom electrically neutral. Thomson's model, called the "plum pudding" model, is illustrated in Figure 36-2. Because classical electromagnetic theory predicted that a charge oscillating with frequency f would radiate electromagnetic energy of that frequency, Thomson searched for configurations that were stable and that had normal modes of vibration of frequencies equal to those of the spectrum of the atom. A difficulty of this model and all other models was that, according to classical physics, electric forces alone cannot produce stable equilibrium. Thomson was unsuccessful in finding a model that predicted the observed frequencies for any atom.

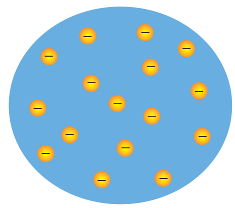


FIGURE 36-2 J. J. Thomson's plum pudding model of the atom. In this model the electrons, which have a negative charge, are embedded in a fluid of positive charge. For a given configuration in such a system, the resonance frequencies of oscillations of the electrons can be calculated. According to classical theory, the atom should radiate light of frequency equal to the frequency of oscillation of the electrons. Thomson could not find any configuration that would give frequencies in agreement with the measured frequencies of the spectrum of any atom.

The Thomson model was essentially ruled out by a set of experiments by H. W. Geiger and E. Marsden, under the supervision of E. Rutherford in approximately 1911, in which alpha particles from radioactive radium were scattered by atoms in a gold foil. Rutherford showed that the number of alpha particles scattered at large angles could not be accounted for by an atom in which the positive charge was distributed throughout the atom (known to be about 0.1 nm in diameter). Instead, the results suggested that the positive charge and most of the mass of an atom is concentrated in a very small region, now called the nucleus, which has a diameter of the order of 10^{-6} nm = 1 fm.

36-2 THE BOHR MODEL OF THE HYDROGEN ATOM

Niels Bohr, working in the Rutherford laboratory in 1912, proposed a model of the hydrogen atom that extended the work of Planck, Einstein, and Rutherford and successfully predicted the observed spectra. According to Bohr's model, the electron of the hydrogen atom moves in either a circular or an elliptical orbit around the positive nucleus according to Coulomb's law and classical mechanics like the planets orbit the Sun. For simplicity, Bohr chose a circular orbit, as shown in Figure 36-3.

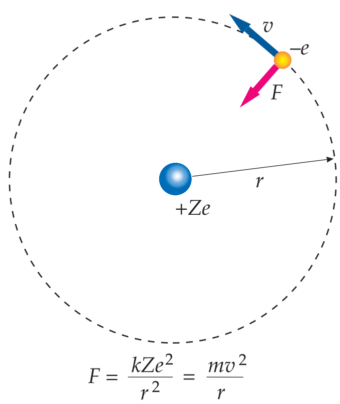

FIGURE 36-3 Electron of charge $-e$ traveling in a circular orbit of radius r around the nuclear charge $+Ze$. The attractive electrical force kZe^2/r^2 keeps the electron in its orbit.

ENERGY FOR A CIRCULAR ORBIT

Consider an electron of charge $-e$ moving in a circular orbit of radius r about a positive charge $+Ze$ such as the nucleus of a hydrogen atom ($Z = 1$) or of a singly ionized helium atom ($Z = 2$). The total energy of the electron can be related to the radius of the orbit. The potential energy of the electron of charge $-e$ at a distance r from a positive charge Ze is

$$U = \frac{kq_1q_2}{r} = \frac{k(Ze)(-e)}{r} = -\frac{kZe^2}{r} \qquad \text{36-3}$$

where k is the Coulomb constant. The kinetic energy K can be obtained as a function of r by using Newton's second law, $F_{\text{net}} = ma$. Setting the Coulomb attractive force equal to the mass multiplied by the centripetal acceleration gives

$$\frac{kZe^2}{r^2} = m\frac{v^2}{r} \qquad \text{36-4}a$$

Multiplying both sides by $r/2$ gives

$$K = \frac{1}{2}mv^2 = \frac{1}{2}\frac{kZe^2}{r} \qquad \text{36-4}b$$

Thus, the kinetic energy and the potential energy vary inversely with r. Note that the magnitude of the potential energy is twice that of the kinetic energy:

$$U = -2K \qquad \text{36-5}$$

Equation 36-5 a general result for particles orbiting under the influence of forces that vary inversely with the square of the distance from a fixed point. [It also holds for circular orbits in a gravitational field (see Example 11-6 in Section 11-3)]. The total energy is the sum of the kinetic energy and the potential energy:

$$E = K + U = \frac{1}{2}\frac{kZe^2}{r} - \frac{kZe^2}{r}$$

or

$$E = -\frac{1}{2}\frac{kZe^2}{r} \qquad \text{36-6}$$

ENERGY IN A CIRCULAR ORBIT FOR A $1/r^2$ FORCE

Although mechanical stability is achieved because the Coulomb attractive force provides the centripetal force necessary for the electron to remain in orbit, classical *electromagnetic* theory says that such an atom would be electrically unstable. The atom would be unstable because the electron must accelerate when moving in a circle and therefore radiate electromagnetic energy of frequency equal to that of its motion. According to the classical theory, such an atom would quickly collapse as the electron spiraled into the nucleus and radiated away the energy.

BOHR'S POSTULATES

Bohr circumvented the difficulty of the collapsing atom by *postulating* that only certain orbits, called stationary states, are allowed and that an atom with an electron in one of these orbits does not radiate. An atom radiates only when the electron makes a transition from one allowed orbit (stationary state) to another.

The electron in the hydrogen atom can move only in certain nonradiating, circular orbits called stationary states.

BOHR'S FIRST POSTULATE—NONRADIATING ORBITS

Bohr's second postulate relates the frequency of radiation to the energies of the stationary states. If E_{i} and E_{f} are the initial and final energies of the atom, the frequency of the emitted radiation during a transition is given by

$$f = \frac{E_{\text{i}} - E_{\text{f}}}{h} \qquad \text{36-7}$$

BOHR'S SECOND POSTULATE—PHOTON FREQUENCY FROM ENERGY CONSERVATION where h is Planck's constant. This postulate is equivalent to the assumption of conservation of energy when a photon of energy hf is emitted. Combining Equation 36-6 and Equation 36-7, we obtain for the frequency

$$f = \frac{E_i - E_f}{h} = \frac{1}{2}\frac{kZe^2}{h}\left(\frac{1}{r_f} - \frac{1}{r_i}\right) \qquad 36\text{-}8$$

where r_i and r_f are the radii of the initial and final orbits.

To obtain the frequencies implied by the Rydberg–Ritz formula, $f = c/\lambda = cR(1/n_2^2 - 1/n_1^2)$, it is evident that the radii of stable orbits must be proportional to the squares of integers. Bohr searched for a quantum condition for the radii of the stable orbits that would yield this result. After much trial and error, Bohr found that he could obtain the desired result if he postulated that the magnitude of the angular momentum of the electron in a stable orbit equals an integer multiplied by $\hbar$. Because the magnitude of the angular momentum of a circular orbit is just mvr, this postulate is

$$mv_nr_n = n\hbar \qquad n = 1, 2, 3, \ldots \qquad 36\text{-}9$$

BOHR'S THIRD POSTULATE—QUANTIZED ANGULAR MOMENTUM

where $\hbar = h/2\pi = 1.055 \times 10^{-34}\,\text{J}\cdot\text{s} = 6.582 \times 10^{-16}\,\text{eV}\cdot\text{s}$.

Equation 36-9 relates the speed v_n to the radius r_n of the orbit that has angular momentum $n\hbar$. Equation 36-4a gives us another equation relating the speed to the radius:

$$\frac{kZe^2}{r_n^2} = m\frac{v_n^2}{r_n}$$

or

$$v_n^2 = \frac{kZe^2}{mr_n} \qquad 36\text{-}10$$

We can determine r_n by first solving for v_n in Equation 36-9. Squaring the result then gives

$$v_n^2 = n^2\frac{\hbar^2}{m^2r_n^2}$$

Equating this expression for v_n^2 with the expression given by Equation 36-10, we get

$$n^2\frac{\hbar^2}{m^2r_n^2} = \frac{kZe^2}{mr_n}$$

Solving for r_n, we obtain

$$r_n = n^2\frac{\hbar^2}{mkZe^2} = n^2\frac{a_0}{Z} \qquad 36\text{-}11$$

RADII OF THE BOHR ORBITS

where a_0 is called the **first Bohr radius.** According to the Bohr model, a_0 is the orbital radius of the electron in a hydrogen atom that has $n = 1$.

$$a_0 = \frac{\hbar^2}{mke^2} = \frac{\epsilon_0 h^2}{\pi me^2} = 0.0529\text{ nm} \qquad 36\text{-}12$$

FIRST BOHR RADIUS

Substituting the expressions for r_n in Equation 36-11 into Equation 36-8 for the frequency gives

$$f = \frac{1}{2}\frac{kZe^2}{h}\left(\frac{1}{r_{\mathrm{f}}} - \frac{1}{r_{\mathrm{i}}}\right) = Z^2\frac{mk^2e^4}{4\pi\hbar^3}\left(\frac{1}{n_{\mathrm{f}}^2} - \frac{1}{n_{\mathrm{i}}^2}\right) \qquad 36\text{-}13$$

If we compare this expression where $Z = 1$ and $f = c/\lambda$ with the empirical Rydberg–Ritz formula (Equation 36-2), we obtain for the Rydberg constant

$$R = \frac{mk^2e^4}{4\pi c\hbar^3} = \frac{me^4}{8\epsilon_0^2 ch^3} \qquad 36\text{-}14$$

Using the values of m, e, c, k, and $\hbar$ known in 1913, Bohr calculated R and found his result to agree (within the limits of the uncertainties of the constants) with the value obtained from spectroscopy.

Example 36-1 Standing-Wave Condition Implies Quantization of Angular Momentum

For waves in a circle, the standing-wave condition is that there is an integral number of wavelengths in the circumference. That is, $n\lambda_n = 2\pi r_n$, where $n = 1, 2, 3,$ and so on. Show that this condition for electron waves implies quantization of angular momentum.

PICTURE The wavelength and the momentum are related by the de Broglie relation $p = h/\lambda$ (Equation 34-13). Using this relation and the standing wave condition $n\lambda_n = 2\pi r_n$ to relate the momentum to the radius.

SOLVE

1. Write the standing-wave condition: $\quad n\lambda_n = 2\pi r_n$
2. Use the de Broglie relation (Equation 34-13) to relate the momentum p to λ_n: $\quad p = \dfrac{h}{\lambda_n} = \dfrac{nh}{2\pi r_n} = n\dfrac{\hbar}{r_n}$
3. Solve for pr_n. The angular momentum of an electron in a circular orbit is $mvr_n = pr_n$, where $p = mv$: $\quad pr_n = \boxed{mvr_n = n\hbar}$

CHECK The step-3 result is the check. It is what the problem statement asks us to show.

ENERGY LEVELS

The total mechanical energy of the electron in the hydrogen atom is related to the radius of the circular orbit by Equation 36-6. If we substitute the quantized values of r as given by Equation 36-11, we obtain

$$E_n = -\frac{1}{2}\frac{kZe^2}{r_n} = -\frac{1}{2}\frac{kZ^2e^2}{n^2a_0} = -\frac{1}{2}\frac{mk^2Z^2e^4}{n^2\hbar^2}$$

or

$$E_n = -Z^2\frac{E_0}{n^2} \qquad 36\text{-}15$$

ENERGY LEVELS IN THE HYDROGEN ATOM

where

$$E_0 = \frac{mk^2e^4}{2\hbar^2} = \frac{1}{2}\frac{ke^2}{a_0} = 13.6\ \text{eV} \qquad 36\text{-}16$$

The energies E_n corresponding to $Z = 1$ are the quantized allowed energies for the hydrogen atom.

Transitions between these allowed energies result in the emission or absorption of a photon whose frequency is given by $f = (E_i - E_f)/h$, and whose wavelength is

$$\lambda = \frac{c}{f} = \frac{hc}{E_i - E_f} \qquad 36\text{-}17$$

As we found in Chapter 34, it is convenient to have the value of hc in electron-volt nanometers:

$$hc = 1240\ \text{eV}\cdot\text{nm} \qquad 36\text{-}18$$

Because the energies are quantized, the frequencies and wavelengths of the radiation emitted by the hydrogen atom are quantized in agreement with the observed line spectrum.

Figure 36-4 shows the energy-level diagram for hydrogen. The energy of the hydrogen atom in the ground state is $E_1 = -13.6$ eV. As n approaches infinity the energy approaches zero. The process of removing an electron from an atom is called **ionization,** and the minimum amount of energy required to remove the electron is the **ionization energy.** The ionization energy of the ground-state hydrogen atom, which is also its **binding energy,** is 13.6 eV. A few transitions from a higher state to a lower state are indicated in Figure 36-4. When Bohr published his model of the hydrogen atom, the Balmer series (corresponding to $n_f = 2$ and $n_i = 3, 4, 5, \ldots$) and the Paschen series (corresponding to $n_f = 3$ and $n_i = 4, 5, 6, \ldots$) were known. In 1916, T. Lyman found the series corresponding to $n_f = 1$. F. Brackett in 1922 and H. A. Pfund in 1924 found the series corresponding to $n_f = 4$ and $n_f = 5$, respectively. Only the Balmer series lies in the visible portion of the electromagnetic spectrum.

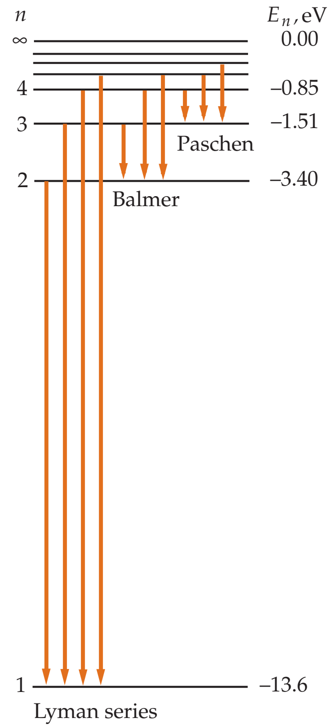

FIGURE 36-4 Energy-level diagram for hydrogen showing the first few transitions in each of the Lyman, Balmer, and Paschen series. The energies of the levels are given by Equation 36-15.

! Do not think the λ in Equation 36-17 is the wavelength of the electron. It is not. It is the wavelength of the emitted or absorbed photon.

Example 36-2 Longest Wavelength in the Lyman Series

Find (*a*) the energy and (*b*) the wavelength of the spectral line that has the longest wavelength in the Lyman series.

PICTURE For the Lyman series $n_f = 1$. From Figure 36-4, we can see that the Lyman series corresponds to transitions ending at the ground-state energy, $E_f = E_1 = -13.6$ eV. Because the photon wavelength λ varies inversely with energy, the transition that has the longest wavelength is the transition that has the lowest energy, which is from the first excited state $n = 2$ to the ground state $n = 1$.

SOLVE

1. The energy of the photon is the difference in the energies of the initial and final atomic states:

$$E_{\text{photon}} = \Delta E_{\text{atom}} = E_i - E_f$$
$$= E_2 - E_1 = \frac{-13.6\ \text{eV}}{2^2} - \frac{-13.6\ \text{eV}}{1^2}$$
$$= -3.40\ \text{eV} + 13.6\ \text{eV} = \boxed{10.2\ \text{eV}}$$

2. The wavelength of the photon is

$$\lambda = \frac{hc}{E_2 - E_1} = \frac{1240\ \text{eV}\cdot\text{nm}}{10.2\ \text{eV}} = \boxed{122\ \text{nm}}$$

CHECK The step-1 result of 10.2 eV is less than 13.6 eV (the binding energy of ground-state hydrogen). This result is expected.

TAKING IT FURTHER This photon has a wavelength that corresponds to the ultraviolet region of the electromagnetic spectrum. Because all the other lines in the Lyman series have even greater energies and shorter wavelengths, the Lyman series is completely in the ultraviolet region.

PRACTICE PROBLEM 36-1 Find the shortest wavelength for a line in the Lyman series.

Despite its spectacular successes, the Bohr model of the hydrogen atom had many shortcomings. There was no justification for the postulates of stationary states or for the quantization of angular momentum other than the fact that these postulates led to energy levels that agreed with spectroscopic data. Furthermore, attempts to apply the model to atoms that have more electrons and protons had little success. The quantum-mechanical model resolves these difficulties. The stationary states of the Bohr model are replaced by the standing-wave solutions of the Schrödinger equation analogous to the standing electron waves for a particle in a box discussed in Chapter 34 and Chapter 35. Energy quantization is a direct consequence of the standing-wave solutions of the Schrödinger equation. For hydrogen, these quantized energies agree with those obtained from the Bohr model and with experiment. The quantization of angular momentum that had to be postulated in the Bohr model is predicted by the quantum theory.

36-3 QUANTUM THEORY OF ATOMS

THE SCHRÖDINGER EQUATION IN SPHERICAL COORDINATES

In quantum theory, an electron in an atom is described by its wave function ψ. The probability of finding the electron in some volume dV of space equals the square of the absolute value of the wave function $|\psi|^2$ multiplied by dV. Boundary conditions on the wave function lead to the quantization of the wavelengths and frequencies and thereby to the quantization of the electron energy.

Consider a single electron of mass m moving in three dimensions in a region in which the potential energy is U. The time-independent Schrödinger equation for such a particle is given by Equation 35-30:

$$-\frac{\hbar^2}{2m}\left(\frac{\partial^2\psi}{\partial x^2}+\frac{\partial^2\psi}{\partial y^2}+\frac{\partial^2\psi}{\partial z^2}\right)+U(x,y,z)\psi=E\psi \qquad \text{36-19}$$

For a single isolated atom, the potential energy U depends only on the radial distance $r=\sqrt{x^2+y^2+z^2}$ of the electron from the center of the nucleus. The problem is then most conveniently treated using the spherical coordinates r, θ, and ϕ, which are related to the rectangular coordinates x, y, and z by

$$\begin{aligned} z &= r\cos\theta \\ x &= r\sin\theta\cos\phi \\ y &= r\sin\theta\sin\phi \end{aligned} \qquad \text{36-20}$$

These relations are shown in Figure 36-5. The transformation of Equation 36-19 from rectangular to spherical coordinates is a straightforward, but tedious, calculation, which we will omit. The result of this transformation can be found in Problem 42. We will discuss qualitatively some of the interesting features of the wave functions that satisfy this equation.

The transformed version of Equation 36-19 can be solved using the technique called separation of variables. This is accomplished by expressing the wave function $\psi(r,\theta,\phi)$ as a product of three functions, each of which is a function of only one of the three spherical coordinates:

$$\psi(r,\theta,\phi)=R(r)f(\theta)g(\phi) \qquad \text{36-21}$$

where R is a function that depends only on the radial coordinate r, f is a function that depends only on the polar coordinate θ, and g is a function that depends only on the azimuth coordinate ϕ. When this form of $\psi(r,\theta,\phi)$ is substituted into the Schrödinger equation, the Schrödinger equation can be transformed into three ordinary differential equations, one for $R(r)$, one for $f(\theta)$, and one for $g(\phi)$. The potential energy $U(r)$ appears only in the equation for $R(r)$, which is called the **radial equation.**

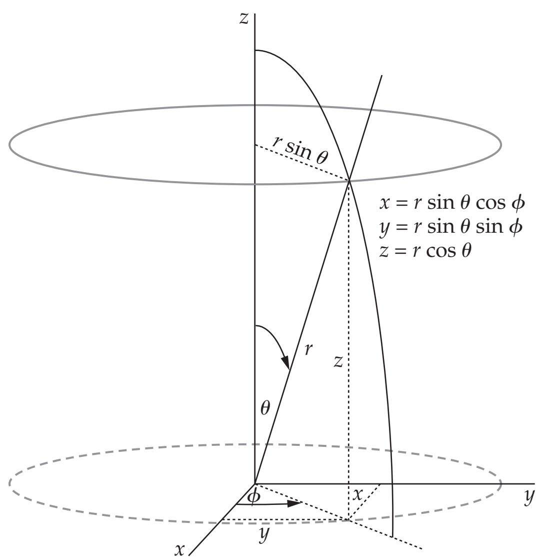

FIGURE 36-5 Geometric relations between spherical coordinates and rectangular coordinates.

Because the potential energy depends only on the coordinate r, the potential energy has no effect on the solutions of the equations for $f(\theta)$ and $g(\phi)$, and therefore has no effect on the angular dependence of the wave function $\psi(r, \theta, \phi)$. These solutions are applicable to *any* problem in which the potential energy depends only on r.

QUANTUM NUMBERS IN SPHERICAL COORDINATES

In three dimensions, the requirement that the wave function be continuous and normalizable introduces three quantum numbers, one associated with each spatial dimension. In spherical coordinates, the quantum number associated with r is labeled n, that associated with θ is labeled ℓ, and that associated with ϕ is labeled m_ℓ.* The quantum numbers n_1, n_2, and n_3 that we found in Chapter 35 for a particle in a three-dimensional square well in rectangular coordinates x, y, and z were independent of one another, but the quantum numbers associated with wave functions in spherical coordinates are dependent on each other. The possible values of these quantum numbers are

$$n = 1, 2, 3, \ldots$$
$$\ell = 0, 1, 2, 3, \ldots, n-1$$
$$m_\ell = -\ell, -\ell+1, -\ell+2, \ldots, 0, \ldots, \ell-2, \ell-1, \ell \qquad \text{36-22}$$

QUANTUM NUMBERS IN SPHERICAL COORDINATES

That is, n can be any positive integer; ℓ can be 0 or any positive integer up to $n - 1$; and m_ℓ can have $2\ell + 1$ possible values, ranging from $-\ell$ to $+\ell$ in integral steps.

The number n is called the **principal quantum number.** It is associated with the dependence of the wave function on the distance r and therefore with the probability of finding the electron at various distances from the nucleus. The quantum numbers ℓ and m_ℓ are associated with the orbital angular momentum of the electron and with the angular dependence of the electron wave function. The quantum number ℓ is called the **orbital quantum number.** The magnitude L of the orbital angular momentum $\vec{L}$ is related to the orbital quantum number ℓ by

$$L = \sqrt{\ell(\ell+1)}\hbar \qquad \text{36-23}$$

The quantum number m_ℓ is called the **magnetic quantum number.** It is related to the component of the orbital angular momentum along some direction in space. All spatial directions are equivalent for an isolated atom, but placing the atom in a magnetic field results in the direction of the magnetic field being separated out from the other directions. The convention is that the $+z$ direction is chosen for the magnetic-field direction. Then the z component of the orbital angular momentum of the electron is given by the quantum condition

$$L_z = m_\ell \hbar \qquad \text{36-24}$$

This quantum condition arises from the boundary condition on the azimuth coordinate ϕ that the probability of finding the electron at some arbitrary angle ϕ_1 must be the same as that of finding the electron at angle $\phi_2 = \phi_1 + 2\pi$, because these two values of ϕ represent the same point in space.

If we measure the angular momentum of the electron in units of $\hbar$, we see that the magnitude of the orbital angular momentum is quantized to the value $\sqrt{\ell(\ell+1)}$ units, and that its component along any direction can have only the $2\ell + 1$ values ranging from $-\ell$ to $+\ell$ units. Figure 36-6 shows a vector-model diagram illustrating the possible orientations of the angular-momentum vector for $\ell = 2$. Note that only specific values of θ are allowed; that is, the directions in space are quantized.

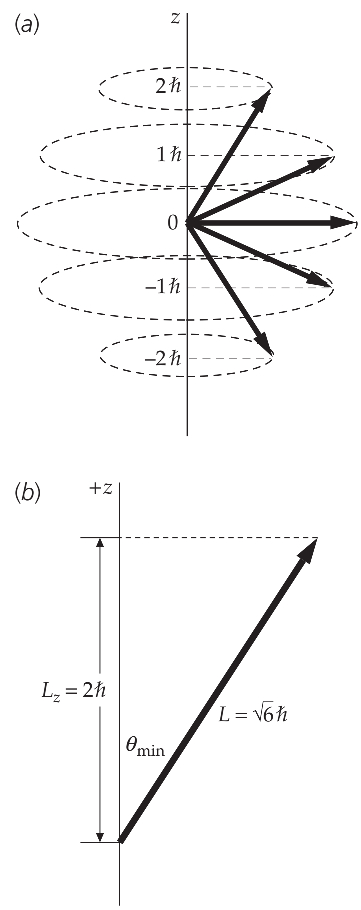

FIGURE 36-6 (*a*) Vector-model diagram illustrating the possible values of the z component of the orbital angular-momentum vector for the case $\ell = 2$. The magnitude of the orbital angular momentum is $L = \hbar\sqrt{\ell(\ell+1)} = \hbar\sqrt{2(2+1)} = \hbar\sqrt{6}$. (*b*) The values of the z component of the orbital angular-momentum vector for the case $\ell = 2$ and $m_\ell = 2$. The value of the z component of the orbital angular momentum is $L_z = 2\hbar$.

* For simplicity, m_ℓ is sometimes written as m.

Example 36-3 The Directions of the Angular Momentum

If the orbital angular momentum is characterized by the quantum number $\ell = 2$, what are the possible values of L_z, and what is the smallest possible angle between $\vec{L}$ and the direction of increasing z?

PICTURE The possible orientations of $\vec{L}$ and the z axis are shown in Figure 36-6. The direction of increasing z is the direction of the external magnetic field in the vicinity of the atom.

SOLVE

1. Write the possible values of L_z:

$$\boxed{L_z = m_\ell \hbar \qquad \text{where} \qquad m_\ell = -2, -1, 0, 1, 2}$$

2. Express the angle θ between $\vec{L}$ and the $+z$ direction in terms of L and L_z:

$$\cos\theta = \frac{L_z}{L} = \frac{m_\ell \hbar}{\sqrt{\ell(\ell+1)}\hbar} = \frac{m_\ell}{\sqrt{\ell(\ell+1)}}$$

3. The smallest angle occurs when $\ell = 2$ and $m_\ell = 2$:

$$\cos\theta_{\min} = \frac{2}{\sqrt{2(2+1)}} = \frac{2}{\sqrt{6}} = 0.816$$

$$\theta_{\min} = \boxed{35.3^\circ}$$

CHECK The angle in Figure 36-6*b* looks to be between about 30° and 40°, so the step-3 result of 35.3° is plausible.

TAKING IT FURTHER We note the somewhat strange result that the orbital angular-momentum vector cannot be parallel to the z axis.

PRACTICE PROBLEM 36-2 An atom is in a region that has a magnetic field. An electron in the atom has an angular momentum characterized by the quantum number $\ell = 4$. What are the possible values of m_ℓ for this electron?

36-4 QUANTUM THEORY OF THE HYDROGEN ATOM

We can treat the simplest atom, the hydrogen atom, as a stationary nucleus (a proton) and a single moving particle, an electron, which has linear momentum p and kinetic energy $p^2/2m$. The potential energy $U(r)$ due to the electrostatic attraction between the electron and the proton* is

$$U(r) = \frac{kZe^2}{r} \qquad \text{36-25}$$

For this potential-energy function, the Schrödinger equation can be solved exactly. In the lowest energy state, which is the ground state, the principal quantum number n has the value 1, ℓ is 0, and m_ℓ is 0.

ENERGY LEVELS

The allowed energies of the hydrogen atom that result from the solution of the Schrödinger equation are

$$E_n = -Z^2 \frac{E_0}{n^2} \qquad n = 1, 2, 3, \ldots \qquad \text{36-26}$$

ENERGY LEVELS FOR HYDROGEN

* We include the factor Z, which is 1 for hydrogen, so that we can apply our results to other one-electron "atoms," such as singly ionized helium He^+, for which $Z = 2$.

where

$$E_0 = \frac{mk^2e^4}{2\hbar^2} = 13.6 \text{ eV} \qquad 36\text{-}27$$

These energies are the same as those obtained using the Bohr model. Note that the energies E_n are negative, indicating that the electron is bound to the nucleus (thus the term *bound state*), and that the energies depend only on the principal quantum number n. The fact that the energy does not depend on the orbital quantum number ℓ is a peculiarity of the inverse-square force and holds only for an inverse r potential such as Equation 36-25. For atoms having multiple electrons, the interaction of the electrons leads to a dependence of the energy on ℓ. In general, the lower the value of ℓ, the lower the energy for such atoms. Because there is usually no preferred direction in space, the energy for any atom does not ordinarily depend on the magnetic quantum number m_ℓ, which is related to the z component of the angular momentum. However, the energy does depend on m_ℓ if the atom is in a magnetic field.

Figure 36-7 shows an energy-level diagram for hydrogen. This diagram is similar to Figure 36-4, except that the states which have the same value of n but different values of ℓ are shown separately. These states (called *terms*) are referred to by giving the value of n along with a code letter: s for $\ell = 0$, p for $\ell = 1$, d for $\ell = 2$, and f for $\ell = 3$.* (Lowercase letters s, p, d, f, and so on, are used to specify the orbital angular momentum of an individual electron, whereas uppercase letters S, P, D, F, and so on, are used to identify the orbital angular momentum for the entire multielectron atom. For a single-electron atom, like hydrogen, either uppercase or lowercase letters will suffice.) When an atom makes a transition from one allowed energy state to another, electromagnetic radiation in the form of a photon is emitted or absorbed. Such transitions result in spectral lines that are characteristic of the atom. The transitions obey the **selection rules:**

$$\Delta m_\ell = -1, 0, \text{ or } +1$$
$$\Delta \ell = -1 \text{ or } +1 \qquad 36\text{-}28$$

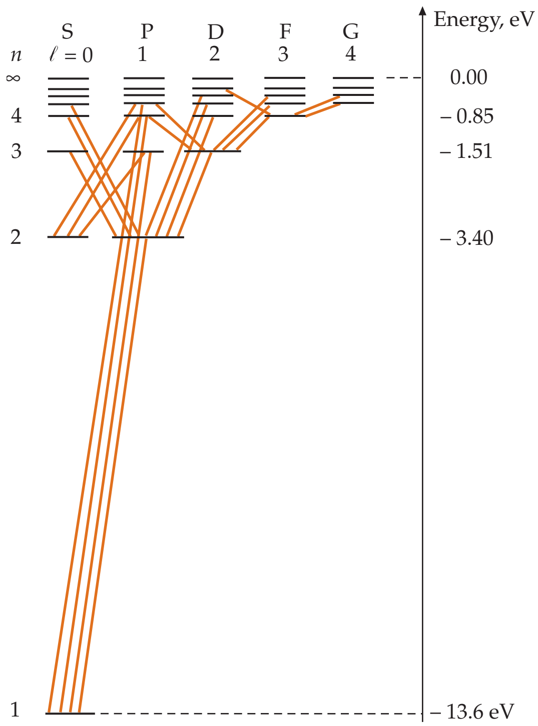

FIGURE 36-7 Energy-level diagram for hydrogen. The diagonal lines show transitions that involve emission or absorption of radiation and obey the selection rule $\Delta\ell = \pm 1$. States that have the same value of n but with different values of ℓ have the same energy $-E_0/n^2$, where $E_0 = 13.6$ eV as in the Bohr model.

These selection rules are related to the conservation of angular momentum and to the fact that the photon itself has an intrinsic angular momentum that has a maximum angular-momentum component of $1\hbar$ in any direction. The wavelengths of the light emitted by hydrogen (and by other atoms) are related to the energy levels by

$$hf = \frac{hc}{\lambda} = E_i - E_f \qquad 36\text{-}29$$

where E_i and E_f are the energies of the initial and final states.

WAVE FUNCTIONS AND PROBABILITY DENSITIES

The solutions of the Schrödinger equation in spherical coordinates are characterized by the quantum numbers n, ℓ, and m_ℓ, and are written $\psi_{n\ell m_\ell}$. The principal quantum number n can take on any of the values 1, 2, 3, ... In addition, for each value of n, ℓ can take on any of the values $0, 1, \ldots, n-1$, and for each value of ℓ, m_ℓ can take on any of the values $-\ell, -\ell+1, -\ell+2, \ldots, +\ell$. Thus, for any given value of n, there are n possible values of ℓ, and for any given value of ℓ, there are $2\ell + 1$ possible values of m_ℓ. For hydrogen, the energy depends only on n, so there are generally many different wave functions that correspond to the same

* These code letters for the values of ℓ are remnants of spectroscopists' descriptions of various spectral lines as *sharp, principal, diffuse*, and *fundamental*. For values greater than 3, the letters follow alphabetically, starting with g for $\ell = 4$.

energy (except at the lowest energy level, for which $n = 1$ and therefore ℓ and m_ℓ must both equal 0). These energy levels are therefore degenerate (see Section 35-5). The origins of this degeneracy are the $1/r$ dependence of the potential energy and the fact that, in the absence of any external fields, there is no preferred direction in space.*

The ground state In the lowest energy state, the ground state of hydrogen, the principal quantum number n has the value 1, ℓ is 0, and m_ℓ is 0. The energy is –13.6 eV, and the angular momentum is zero. (In the Bohr model of the atom the angular momentum in the ground state is equal to $\hbar$, not zero.) The wave function for the ground state is

$$\psi_{100} = C_{100} e^{-Zr/a_0} \qquad \text{36-30}$$

where

$$a_0 = \frac{\hbar^2}{mke^2} = 0.0529 \text{ nm}$$

is the first Bohr radius and C_{100} is a constant that is determined by normalization. In three dimensions, the normalization condition is

$$\int |\psi|^2 dV = 1$$

where dV is a volume element and the integration is performed over all space. In spherical coordinates, the volume element (Figure 36-8) is

$$dV = (r \sin\theta \, d\phi)(r \, d\theta) dr = r^2 \sin\theta \, d\theta \, d\phi \, dr$$

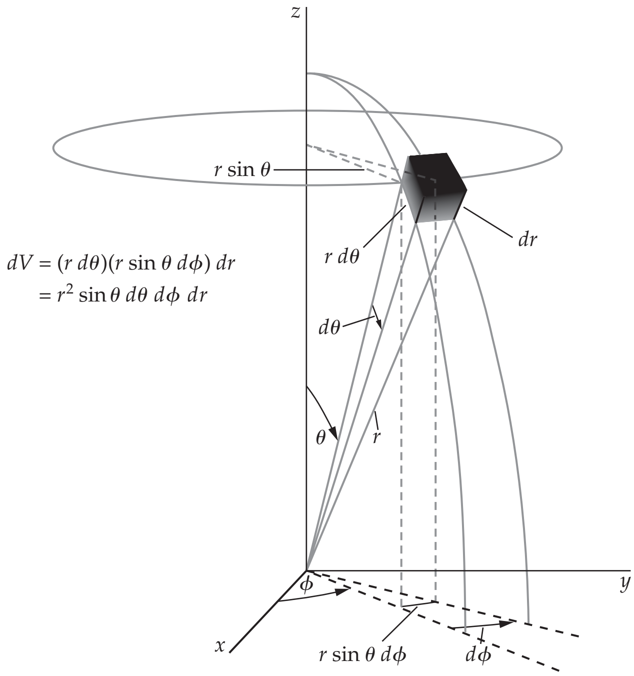

FIGURE 36-8 Volume element in spherical coordinates.

We integrate over all space by integrating over ϕ from $\phi = 0$ to $\phi = 2\pi$, over θ from $\theta = 0$ to $\theta = \pi$, and over r from $r = 0$ to $r = \infty$. The normalization condition is thus

$$\int |\psi|^2 \, dV = \int_0^\infty \left[\int_0^\pi \left(\int_0^{2\pi} |\psi|^2 r^2 \sin\theta \, d\phi \right) d\theta \right] dr$$

$$= \int_0^\infty \left[\int_0^\pi \left(\int_0^{2\pi} C_{100}^2 e^{-2Zr/a_0} r^2 \sin\theta \, d\phi \right) d\theta \right] dr = 1$$

Because there is no θ or ϕ dependence in ψ_{100}, the triple integral can be factored into the product of three integrals. This gives

$$\int |\psi|^2 \, dV = \left(\int_0^{2\pi} d\phi \right) \left(\int_0^\pi \sin\theta \, d\theta \right) \left(\int_0^\infty C_{100}^2 e^{-2Zr/a_0} r^2 \, dr \right)$$

$$= 2\pi \cdot 2 \cdot C_{100}^2 \left(\int_0^\infty e^{-2Zr/a_0} r^2 \, dr \right) = 1$$

The remaining integral is of the form $\int_0^\infty x^n e^{-ax} \, dx$, where n a positive integer and $a > 0$. Using successive integration-by-parts operations† yields the result

$$\int_0^\infty x^n e^{-ax} \, dx = \frac{n!}{a^{n+1}}$$

so

$$\int_0^\infty r^2 e^{-2Zr/a_0} \, dr = \frac{a_0^3}{4Z^3}$$

See **Math Tutorial** *for more information on* **Integrals**

* If spin, relativistic effects, the spin of the nucleus, and quantum electrodynamics are considered, the degeneracy is broken.

† This integral can also be looked up in a table of integrals.

Then

$$4\pi C_{100}^2\left(\frac{a_0^3}{4Z^3}\right) = 1$$

so

$$C_{100} = \frac{1}{\sqrt{\pi}}\left(\frac{Z}{a_0}\right)^{3/2} \qquad 36\text{-}31$$

The normalized ground-state wave function is thus

$$\psi_{100} = \frac{1}{\sqrt{\pi}}\left(\frac{Z}{a_0}\right)^{3/2} e^{-Zr/a_0} \qquad 36\text{-}32$$

The probability of finding the electron in a volume dV is $|\psi|^2\, dV$. The probability density $|\psi|^2$ is shown in Figure 36-9. Note that this probability density is spherically symmetric; that is, the probability density depends only on r, and is independent of θ or ϕ. The probability density is maximum at the origin.

We are more often interested in the probability of finding the electron at some radial distance r between r and $r + dr$. This radial probability $P(r)\, dr$ is the probability density $|\psi|^2$ multiplied by the volume of the spherical shell of thickness dr, which is $dV = 4\pi r^2\, dr$. The probability of finding the electron in the range from r to $r + dr$ is thus $P(r)\, dr = |\psi|^2\, 4\pi r^2\, dr$, and the **radial probability density** is

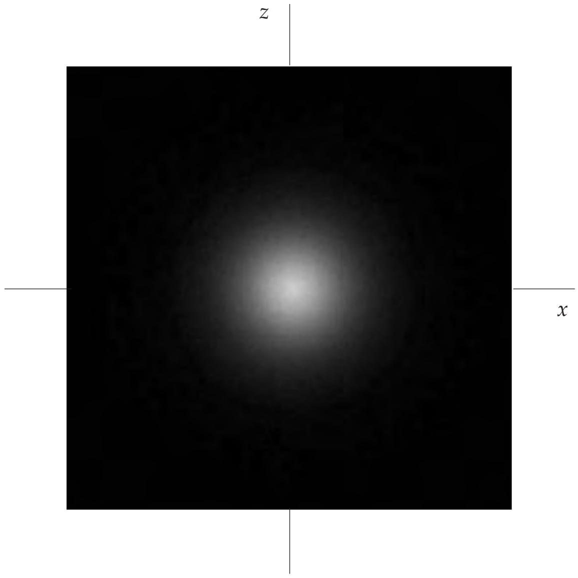

FIGURE 36-9 Computer-generated picture of the probability density $|\psi|^2$ for the ground state of hydrogen. The quantity $-e|\psi|^2$ can be thought of as the electron charge density in the atom. The density is spherically symmetric, is greatest at the origin, and decreases exponentially with r.

$$P(r) = 4\pi r^2|\psi|^2 \qquad 36\text{-}33$$

RADIAL PROBABILITY DENSITY

For the hydrogen atom in the ground state, the radial probability density is

$$P(r) = 4\pi r^2|\psi|^2 = 4\pi C_{100}^2 r^2 e^{-2Zr/a_0} = 4\left(\frac{Z}{a_0}\right)^3 r^2 e^{-2Zr/a_0} \qquad 36\text{-}34$$

Figure 36-10 shows the radial probability density $P(r)$ as a function of r. The maximum value of $P(r)$ occurs at $r = a_0/Z$, which for $Z = 1$ is the first Bohr radius. In contrast to the Bohr model, in which the electron stays in a well-defined orbit at $r = a_0$, we see that it is possible for the electron to be found at any distance from the nucleus. However, the most probable distance is a_0 (assuming $Z = 1$), and the chance of finding the electron at a much different distance is small. It is often useful to think of the electron in an atom as a charged cloud of charge density $\rho = -e|\psi|^2$, but we should remember that when it interacts with matter, an electron is always observed as a single charge.

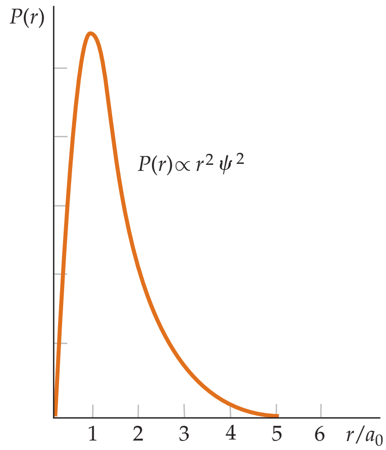

FIGURE 36-10 Radial probability density $P(r)$ versus r/a_0 for the ground state of the hydrogen atom. $P(r)$ is proportional to $r^2\psi^2$. The value of r for which $P(r)$ is maximum is the most probable distance $r = a_0$.

Example 36-4 Probability That the Electron Is in a Thin Spherical Shell

Consider a hydrogen atom that is in the ground state. Estimate the probability of finding the electron in a thin spherical shell of inner radius r and outer radius $r + \Delta r$, where $\Delta r = 0.06a_0$ at (*a*) $r = a_0$ and (*b*) $r = 2a_0$.

PICTURE Because Δr is so small compared to r, the variation in the radial probability density $P(r)$ in the shell can be neglected. The probability of finding the electron in some small range Δr is then $P(r)\, \Delta r$.

SOLVE

1. Substitute $Z = 1$ and $r = a_0$ into Equation 36-34:

$$P(r)\Delta r = \left[4\left(\frac{1}{a_0}\right)^3 r^2 e^{-2r/a_0}\right]\Delta r$$

$$P(a_0)(0.06a_0) = \left[4\left(\frac{1}{a_0}\right)^3 a_0^2 e^{-2}\right](0.06a_0) = \boxed{0.0325}$$

2. Substitute $Z = 1$ and $r = 2a_0$ into Equation 36-34:

$$P(r)\Delta r = \left[4\left(\frac{1}{a_0}\right)^3 r^2 e^{-2r/a_0}\right]\Delta r$$

$$P(2a_0)(0.06a_0) = \left[4\left(\frac{1}{a_0}\right)^3 4a_0^2 e^{-4}\right](0.06a_0) = \boxed{0.0176}$$

CHECK The probability of finding the electron between $r = a_0$ and $r = a_0 + 0.06a_0$ is larger than the probability of finding the particle between $r = 2a_0$ and $r = 2a_0 + 0.06a_0$, as expected.

TAKING IT FURTHER The volume of the spherical shell that has an inner radius $2a_0$ and outer radius $2a_0 + 0.06a_0$ is almost four times larger than the volume of the spherical shell that has an inner radius a_0 and outer radius $a_0 + 0.06a_0$. In spite of this there is approximately a 3 percent chance of finding the electron in this range at $r = a_0$, but at $r = 2a_0$ the chance is slightly less than 2 percent.

The first excited state In the first excited state of a hydrogen atom, n is equal to 2 and ℓ can equal either 0 or 1. For $\ell = 0$, $m_\ell = 0$, and we again have a spherically symmetric wave function, this time given by

$$\psi_{200} = C_{200}\left(2 - \frac{Zr}{a_0}\right)e^{-Zr/(2a_0)} \tag{36-35}$$

For $\ell = 1$, m_ℓ can be $+1$, 0, or -1. The corresponding wave functions are

$$\psi_{210} = C_{210}\frac{Zr}{a_0}e^{-Zr/(2a_0)}\cos\theta \tag{36-36}$$

$$\psi_{21\pm1} = C_{211}\frac{Zr}{a_0}e^{-Zr/(2a_0)}\sin\theta\, e^{\pm i\phi} \tag{36-37}$$

where C_{200}, C_{210}, and C_{211} are normalization constants. The probability densities are given by

$$\psi_{200}^2 = C_{200}^2\left(2 - \frac{Zr}{a_0}\right)^2 e^{-Zr/a_0} \tag{36-38}$$

$$\psi_{210}^2 = C_{210}^2\left(\frac{Zr}{a_0}\right)^2 e^{-Zr/a_0}\cos^2\theta \tag{36-39}$$

$$|\psi_{21\pm1}|^2 = C_{211}^2\left(\frac{Zr}{a_0}\right)^2 e^{-Zr/a_0}\sin^2\theta \tag{36-40}$$

The wave functions and probability densities for $\ell \neq 0$ are not spherically symmetric, but instead depend on the angle θ. The probability densities do not depend on ϕ. Figure 36-11 shows the probability density $|\psi|^2$ for $n = 2$, $\ell = 0$, and $m_\ell = 0$ (Figure 36-11*a*); for $n = 2$, $\ell = 1$, and $m_\ell = 0$ (Figure 36-11*b*); and for $n = 2$, $\ell = 1$, and $m_\ell = \pm1$ (Figure 36-11*c*). An important feature of these plots is that the electron cloud is spherically symmetric for $\ell = 0$ and is not spherically symmetric for $\ell \neq 0$. These angular distributions of the electron charge density depend only on the values of ℓ and m_ℓ and not on the radial part of the wave function. Similar charge distributions for the valence electrons of more complicated atoms play an important role in the chemistry of molecular bonding. (Electrons in the outermost shell are called **valence electrons.**)

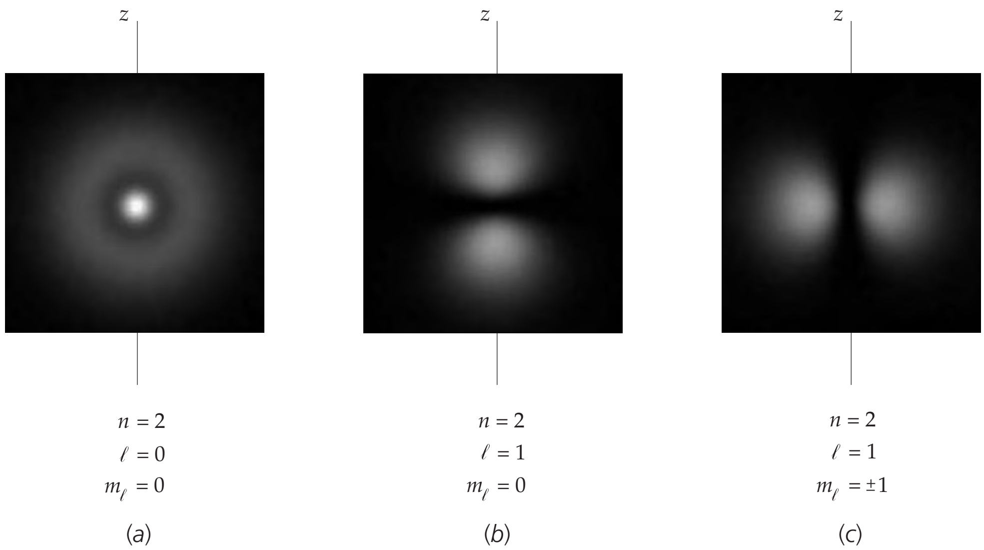

FIGURE 36-11 Computer-generated picture of the probability densities $|\psi|^2$ for the electron in the $n = 2$ states of hydrogen. All three images represent figures of revolution about the z axis. (*a*) For $\ell = 0$, $|\psi|^2$ is spherically symmetric. (*b*) For $\ell = 1$ and $m_\ell = 0$, $|\psi|^2$ is proportional to $\cos^2\theta$. (*c*) For $\ell = 1$ and $m_\ell = +1$ or -1, $|\psi|^2$ is proportional to $\sin^2\theta$.

Figure 36-12 shows the probability density for finding the electron at a distance r from the nucleus for $n = 2$, when $\ell = 1$ and when $\ell = 0$. We can see from the figure that this radial probability density depends on ℓ as well as on n.

For $n = 1$, we found that the most likely distance between the electron and the nucleus is a_0, which is the first Bohr radius, whereas for $n = 2$ and $\ell = 1$, the most probable distance between the electron and the nucleus is $4a_0$. These are the orbital radii for the first and second Bohr orbits (Equation 36-11). For $n = 3$ (and $\ell = 2$),* the most likely distance between the electron and nucleus is $9a_0$, which is the radius of the third Bohr orbit.

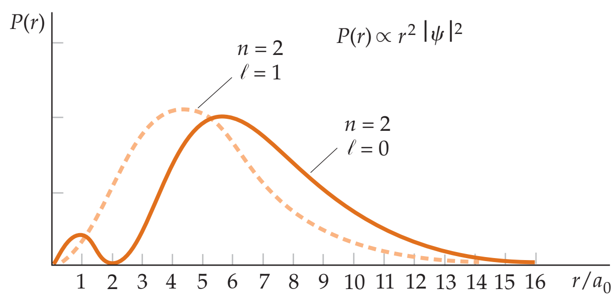

FIGURE 36-12 Radial probability density $P(r)$ versus r/a_0 for the $n = 2$ states of hydrogen. For $\ell = 1$, $P(r)$ is maximum at the Bohr value $r_2 = 2^2 a_0$. For $\ell = 0$, there is a maximum near this value and a much smaller maximum near the origin.

36-5 THE SPIN–ORBIT EFFECT AND FINE STRUCTURE

The orbital magnetic moment of an electron in an atom can be derived semiclassically, even though it is quantum mechanical in origin.† Consider a particle of mass m and charge q moving with speed v in a circle of radius r. The magnitude of the orbital angular momentum of the particle is $L = mvr$, and the magnitude of the magnetic moment is the product of the current and the area of the circle $\mu = IA = I\pi r^2$. If T is the time for the charge to complete one revolution, the current (charge passing a point per unit time) is q/T. Because the period T is the distance $2\pi r$ divided by the velocity v, the current is $I = q/T = qv/(2\pi r)$. The magnetic moment is then

$$\mu = IA = \frac{qv}{2\pi r}\pi r^2 = \frac{1}{2}qvr = \frac{q}{2m}L$$

where we have substituted L/m for vr. If the charge q is positive, the orbital angular momentum and orbital magnetic moment vectors are in the same direction. We can therefore write

$$\vec{\boldsymbol{\mu}} = \frac{q}{2m}\vec{\boldsymbol{L}} \qquad \text{36-41}$$

* The correspondence with the Bohr model is closest for the maximum value of ℓ, which is $n - 1$.

† This topic was first presented in Section 27-5.

Equation 36-41 is the general classical relation between magnetic moment and angular momentum. It also holds in the quantum theory of the atom for orbital angular momentum, but not for the intrinsic spin angular momentum of the electron. For electron spin, the magnetic moment is twice that predicted by Equation 36-41.* The extra factor of 2 is a result from quantum theory that has no analog in classical mechanics.

The quantum of angular momentum is $\hbar$, so we express the magnetic moment in terms of $\vec{L}/\hbar$:

$$\vec{\mu} = \frac{q\hbar}{2m}\frac{\vec{L}}{\hbar}$$

For an electron, $m = m_e$ and $q = -e$, so the magnetic moment of the electron due to its orbital motion is

$$\vec{\mu}_\ell = -\frac{e\hbar}{2m_e}\frac{\vec{L}}{\hbar} = -\mu_B\frac{\vec{L}}{\hbar}$$

where $\mu_B = e\hbar/(2m_e) = 5.79 \times 10^{-5}$ eV/T is the quantum unit of magnetic moment called a Bohr magneton. The magnetic moment of an electron due to its intrinsic spin angular momentum $\vec{S}$ is

$$\vec{\mu}_S = -2\frac{e\hbar}{2m_e}\frac{\vec{S}}{\hbar} = -2\mu_B\frac{\vec{S}}{\hbar}$$

In general, an electron in an atom has both orbital angular momentum characterized by the quantum number ℓ and spin angular momentum characterized by the quantum number s. Analogous classical systems that have two kinds of angular momentum are Earth, which is spinning about its axis of rotation in addition to revolving about the Sun, and a precessing gyroscope that has angular momentum of precession in addition to its spin. The total angular momentum $\vec{J}$ is the sum of the orbital angular momentum $\vec{L}$ and the spin angular momentum $\vec{S}$, where

$$\vec{J} = \vec{L} + \vec{S} \qquad \text{36-42}$$

Classically $\vec{J}$ is an important quantity because the resultant torque on a system equals the rate of change of the total angular momentum, and in the case of only central forces, the total angular momentum is conserved. For a classical system, the direction of the total angular momentum $\vec{J}$ is without restrictions and the magnitude of $\vec{J}$ can take on any value between $J_{max} = L + S$ and $J_{min} = |L - S|$. In quantum mechanics, however, the directions of both $\vec{L}$ and $\vec{S}$ are more restricted and the magnitudes L and S are both quantized. Furthermore, like $\vec{L}$ and $\vec{S}$, the direction of the total angular momentum $\vec{J}$ is restricted and the magnitude of $\vec{J}$ is quantized. For an electron that has an orbital angular momentum characterized by the quantum number ℓ and spin $s = \frac{1}{2}$, the total angular-momentum magnitude J is equal to $\sqrt{j(j+1)}\hbar$, where the quantum number j is given by

$$j = +\tfrac{1}{2} \qquad \text{if} \qquad \ell = 0$$

and either

$$j = \ell + \tfrac{1}{2} \quad \text{or} \quad j = \ell - \tfrac{1}{2} \qquad \text{if} \qquad \ell > 0 \qquad \text{36-43}$$

Figure 36-13 is a vector model illustrating the two possible combinations $j = \frac{3}{2}$ and $j = \frac{1}{2}$ for the case of $\ell = 1$. The lengths of the vectors are proportional to $\sqrt{\ell(\ell+1)}\hbar$, $\sqrt{s(s+1)}\hbar$, and $\sqrt{j(j+1)}\hbar$. The spin angular momentum and the orbital angular momentum are said to be *parallel* when $j = \ell + s$ and *antiparallel* when $j = \ell - s$.

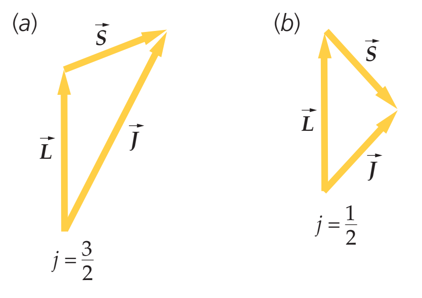

FIGURE 36-13 Vector diagrams illustrating the addition of orbital angular momentum and spin angular momentum for the case $\ell = 1$ and $s = \frac{1}{2}$. There are two possible values of the quantum number for the total angular momentum: $j = \ell + s = \frac{3}{2}$ and $j = \ell - s = \frac{1}{2}$.

* This result and the phenomenon of electron spin itself, was predicted in 1927 by Paul Dirac, who combined special relativity and quantum mechanics into a relativistic wave equation called the *Dirac equation*. Precise measurements indicate that the magnetic moment of the electron due to its spin is 2.00232 times that predicted by Equation 36-42. The fact that the intrinsic magnetic moment of the electron is approximately twice what we would expect makes it clear that the simple model of the electron as a spinning ball is not to be taken literally.

Atomic states that have the same n and ℓ values but with different j values have slightly different energies because of the interaction of the spin of the electron with its orbital motion. This effect is called the **spin–orbit effect.** The resulting splitting of spectral lines is called **fine-structure splitting.**

In the notation $n\ell_j$, the ground state of the hydrogen atom is written $1s_{1/2}$, where the 1 indicates that $n = 1$, the s indicates that $\ell = 0$, and the 1/2 indicates that $j = \frac{1}{2}$. The $n = 2$ states can have either $\ell = 0$ or $\ell = 1$, and the $\ell = 1$ state can have either $j = \frac{3}{2}$ or $j = \frac{1}{2}$. These states are thus denoted by $2s_{1/2}$, $2p_{3/2}$, and $2p_{1/2}$. Because of the spin–orbit effect, the $2p_{3/2}$ and $2p_{1/2}$ states have slightly different energies resulting in the fine-structure splitting of the transitions $2p_{3/2} \rightarrow 2p_{1/2}$ and $2p_{1/2} \rightarrow 2s_{1/2}$.

We can understand the spin–orbit effect qualitatively from a simple Bohr-model picture, as shown in Figure 36-14. In this figure, the electron moves in a circular orbit around a fixed proton. In Figure 36-14*a*, the orbital angular momentum $\vec{L}$ is up. In an inertial reference frame in which the electron is momentarily at rest (see Figure 36-14*b*), the proton is moving at right angles to the line connecting the proton and the electron. The moving proton produces a magnetic field $\vec{B}$ at the position of the electron. The direction of $\vec{B}$ is up, parallel to $\vec{L}$. The energy of the electron depends on its spin because of the magnetic moment $\vec{\mu}_s$ associated with the electron's spin. The energy is lowest when $\vec{\mu}_s$ is parallel to $\vec{B}$ and the energy is highest when it is antiparallel. This energy is given by (Equation 36-16)

$$U = -\vec{\mu}_s \cdot \vec{B} = -\mu_{s_z} B \approx -\mu_B B \qquad \text{36-44*}$$

Because $\vec{\mu}_s$ is directed opposite to its spin (because the electron has a negative charge), the energy is lowest when the spin $\vec{S}$ is antiparallel to $\vec{B}$ and thus to $\vec{L}$. The energy of the $2p_{1/2}$ state in hydrogen, in which $\vec{L}$ and $\vec{S}$ are antiparallel (Figure 36-15), is therefore slightly lower than that of the $2p_{3/2}$ state, in which $\vec{L}$ and $\vec{S}$ are parallel.

* Transferring the energy of the dipole to the frame of the proton gives a factor of 2, which is included in this result.

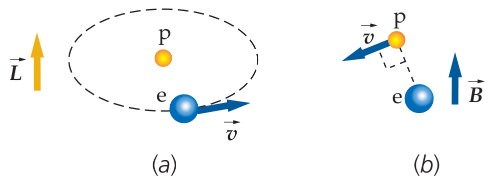

FIGURE 36-14 (*a*) An electron moving about a proton in a circular orbit in the horizontal plane with angular momentum $\vec{L}$ up. (*b*) In an inertial reference frame in which the electron is momentarily at rest there is, at the location of the electron, a magnetic field $\vec{B}$ due to the motion of the proton that is also directed up. When the electron spin $\vec{S}$ is parallel to $\vec{L}$, its magnetic moment $\vec{\mu}_s$ is antiparallel to $\vec{L}$ and $\vec{B}$, so the spin–orbit energy is at its greatest.

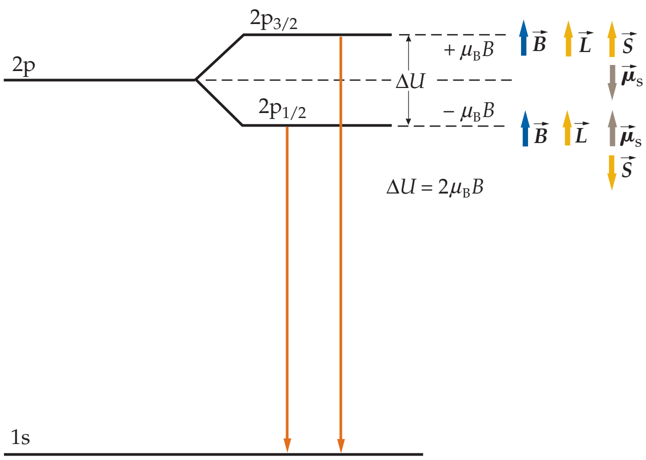

FIGURE 36-15 Fine-structure energy-level diagram. On the left, the levels in the absence of a magnetic field are shown. The effect of the field is shown on the right. Because of the spin-orbit interaction, the magnetic field splits the 2p level into two energy levels, with the $j = \frac{3}{2}$ level having slightly greater energy than the $j = \frac{1}{2}$ level. The spectral line due to the transition $2p \rightarrow 1s$ is therefore split into two lines of slightly different wavelengths.

Example 36-5 Determining *B* by Fine-Structure Splitting

As a consequence of fine-structure splitting, the energies of the $2p_{3/2}$ and $2p_{1/2}$ levels in hydrogen differ by 4.5×10^{-5} eV. If the 2p electron sees an internal magnetic field of magnitude B, the spin–orbit energy splitting will be of the order of $\Delta E = 2\mu_B B$, where μ_B is the Bohr magneton. From this, estimate the magnetic field that the 2p electron in hydrogen experiences.

PICTURE Use the equation $\Delta E = 2\mu_B B$ along with the given value of the energy difference and known value of μ_B.

SOLVE

1. Write the spin–orbit energy splitting in terms of the magnetic moment:

$$\Delta E = 2\mu_B B$$

where

$$\Delta E = 4.5 \times 10^{-5}\ \text{eV}$$

2. Solve for the magnetic field B:

$$B = \frac{\Delta E}{2\mu_B} = \frac{4.5 \times 10^{-5}\ \text{eV}}{2(5.79 \times 10^{-5}\ \text{eV/T})} = \boxed{0.389\ \text{T}}$$

36-6 THE PERIODIC TABLE

For atoms that have more than one electron, the Schrödinger equation cannot be solved exactly. However, powerful approximation methods allow us to calculate the energy levels of the atoms and wave functions of the electrons to a high degree of accuracy. As a first approximation, the Z electrons in an atom are assumed to be noninteracting. The Schrödinger equation can then be solved, and the resulting wave functions used to calculate the interaction of the electrons, which in turn can be used to better approximate the wave functions. Because the spin of an electron can have two possible components along an axis, there is an additional quantum number m_s, which can have the possible values $+\frac{1}{2}$ or $-\frac{1}{2}$. The state of each electron is thus described by the four quantum numbers n, ℓ, m_ℓ, and m_s, and such states are called **stationary states.** The energy of the electron is determined mainly by the principal quantum number n (which is related to the radial dependence of the wave function) and by the orbital angular-momentum quantum number ℓ. Generally, the lower the values of n, the lower the energy; and for a given value of n, the lower the value of ℓ, the lower the energy. The dependence of the energy on ℓ is due to the interaction of the electrons in the atom with each other. In hydrogen, of course, there is only one electron, and the energy is independent of ℓ. The specification of n, ℓ, m_ℓ, and m_s for each electron in an atom is called the **electron configuration.** Customarily, ℓ is specified according to the same code used to label the states of the hydrogen atom rather than by its numerical value. The code is

	s	p	d	f	g	h
ℓ value	0	1	2	3	4	5

The n values are sometimes referred to as shells, which are identified by another letter code: $n = 1$ denotes the K shell*; $n = 2$, the L shell; and so on.

The electron configuration of atoms is constrained by the Pauli exclusion principle—no two electrons in an atom can be in the same quantum state. That is, no two electrons can have the same set of values for the quantum numbers n, ℓ, m_ℓ, and m_s. Using the exclusion principle and the restrictions on the quantum numbers discussed in the previous sections (n is a positive integer, ℓ is an integer that ranges from 0 to $n - 1$, m_ℓ can have $2\ell + 1$ values from $-\ell$ to ℓ in integral steps, and m_s can be either $+\frac{1}{2}$ or $-\frac{1}{2}$), we can understand much of the structure of the periodic table.

We have already discussed the lightest element, hydrogen, which has just one electron. In the ground (lowest energy) state, the electron has $n = 1$ and $\ell = 0$, with $m_\ell = 0$ and $m_s = +\frac{1}{2}$ or $-\frac{1}{2}$. We call this a 1s electron. The 1 signifies that $n = 1$, and the s signifies that $\ell = 0$.

Electrons of atoms whose atomic numbers are greater than 1 will have states that will give the lowest total energy consistent with the Pauli exclusion principle.

CONCEPT CHECK 36-1

The following table lists candidates for the quantum numbers of an electron in an atom. Which of these candidates are not found in nature?

	n	ℓ	m_ℓ	m_s
(a)	2	2	−1	$+\frac{1}{2}$
(b)	3	2	−1	$+\frac{1}{2}$
(c)	2	−1	−1	$-\frac{1}{2}$
(d)	3	0	1	$+\frac{1}{2}$
(e)	3	1	1	$+\frac{1}{2}$

HELIUM ($Z = 2$)

The next element after hydrogen in the periodic table is helium ($Z = 2$); a helium atom has two electrons. In its ground state, both electrons are in the K shell, where $n = 1$, $\ell = 0$, and $m_\ell = 0$; one electron has $m_s = +\frac{1}{2}$ and the other has $m_s = -\frac{1}{2}$. This configuration is lower in energy than any other two-electron configuration. The resultant spin of the two electrons is zero. Because the orbital angular momentum is also zero, the total angular momentum is zero. The electron configuration for helium is written $1s^2$. The 1 signifies that $n = 1$, the s signifies that $\ell = 0$, and the superscript 2 signifies that there are two electrons in this state. Because ℓ

* The designation of the $n = 1$ shell as K is usually found when dealing with X-ray levels where the final shell in an inner electron transition is labeled as K, L, M, and so on.

can be only 0 for $n = 1$, these two electrons fill the K ($n = 1$) shell. The energy required to remove the most loosely bound electron from an atom in the ground state is called the **first ionization energy.** For a helium atom, the first ionization energy is 24.6 eV, which is relatively large. Helium is therefore basically inert.

Example 36-6 Electron Interaction Energy in Helium

(a) Use the measured first ionization energy to calculate the energy of interaction of the two electrons in the ground state of the helium atom. (b) Use your result to estimate the average separation of the two electrons.

PICTURE The energy of one electron in the ground state of helium is given by $E_n = -Z^2E_0/n^2$ (Equation 36-26), where $n = 1$ and $Z = 2$. If the electrons did not interact, the energy of the second electron would also be E_1, the same as that of the first electron. Thus, for an atom that has noninteracting electrons, the ionization energy of the first electron removed would be $|E_1|$ and the ground-state energy would be $E_{non} = 2E_1$. This is represented by the lowest level in Figure 36-16. Because of the interaction energy, the ground-state energy is greater than $2E_1$, which is represented by the higher level labeled E_g in the figure. The measured first ionization energy of helium is 24.6 eV. When we add $E_{ion} = 24.6$ eV to ionize He, we obtain ionized helium, written He^+, which has just one electron and therefore energy E_1.

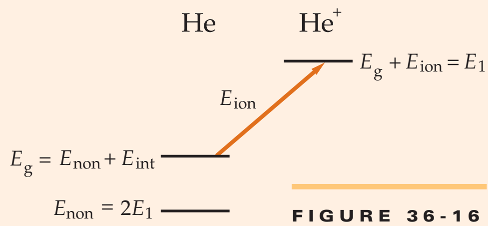

FIGURE 36-16

SOLVE

(a) 1. The sum of the energy of interaction E_{int} and the energy of two noninteracting electrons E_{non} equals the ground-state energy of helium:

$$E_{int} + E_{non} = E_g$$

2. Solve for E_{int} and substitute $E_{non} = 2E_1$:

$$E_{int} = E_g - E_{non} = E_g - 2E_1$$

3. Use Equation 36-26 to calculate the energy E_1 of one electron in the ground state:

$$E_n = -Z^2\frac{E_0}{n^2}$$

so

$$E_1 = -(2)^2\frac{13.6 \text{ eV}}{1^2} = -54.4 \text{ eV}$$

4. Substitute this value for E_1:

$$E_{int} = E_g - 2E_1 = E_g - 2(-54.4 \text{ eV})$$
$$= E_g + 108.8 \text{ eV}$$

5. The sum of the ground-state energy of He E_g and the ionization energy E_{ion} equals the ground-state energy of He^+, which is E_1:

$$E_g + E_{ion} = E_1 = -54.4 \text{ eV}$$

6. Substitute $E_{ion} = 24.6$ eV to calculate E_g:

$$E_g = E_1 - E_{ion} = -54.4 \text{ eV} - 24.6 \text{ eV}$$
$$= -79.0 \text{ eV}$$

7. Substitute this result for E_g to obtain E_{int}:

$$E_{int} = E_g + 108.8 \text{ eV} = -79.0 \text{ eV} + 108.8 \text{ eV}$$
$$= \boxed{29.8 \text{ eV}}$$

(b) 1. The energy of interaction of two electrons separated by distance r_s is the potential energy:

$$U = +\frac{ke^2}{r_s}$$

2. Set U equal to 29.8 eV, and solve for r. It is convenient to express r in terms of a_0, the radius of the first Bohr orbit in hydrogen, and to use $E_0 = ke^2/(2a_0) = 13.6$ eV (Equation 36-16):

$$r_s = \frac{ke^2}{U} = \frac{ke^2}{a_0}\frac{a_0}{U} = 2\frac{ke^2}{2a_0}\frac{a_0}{U} = 2\frac{E_0}{U}a_0$$
$$= 2\frac{13.6 \text{ eV}}{29.8 \text{ eV}}a_0 = \boxed{0.913a_0}$$

CHECK This separation is approximately the size of the diameter d_1 of the first Bohr orbit for an electron in helium, which is $d_1 = 2r_1 = 2a_0/Z = a_0$.

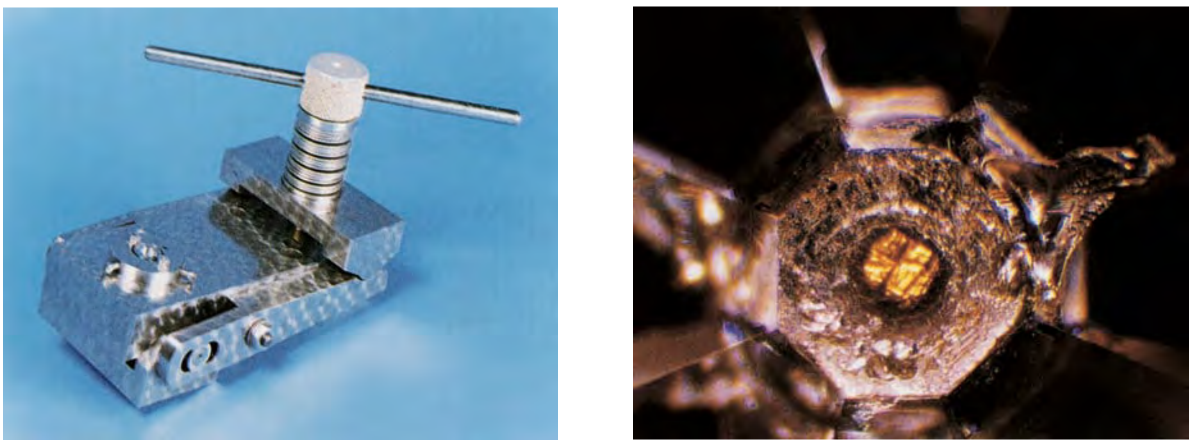
LITHIUM ($Z = 3$)

The next element, lithium, has an atom that has three electrons. Because the K shell ($n = 1$) of a ground-state lithium atom is completely filled with two electrons, the third electron occupies a higher energy shell. The next lowest energy shell after $n = 1$ is the $n = 2$ or L shell. This $n = 2$ electron has a greater probability of being much farther from the nucleus than the two $n = 1$ electrons. It is most likely to be found at a radius near that of the second Bohr orbit, which is four times the radius of the first Bohr orbit.

The nuclear charge is partially screened from the $n = 2$ electron by the two $n = 1$ electrons. Recall that the electric field outside a spherically symmetric charge density is the same as if all the charge were at the center of the sphere. If the $n = 2$ electron were completely outside the charge cloud of the two $n = 1$ electrons, the electric field the $n = 2$ electron would see would be that of a single charge $+e$ at the center due to the nuclear charge of $+3e$ and the charge $-2e$ of the two $n = 1$ electrons. However, the radial probability distribution (Equation 36-33) of the $n = 2$ electron overlaps with the radial probability distributions of the $n = 1$ electrons, so the $n = 2$ electron has a small but finite probability of being closer to the nucleus than one or both of the $n = 1$ electrons. Because of this, the effective nuclear charge $Z'e$ seen by the $n = 2$ electron is somewhat greater than $+1e$. Consequently, the energy of the $n = 2$ electron at a distance r from a point charge $+Z'e$ is given by Equation 36-6, where the nuclear charge $+Z$ replaced by $+Z'$.

$$E = -\frac{1}{2}\frac{kZ'e^2}{r} \qquad 36\text{-}45$$

The greater the overlap of the radial probability distributions of a higher energy electron with lower energy electrons, the greater is the effective nuclear charge $Z'e$ seen by the higher energy electron and the lower is the energy of the higher energy electron. Because the overlap is greater for ℓ values closer to zero (see Figure 36-12), the energy of the $n = 2$ electron in lithium is lower for the s state ($\ell = 0$) than for the p state ($\ell = 1$). The electron configuration of a lithium atom in the ground state is therefore $1s^22s$. The first ionization energy of a lithium atom is only 5.39 eV. Because its $n = 2$ electron is so loosely bound to the atom, lithium is very active chemically. It behaves like a one-electron atom, similar to hydrogen.



(*a*) (*b*)

(*a*) A diamond anvil cell, in which the facets of two diamonds (approximately 1 mm^2 each) are used to compress a sample substance, subjecting it to very high pressure. (*b*) Samarium monosulfide (SmS) is normally a black, dull-looking semiconductor. When it is subjected to pressure above 7000 atm, an electron from the 4f state moves into the 5d state. The resulting compound glitters like gold and behaves like a metal. *((a) and (b) A. Jayaraman/AT&T Bell Labs.)*

Example 36-7 Effective Nuclear Charge for an Electron of a Lithium Atom

Suppose the radial probability distribution of the $n = 2$ electron in the lithium atom in the ground state did not overlap the probability distribution of the two $n = 1$ electrons; the nuclear charge would be shielded by the two $n = 1$ electrons and the effective nuclear charge would be $Z'e$, where $Z' = 1$. Then the energy of the $n = 2$ electron would be $-(13.6\text{ eV})/2^2 = -3.4\text{ eV}$. However, the first ionization energy of lithium is 5.39 eV, not 3.4 eV. Use this fact to calculate the effective nuclear charge Z' seen by the $n = 2$ electron in lithium.

PICTURE Because the $n = 2$ electron is in the $n = 2$ shell, we will take $r = 4a_0$ for its average distance from the nucleus. We can then calculate Z' from Equation 36-45. Because r is given in terms of a_0, it will be convenient to use the fact that $E_0 = ke^2/(2a_0) = 13.6\text{ eV}$ (Equation 36-16).

SOLVE

1. Equation 36-45 relates the energy of the $n = 2$ electron to its average distance r from the nucleus and the effective nuclear charge Z':

$$E = -\frac{1}{2}\frac{kZ'e^2}{r}$$

2. Substitute the given values $r = 4a_0$ and $E = -5.39\text{ eV}$:

$$-5.39\text{ eV} = -\frac{1}{2}\frac{kZ'e^2}{4a_0}$$

3. Use $ke^2/(2a_0) = E_0 = 13.6\text{ eV}$ and solve for Z':

$$-5.39\text{ eV} = -\frac{Z'}{4}\frac{ke^2}{2a_0} = -\frac{Z'}{4}(13.6\text{ eV})$$

so

$$Z' = 4\frac{5.39\text{ eV}}{13.6\text{ eV}} = \boxed{1.59}$$

CHECK We expected Z' to be larger than one and certainly less than 3. Our step-3 result meets these expectations.

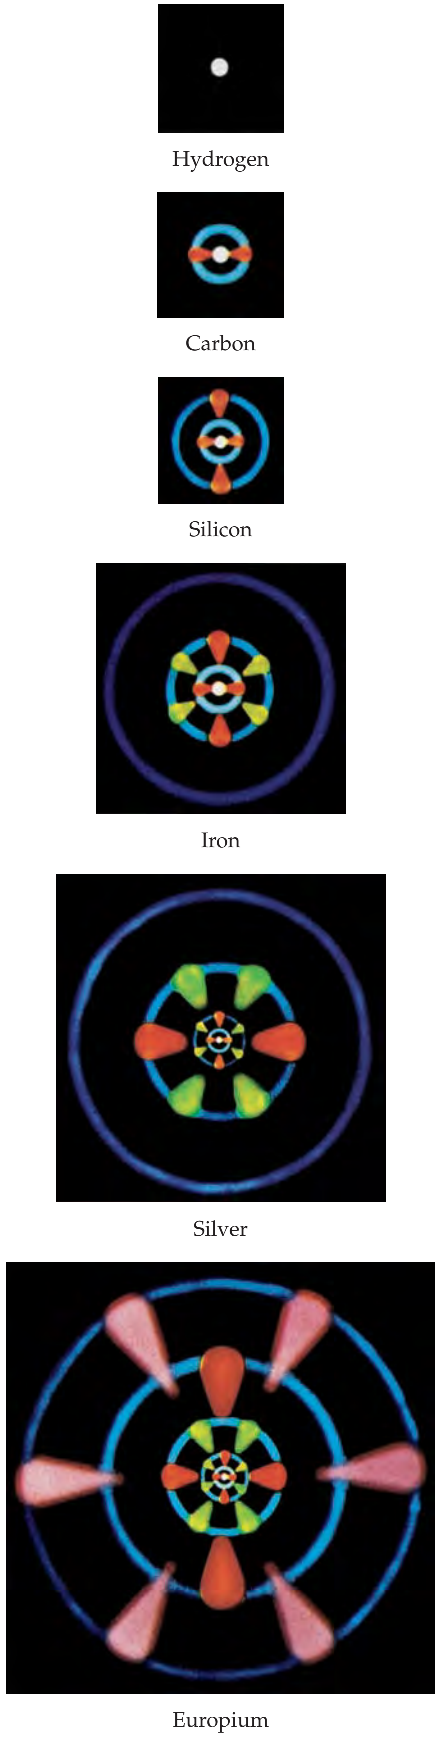
TAKING IT FURTHER This calculation is interesting but not very rigorous. We essentially used the radius ($r = 4a_0$) for the circular orbit from the semiclassical Bohr model and the measured first ionization energy to calculate the effective nuclear charge seen by the $n = 2$ electron. We know, of course, that this $n = 2$ electron does not move in a circular orbit of constant radius, but is better represented by a probability density $|\psi|^2$ that overlaps the probability distributions of the $n = 1$ electrons.

BERYLLIUM ($Z = 4$)

The energy of the beryllium atom is a minimum if both $n = 2$ electrons are in the 2s state. There can be two electrons that have $n = 2$, $\ell = 0$, and $m_\ell = 0$ because of the two possible values for the spin quantum number m_s. The configuration of a beryllium atom is thus $1s^22s^2$.

BORON TO NEON ($Z = 5$ TO $Z = 10$)

If the 2s subshell of a ground-state boron atom is filled, the fifth electron must be in the next available (lowest energy) subshell, which is the 2p subshell, where $n = 2$ and $\ell = 1$. Because there are three possible values of m_ℓ (+1, 0, and −1) and two values of m_s for each value of m_ℓ, there can be six electrons in this subshell.



A schematic depiction of the electron configurations in atoms. The spherically symmetric s states can have 2 electrons and are shown as white and blue. The dumbbell-shaped p states can have up to 6 electrons and are shown as orange. The d states can have up to 10 electrons and are shown as yellow-green. The f states can have up to 14 electrons and are shown as purple. *(David Parker/Photo Researchers.)*

The electron configuration for a boron atom is $1s^22s^22p$. The electron configurations for carbon atoms (Z = 6) to neon atoms (Z = 10) differ from that for boron atoms only in the number of electrons in the 2p subshell. The first ionization energy increases with Z for these elements, reaching the value of 21.6 eV for the last element in the group, neon. A neon atom has the maximum number of electrons allowed in the $n = 2$ shell and its electron configuration is $1s^22s^22p^6$. Because of its very large first ionization energy, neon, like helium, basically is chemically inert. The atom whose atomic number is one less than neon's atomic number is fluorine, which has an unoccupied electron state in the 2p subshell; that is, a fluorine atom can have one more electron in its 2p subshell. Fluorine readily combines with elements such as lithium that have one electron in its highest energy shell (that is, an electron in an unfilled highest energy shell of an atom in the ground state). Lithium, for example, will donate its single valence electron to the fluorine atom to make an F^- ion and a Li^+ ion. These ions then bond together to form lithium fluoride.

SODIUM TO ARGON ($Z = 11$ TO $Z = 18$)

The eleventh electron of a ground-state sodium atom must be the $n = 3$ shell. Because this electron is shielded from the nucleus by $n = 2$ and $n = 1$ electrons, it is weakly bound in the sodium (Z = 11) atom. The first ionization energy of sodium is only 5.14 eV. Sodium atoms therefore combine readily with atoms such as fluorine. With $n = 3$, the value of ℓ can be 0, 1, or 2. A 3s electron has a lower energy than a 3p or 3d electron because its probability density overlap with the probability densities of $n = 2$ and $n = 1$ electrons is greatest. This energy difference between subshells of the same n value becomes greater as the number of electrons increases. The electron configuration of a sodium atom is $1s^22s^22p^63s^1$. For elements whose atoms have larger values of Z, the 3s subshell and then the 3p subshell are occupied. These two subshells can accommodate 2 + 6 = 8 electrons. The configuration of an argon (Z = 18) atom is $1s^22s^22p^63s^23p^6$. One might expect the nineteenth electron of potassium would occupy the third subshell (the d subshell where $\ell = 2$), but the overlap effect is now so strong that the energy of the nineteenth electron is lower in the 4s subshell than in the 3d subshell. There is thus another large energy difference between the eighteenth and nineteenth electrons of a potassium atom, and so an argon atom, with its full 3p subshell, is basically stable and inert.

ELEMENTS WITH Z > 18

The nineteenth electron in a potassium (Z = 19) atom and the twentieth electron in a calcium (Z = 20) atom occupy the 4s subshell rather than the 3d subshell. The electron configurations of the atoms of the next ten elements, scandium (Z = 21) through zinc (Z = 30), differ only in the number of electrons in the 3d shell, except for a chromium (Z = 24) atom and a copper (Z = 29) atom, each of which has only one 4s electron. These ten elements are called **transition elements.**

Figure 36-17 shows a plot of the first ionization energies versus Z for Z = 1 to Z = 60. The peaks in first ionization energy at Z = 2, 10, 18, 36, and 54 mark a filled shell or subshell. Table 36-1 gives the ground-state electron configurations of atoms up to atomic number 111.

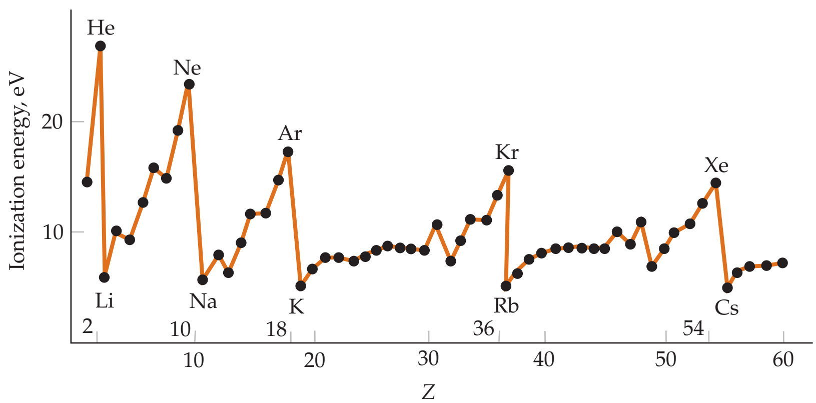


FIGURE 36-17 First ionization energies versus Z for Z = 1 to Z = 60. The first ionization energy increases with Z until a shell is filled at Z = 2, 10, 18, 36, and 54. An atom that has a filled shell and a single valence electron, such as sodium (Z = 11), has a very low ionization energy because the valence electron is shielded by the core electrons.

Table 36-1 **Electron Configurations of the Atoms in Their Ground States**
For some of the rare-earth elements and the heavy elements the configurations are not firmly established.

36-7 OPTICAL SPECTRA AND X-RAY SPECTRA

When an atom is in an excited state (when it is in an energy state above the ground state), it makes transitions to lower energy states, and in doing so emits electromagnetic radiation. The wavelength of the electromagnetic radiation emitted is related to the initial and final states by the Bohr formula (Equation 36-17), $\lambda = hc/(E_i - E_f)$, where E_i and E_f are the initial and final energies and h is Planck's constant. The atom can be excited to a higher energy state by bombarding the atom with a beam of electrons, as in a spectral tube that has a high voltage across it. Because the excited energy states of an atom form a discrete (rather than continuous) set, only certain wavelengths are emitted. These wavelengths of the emitted radiation constitute the emission spectrum of the atom.

OPTICAL SPECTRA

To understand atomic spectra we need to understand the excited states of the atom. The situation for an atom that has many electrons is, in general, much more complicated than that of a hydrogen atom that has just one electron. An excited state of the atom may involve a change in the state occupied by any one of the electrons, or even two or more electrons. Fortunately, in most cases, an excited state of an atom involves the excitation of just one of the electrons in the atom. The energies of excitation of the valence electrons of an atom are of the order of a few electron volts. Transitions involving these electrons result in photons in or near the visible or **optical spectrum.** (Recall that the energies of visible photons range from approximately 1.5 eV to 3 eV.) The excitation energies can often be calculated from a simple model in which the atom is pictured as a single electron plus a stable core consisting of the nucleus plus the other electrons. This model works particularly well for the alkali metals: Li, Na, K, Rb, and Cs. These elements are in the first column of the periodic table. The optical spectra of these elements are similar to the optical spectra of hydrogen.

Figure 36-18 shows an energy-level diagram for the optical transitions of a sodium atom, whose electrons form a neon core plus one electron. Because the total spin angular momentum of the core adds up to zero, the spin of each state of the sodium atom is $\frac{1}{2}$ (the spin of the valence electron). Because of the spin–orbit effect, the atomic states for which $J = L - \frac{1}{2}$ have a slightly different energy than those for which $J = L + \frac{1}{2}$ (except for states with $L = 0$). Each state (except for the $L = 0$ states) is therefore split into two states, called a doublet. The doublet splitting is very small and not evident on the energy scale of this diagram. The usual spectroscopic notation is that the states of these atoms are labeled with a superscript given by $2S + 1$, followed by a letter denoting the orbital angular momentum, followed by a subscript denoting the total angular momentum J. For states that have a total spin angular momentum $S = \frac{1}{2}$ the superscript is 2, indicating the state is a doublet. Thus, ${}^2\mathrm{P}_{3/2}$, read as "doublet P three halves," denotes a state in which $L = 1$ and $J = \frac{3}{2}$. (The $L = 0$, or S, states are customarily labeled as if they were doublets even though they are not.) For a sodium atom in the first excited state, the electron is excited from the 3s level to the 3p level, which is approximately 2.1 eV above the ground state. The energy difference between the $\mathrm{P}_{3/2}$ and $\mathrm{P}_{1/2}$ states due to the spin–orbit effect is about 0.002 eV. Transitions from these states to the ground state give the familiar sodium yellow doublet:

$$3\mathrm{p}({}^2\mathrm{P}_{1/2}) \rightarrow 3\mathrm{s}({}^2\mathrm{S}_{1/2}) \qquad \lambda = 589.6\ \mathrm{nm}$$
$$3\mathrm{p}({}^2\mathrm{P}_{3/2}) \rightarrow 3\mathrm{s}({}^2\mathrm{S}_{1/2}) \qquad \lambda = 589.0\ \mathrm{nm}$$

The energy levels and spectra of other alkali metal atoms are similar to those for sodium. The optical spectrum for atoms such as helium, beryllium, and magnesium that have two valence electrons is considerably more complex because of the interaction of the two electrons.

X-RAY SPECTRA

X rays are usually produced in the laboratory by bombarding a target element with a high-energy beam of electrons in an X-ray tube. The result (Figure 36-19) consists of a continuous spectrum that depends only on the energy of the bombarding electrons and a line spectrum that is characteristic of the target element. The characteristic spectrum results from excitation of the core electrons in the target element.

The energy needed to excite a core electron—for example, an electron in the $n = 1$ state (K shell)—is much greater than the energy required to excite a valence

A neon sign outside a Chinatown restaurant in Paris. Neon atoms in the tube are excited by an electron current passing through the tube. The excited neon atoms emit light in the visible range as they decay toward their ground states. The colors of neon signs result from the characteristic red-orange spectrum of neon plus the color of the glass tube itself. *(Robert Landau/Westlight.)*

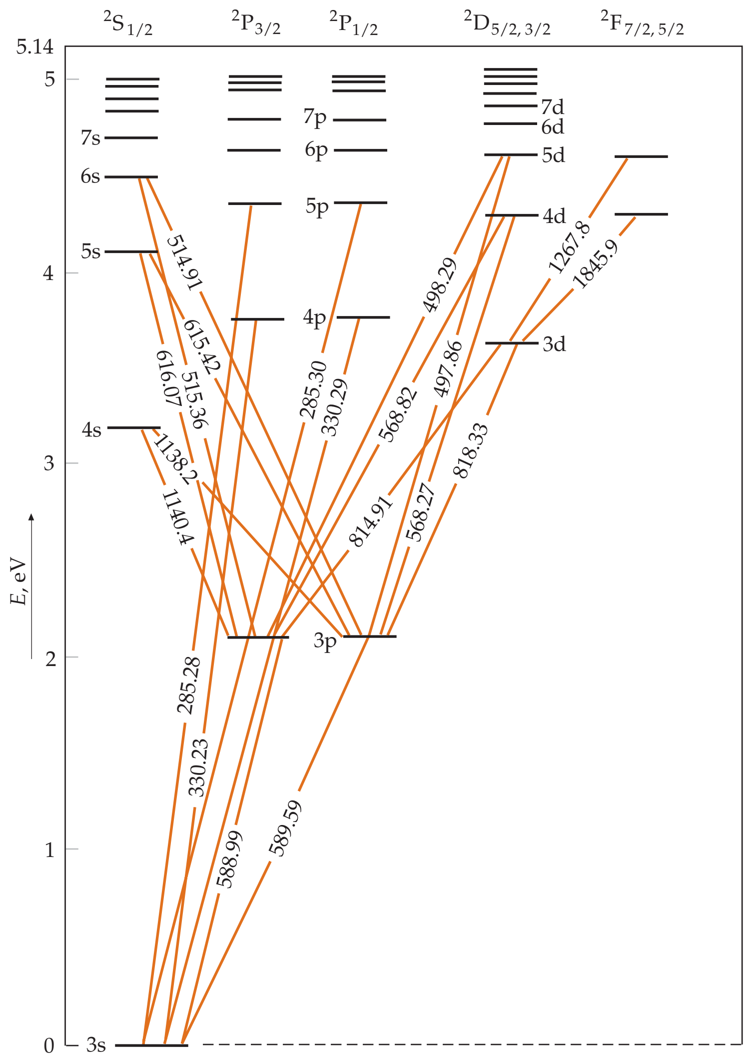

FIGURE 36-18 Energy-level diagram for sodium. The diagonal lines show observed optical transitions, where wavelengths are given in nanometers. The energy of the ground state has been chosen as the zero point for the scale on the left.

electron. A core electron cannot be excited to any of the filled states (for example, the $n = 2$ states in an atom with $Z \geq 10$) because of the exclusion principle. The energy required to excite a core electron to an unoccupied state is typically of the order of several thousand electron volts. If an electron is knocked out of the $n = 1$ shell (the K shell), there is a vacancy left in that shell. The vacancy can be filled if an electron in a higher energy shell makes a transition into the K shell. The photons emitted by electrons making such transitions also have energies of the order of several thousand electron volts and produce the sharp peaks in the X-ray spectrum, as shown in Figure 36-19. The K_α spectral line arises from transitions from the $n = 2$ shell (the L shell) to the $n = 1$ shell (the K shell). The K_β spectral line arises from transitions from the $n = 3$ shell to the $n = 1$ shell. These and other lines arising from transitions ending at the $n = 1$ shell make up the K series of the characteristic X-ray spectrum of the target element. Similarly, a second series, the L series, is produced by transitions from higher energy states to a vacated place in the $n = 2$ (L) shell. The letters K, L, M, and so on, designate the final shell of the electron making the transition and the series α, β, and so on, designates the number of shells above the final shell for the initial state of the electron.

In 1913, the English physicist Henry Moseley measured the wavelengths of the characteristic K_α X-ray spectra for approximately forty elements. Using this data, Moseley showed that a plot of $\lambda^{-1/2}$ versus the order in which the elements appeared in the periodic table resulted in a straight line (with a few gaps and a few outliers). From his data, Moseley was able to accurately determine the atomic

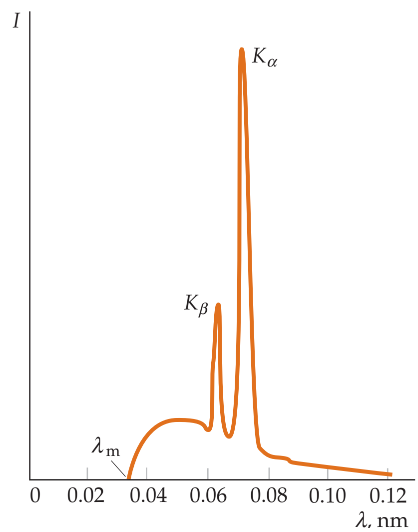

FIGURE 36-19 X-ray spectrum of molybdenum. The sharp peaks labeled K_α and K_β are characteristic of the element. The cutoff wavelength λ_m is independent of the target element and is related to the voltage V of the X-ray tube by $\lambda_m = hc/eV$.

number Z for each known element, and to predict the existence of some elements that were later discovered. The equation of the straight line of his plot is given by

$$\frac{1}{\sqrt{\lambda_{K_\alpha}}} = a(Z - 1)$$

The work of Bohr and Moseley can be combined to obtain an equation relating the wavelength of the emitted photon and the atomic number. According to the Bohr model of a single-electron atom (see Equation 36-13), the wavelength of the emitted photon when the electron makes the transition from $n = 2$ to $n = 1$ is given by

$$\frac{1}{\lambda} = Z^2 \frac{E_0}{hc}\left(1 - \frac{1}{2^2}\right)$$

where $E_0 = 13.6\text{ eV}$ is the binding energy of the ground-state hydrogen atom. Taking the square root of both sides gives

$$\frac{1}{\sqrt{\lambda_{K_\alpha}}} = \left[\frac{E_0}{hc}\left(1 - \frac{1}{2^2}\right)\right]^{1/2} Z$$

Moseley's equation and this equation are in agreement if $Z - 1$ is substituted for Z in Bohr's equation and if $a = 3E_0/(4hc)$. This result raises the question, why a factor of $Z - 1$ instead of a factor of Z? Part of the explanation is that the formula from the Bohr theory ignores the shielding of the nuclear charge. In a multielectron atom, electrons in the $n = 2$ states are electrically shielded from the nuclear charge by the two electrons in the $n = 1$ state, so the $n = 2$ state electrons are attracted by an effective nuclear charge of about $(Z - 2)e$. However, when there is only one electron in the K shell, the $n = 2$ electrons are attracted by an effective nuclear charge of about $(Z - 1)e$. When an electron from state n drops into the vacated state in the $n = 1$ shell, a photon of energy $E_n - E_1$ is emitted. For $n = 2$, the wavelength of this photon is

$$\lambda_{K_\alpha} = \frac{hc}{(Z - 1)^2 E_0\left(1 - \frac{1}{2^2}\right)} \qquad 36\text{-}46$$

which is obtained from the previous equation with $Z - 1$ substituted for Z.

Example 36-8 Identifying the Element from the K_α X-Ray Line

The wavelength of the K_α X-ray line for a certain element is $\lambda = 0.0721\text{ nm}$. What is the element?

PICTURE The K_α line corresponds to a transition from $n = 2$ to $n = 1$. The wavelength is related to the atomic number Z by Equation 36-46.

SOLVE

1. Solve Equation 36-46 for $(Z - 1)^2$:

$$\lambda_{K_\alpha} = \frac{hc}{(Z - 1)^2 E_0\left(1 - \frac{1}{2^2}\right)}$$

so

$$(Z - 1)^2 = \frac{4hc}{3\lambda_{K_\alpha} E_0}$$

2. Substitute the given data and solve for Z:

$$(Z - 1)^2 = \frac{4(1240\text{ eV}\cdot\text{nm})}{3(0.0721\text{ nm})(13.6\text{ eV})} = 1686$$

so

$$Z = 1 + \sqrt{1686} = 42.06$$

3. Because Z is an integer, we round to the nearest integer:

$$Z = 42$$

$\boxed{\text{The element is molybdenum.}}$

CHECK The naturally occurring atom that has the largest atomic number is uranium, which has an atomic number $Z = 92$. That our step-3 result is greater than 0 and less than 93 is as expected.

Summary

1. The Bohr model is important because it was the first model to succeed at explaining the discrete optical spectrum of atoms in terms of the quantization of energy. It has been superceded by the quantum-mechanical model.
2. The quantum theory of atoms results from the application of the Schrödinger equation to a bound system consisting of nucleus of charge $+Ze$ and Z electrons of charge $-e$.
3. For the hydrogen atom, an atom that consists of one proton and one electron, the time-independent Schrödinger equation can be solved exactly to obtain the wave functions ψ, which depend on the quantum numbers n, ℓ, m_ℓ, and m_s.
4. The electron configuration of atoms is governed by the Pauli exclusion principle—no two electrons in an atom can have the same set of values for the quantum numbers n, ℓ, m_ℓ, and m_s. Using the exclusion principle and the restrictions on the quantum numbers, we can understand much of the structure of the periodic table.

TOPIC	RELEVANT EQUATIONS AND REMARKS	
1. The Bohr Model of the Hydrogen Atom		
Postulates for the hydrogen atom		
Nonradiating orbits	The idea that an electron moves in a circular nonradiating orbit around the proton.	
Photon frequency from energy conservation	$f = \dfrac{E_i - E_f}{h}$	36-7
Quantized angular momentum	$L_n = mv_nr_n = n\hbar \qquad n = 1, 2, 3, \ldots$	36-9
First Bohr radius	$a_0 = \dfrac{\hbar^2}{mke^2} = 0.0529\text{ nm}$	36-12
Radii of the Bohr orbits	$r_n = n^2\dfrac{a_0}{Z}$	36-11
Energy levels in hydrogen-like atoms	$E_n = -Z^2\dfrac{E_0}{n^2}$	36-15
	where	
	$E_0 = -\dfrac{mk^2e^4}{2\hbar^2} = \dfrac{1}{2}\dfrac{ke^2}{a_0} = 13.6\text{ eV}$	36-16
Wavelengths emitted by the hydrogen atom	$\lambda = \dfrac{c}{f} = \dfrac{hc}{E_i - E_f} = \dfrac{1240\text{ eV}\cdot\text{nm}}{E_i - E_f}$	36-17, 36-18
2. Quantum Theory of Atoms	The electron is described by a wave function ψ that is a solution of the Schrödinger equation. Energy quantization arises from standing-wave conditions. ψ is described by the principal, orbital, and magnetic quantum numbers n, ℓ, and m_ℓ, and the spin quantum number $m_s = \pm\frac{1}{2}$.	
Time-independent Schrödinger equation	$-\dfrac{\hbar^2}{2m}\left(\dfrac{\partial^2\psi}{\partial x^2} + \dfrac{\partial^2\psi}{\partial y^2} + \dfrac{\partial^2\psi}{\partial z^2}\right) + U\psi = E\psi$	36-19
For an isolated atom, the solutions can be written as products of functions of r, θ, and ϕ separately	$\psi(r, \theta, \phi) = R(r)f(\theta)g(\phi)$	36-21
Quantum numbers in spherical coordinates		
Principal quantum number	$n = 1, 2, 3, \ldots$	
Orbital quantum number	$\ell = 0, 1, 2, 3, \ldots, n-1$	
Magnetic quantum number	$m_\ell = -\ell, (-\ell+1), \ldots, 0, \ldots, (\ell+1), \ell$	36-22
Orbital angular momentum	$L = \sqrt{\ell(\ell+1)}\hbar$	36-23

TOPIC	RELEVANT EQUATIONS AND REMARKS	
z component of orbital angular momentum	$L_z = m_\ell \hbar$	36-24
3. Quantum Theory of the Hydrogen Atom		
Energy levels for hydrogen-like atoms (same as for the Bohr model)	$E_n = -Z^2 \dfrac{E_0}{n^2} \qquad n = 1, 2, 3, \ldots$	36-26
	where $E_0 = -\dfrac{mk^2e^4}{2\hbar^2} = 13.6\text{ eV}$	36-27
Wavelengths emitted by the hydrogen atom (same as for Bohr model)	$\lambda = \dfrac{c}{f} = \dfrac{hc}{E_\mathrm{i} - E_\mathrm{f}} = \dfrac{1240\text{ eV}\cdot\text{nm}}{E_\mathrm{i} - E_\mathrm{f}}$	36-17, 36-18
Wave functions		
The ground state	$\psi_{100} = C_{100}e^{-Zr/a_0} = \dfrac{1}{\sqrt{\pi}}\left(\dfrac{Z}{a_0}\right)^{3/2} e^{-Zr/a_0}$	36-30, 36-32
The first excited state	$\psi_{200} = C_{200}\left(2 - \dfrac{Zr}{a_0}\right)e^{-Zr/2a_0}$	36-35
	$\psi_{210} = C_{210}\dfrac{Zr}{a_0}e^{-Zr/2a_0}\cos\theta$	36-36
	$\psi_{21\pm1} = C_{21\pm1}\dfrac{Zr}{a_0}e^{-Zr/2a_0}\sin\theta\, e^{\pm i\phi}$	36-37
Probability densities	For $\ell = 0$, $\lvert\psi\rvert^2$ is spherically symmetric. For $\ell > 0$, $\lvert\psi\rvert^2$ depends on the angle θ.	
Radial probability density	$P(r) = 4\pi r^2\lvert\psi\rvert^2$ The radial probability density is maximum at the distances corresponding roughly to the Bohr orbits.	36-33
4. The Spin–Orbit Effect and Fine Structure	The total angular momentum of an electron in an atom is a combination of the orbital angular momentum and spin angular momentum. It is characterized by the quantum number j, which can be either $\lvert\ell - \frac{1}{2}\rvert$ or $\ell + \frac{1}{2}$. Because of the interaction of the orbital and spin magnetic moments, the state $j = \lvert\ell - \frac{1}{2}\rvert$ has lower energy than the state $j = \ell + \frac{1}{2}$, for $\ell > 0$. This small splitting of the energy states gives rise to a small splitting of the spectral lines called fine structure.	
5. The Periodic Table	An atom of an element has Z electrons, where Z is the atomic number of the element. For an atom in the ground state, the electrons are in those states that will give the lowest energy consistent with the Pauli exclusion principle. The state of an atom is described by its electron configuration, which gives the values of n and ℓ for each electron. The ℓ values are specified by a code: s p d f g h ℓ value 0 1 2 3 4 5	
Pauli exclusion principle	No two electrons in an atom can have the same set of values for the quantum numbers n, ℓ, m_ℓ, and m_s.	
6. Atomic Spectra	Atomic spectra include optical spectra and X-ray spectra. Optical spectra result from transitions between energy levels of a single valence electron moving in the field of the nucleus and core electrons of the atom. Characteristic X-ray spectra result from the excitation of a core electron and the subsequent filling of the vacancy by other electrons in the atom.	
Selection rules	Transitions between energy states with the emission of a photon are governed by the following selection rules $\Delta m_\ell = 0 \quad \text{or} \quad \Delta m_\ell = \pm 1$ $\Delta\ell = \pm 1$	36-28

Answers to Concept Checks

36-1 (*a*), (*c*), and (*d*)

Answers to Practice Problems

36-1 91.2 nm

36-2 −4, −3, −2, −1, 0, 1, 2, 3, 4

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • For the hydrogen atom, as n increases, does the spacing of adjacent energy levels on an energy-level diagram increase or decrease? SSM

2 • The energy of the ground state of doubly ionized lithium ($Z = 3$) is _______, where $E_0 = 13.6$ eV. (*a*) $-9E_0$, (*b*) $-3E_0$, (*c*) $-E_0/3$, (*d*) $-E_0/9$

3 • Bohr's quantum condition on electron orbits requires (*a*) that the orbital angular momentum of the electron about the hydrogen nucleus equals $n\hbar$, where n is an integer, (*b*) that no more than one electron occupy a given state, (*c*) that the electrons spiral into the nucleus while radiating electromagnetic waves, (*d*) that the energies of an electron in a hydrogen atom be equal to nE_0, where E_0 is a constant and n is an integer, (*e*) none of the above.

4 • According to the Bohr model, if an electron moves to a larger orbit, does the electron's total energy increase or decrease? Does the electron's kinetic energy increase or decrease?

5 • According to the Bohr model, the kinetic energy of the electron in the ground state of hydrogen is E_0, where $E_0 = 13.6$ eV. The kinetic energy of the electron in the state $n = 2$ is (*a*) $4E_0$, (*b*) $2E_0$, (*c*) $E_0/2$, (*d*) $E_0/4$.

6 • According to the Bohr model, the radius of the $n = 1$ orbit in the hydrogen atom is $a_0 = 0.053$ nm. What is the radius of the $n = 5$ orbit? (*a*) $25a_0$, (*b*) $5a_0$, (*c*) a_0, (*d*) $a_0/5$, (*e*) $a_0/25$.

7 • For the principal quantum number $n = 4$, how many different values can the orbital quantum number ℓ have? (*a*) 4, (*b*) 3, (*c*) 7, (*d*) 16, (*e*) 25 SSM

8 • For the principal quantum number $n = 4$, how many different combinations of ℓ and m_ℓ can occur? (*a*) 4, (*b*) 3, (*c*) 7, (*d*) 16, (*e*) 25

9 •• Why is the energy of the 3s state considerably lower than the energy of the 3p state for sodium, whereas in hydrogen 3s and 3p states have essentially the same energy? SSM

10 • The d state of an electron configuration corresponds to (*a*) $n = 2$, (*b*) $\ell = 3$, (*c*) $\ell = 2$, (*d*) $n = 3$, (*e*) $\ell = 0$.

11 •• Why are three quantum numbers inadequate to describe the states of the electrons in atoms that have more than one electron?

12 •• Group the following six atoms—potassium, calcium, titanium, chromium, manganese, and copper—according to their ground-state electron configurations for the $n = 4$ shell.

13 • What element has the electron configuration (*a*) $1s^22s^22p^63s^23p^3$ and (*b*) $1s^22s^22p^63s^23p^63d^54s^1$?

14 • For the principal quantum number $n = 3$, what are the possible combinations of the quantum numbers ℓ and m_ℓ?

15 • An electron in the *L* shell means that the electron is represented by (*a*) $\ell = 0$, (*b*) $\ell = 1$, (*c*) $n = 1$, (*d*) $n = 2$, or (*e*) $m_\ell = 2$.

16 •• The Bohr model and the quantum-mechanical model of the hydrogen atom give the same results for the energy levels. Discuss the advantages and disadvantages of each model.

17 •• The Sommerfeld–Hosser displacement theorem states that the optical spectrum of any atom is very similar to the spectrum of the singly charged positive ion of the element immediately following it in the periodic table. Discuss why this theorem is accurate.

18 • Using the triplet of numbers (n, ℓ, m_ℓ) to represent an electron that has the principal quantum number n, orbital quantum number ℓ, and magnetic quantum number m_ℓ, which of the following transitions is allowed? (*a*) $(5, 2, 2) \rightarrow (3, 1, -2)$, (*b*) $(2, 1, 0) \rightarrow (3, 0, 0)$, (*c*) $(4, 3, -2) \rightarrow (3, 2, -1)$, (*d*) $(1, 0, 0) \rightarrow (2, 1, -1)$, (*e*) $(2, 1, 0) \rightarrow (3, 1, 0)$.

19 •• The Ritz combination principle states that for any atom, one can find different spectral lines λ_1, λ_2, λ_3, and λ_4, so that $1/\lambda_1 + 1/\lambda_2 = 1/\lambda_3 + 1/\lambda_4$. Show why this is true using an energy-level diagram. SSM

ESTIMATION AND APPROXIMATION

20 •• (*a*) We can define a thermal de Broglie wavelength λ_T for an atom in a gas at temperature T as being the de Broglie wavelength for an atom moving at the rms speed appropriate to that temperature. (The average kinetic energy of an atom is equal to $\frac{3}{2}kT$, where k is the Boltzmann constant. Use this value to calculate the rms speed of the atoms.) Show that $\lambda_T = h/\sqrt{3mkT}$ where m is the mass of the atom. (*b*) Cooled atoms can form a Bose *condensate* (a new state of matter) when their thermal de Broglie wavelength becomes larger than the average interatomic spacing. From this criterion, estimate the temperature needed to create a Bose condensate in a gas of ^{85}Rb atoms whose number density is 10^{12} atoms/cm^3.

21 •• In laser cooling and trapping, a beam of atoms traveling in one direction is slowed by interaction with an intense laser beam in the opposite direction. The photons scatter off the atoms by resonance absorption, a process by which the incident photon is

absorbed by the atom, and a short time later a photon of equal energy is emitted in a random direction. The net result of a single such scattering event is a transfer of momentum to the atom in a direction opposite to the motion of the atom, followed by a second transfer of momentum to the atom in a random direction. Thus, during photon absorption the atom loses speed, but during photon emission the change in speed of the atom is, on average, zero (because the directions of the emitted photons are random). An analogy often made to this process is that of slowing down a bowling ball by bouncing ping-pong balls off of it. (*a*) Given that the typical photon energy used in these experiments is about 1 eV, and that the typical kinetic energy of an atom in the beam is the typical kinetic energy of the atoms in a gas that has a temperature of about 500 K (a typical temperature for an oven that produces an atomic beam), estimate the number of photon–atom collisions that are required to bring an atom to rest. (The average kinetic energy of an atom is equal to $\frac{3}{2}kT$, where k is the Boltzmann constant and T is the temperature. Use this to estimate the speed of the atoms.) (*b*) Compare the Part (*a*) result with the number of ping-pong ball–bowling ball collisions that are required to bring the bowling ball to rest. (Assume the typical speed of the incident ping-pong balls are all equal to the initial speed of the bowling ball.) (*c*) ^{85}Rb is a type of atom often used during cooling experiments. The wavelength of the light resonant with the cooling transition of the atoms is $\lambda = 780.24$ nm. Estimate the number of photons needed to slow down an ^{85}Rb atom from a typical thermal velocity of 300 m/s to a stop. SSM

THE BOHR MODEL OF THE HYDROGEN ATOM

22 • The first Bohr radius is given by $a_0 = \hbar^2/(mke^2) = 0.0529$ nm (Equation 36-12). Use the known values of the constants in the equation to show that a_0 is equal to 0.0529 nm.

23 • The longest wavelength in the Lyman series for the hydrogen atom was calculated in Example 36-2. Find the wavelengths for the transitions (*a*) $n_i = 3$ to $n_f = 1$ and (*b*) $n_i = 4$ to $n_f = 1$.

24 • Find the photon energies for the three longest wavelengths in the Balmer series for the hydrogen atom, and calculate the three wavelengths.

25 •• Find the photon energy and wavelength for the series limit (shortest wavelength) in the Paschen series ($n_f = 3$) for the hydrogen atom. (*b*) Calculate the wavelength for the three longest wavelengths in Paschen series.

26 •• (*a*) Find the photon energy and wavelength for the series limit (shortest wavelength) in the Brackett series ($n_f = 4$) for the hydrogen atom. (*b*) Calculate the wavelength for the three longest wavelengths in Brackett series.

27 ••• In the center-of-mass reference frame of a hydrogen atom, the electron and nucleus have momenta that have equal magnitudes p and opposite directions. (*a*) Using the Bohr model, show that the total kinetic energy of the electron and nucleus can be written $K = p^2/(2\mu)$ where $\mu = m_e M/(M + m_e)$ is called the reduced mass, m_e is the mass of the electron, and M is the mass of the nucleus. (*b*) For the equations for the Bohr model of the atom, the motion of the nucleus can be taken into account by replacing the mass of the electron with the reduced mass. Use Equation 36-14 to calculate the Rydberg constant for a hydrogen atom that has a nucleus of mass $M = m_p$. Find the approximate value of the Rydberg constant by letting M go to infinity in the reduced mass formula. To how many figures does this approximate value agree with the actual value? (*c*) Find the percentage correction for the ground-state energy of the hydrogen atom by using the reduced mass in Equation 36-16. *Note:* In general, the reduced mass for a two-body problem with masses m_1 and m_2 is given by

$$\mu = \frac{m_1 m_2}{m_1 + m_2}$$ SSM

28 •• The Pickering series of the spectrum of He$^+$ (singly ionized helium) consists of spectral lines due to transitions to the $n = 4$ state of He$^+$. Every other line of the Pickering series is very close to a spectral line in the Balmer series for hydrogen transitions to $n = 2$. (*a*) Show that this statement is accurate. (*b*) Calculate the wavelength of the photon during a transition from the $n = 6$ level to the $n = 4$ level of He$^+$, and show that it corresponds to one of the Balmer series lines.

QUANTUM NUMBERS IN SPHERICAL COORDINATES

29 • For an electron in an atom that has an orbital quantum number $\ell = 1$, find (*a*) the magnitude of the angular momentum L and (*b*) the possible values of the magnetic quantum number m_ℓ. (*c*) Draw a vector diagram to scale showing the possible orientations of $\vec{L}$ relative to the $+z$ direction.

30 • For an electron in an atom that has an orbital quantum number $\ell = 3$, find (*a*) the magnitude of the angular momentum L and (*b*) the possible values of m_ℓ. (*c*) Draw a vector diagram to scale showing the possible orientations of $\vec{L}$ relative to the $+z$ direction.

31 • An electron in an atom has principal quantum number $n = 3$. (*a*) What are the possible values of ℓ? (*b*) What are the possible combinations of ℓ and m_ℓ? (*c*) Using the fact that there are two quantum states for each combination of ℓ and m_ℓ because of electron spin, find the total number of electron states for $n = 3$.

32 • In an atom, find the total number of electron states that have (*a*) $n = 4$ and (*b*) $n = 2$. (See Problem 31.)

33 •• Find the minimum value of the angle θ between $\vec{L}$ and the $+z$ direction for an electron in an atom that has (*a*) $\ell = 1$, (*b*) $\ell = 4$, and (*c*) $\ell = 50$. SSM

34 •• What are the possible values of n and m_ℓ for an electron in an atom that has (*a*) $\ell = 3$, (*b*) $\ell = 4$, and (*c*) $\ell = 0$?

35 •• For an electron in an atom that is in an $\ell = 2$ state, find (*a*) the magnitude of the angular momentum squared L^2, (*b*) the maximum value of L_z^2, and (*c*) the smallest value of $L_x^2 + L_y^2$.

QUANTUM THEORY OF THE HYDROGEN ATOM

36 • For the ground state of the hydrogen atom, find the values of (*a*) $\psi(r)$ at $r = a_0$, (*b*) $\psi^2(r)$ at $r = a_0$, and (*c*) the radial probability density $P(r)$ at $r = a_0$. Give your answers in terms of a_0.

37 • (*a*) If electron spin is not included, how many different wave functions are there corresponding to the first excited energy level $n = 2$ for a hydrogen atom? (*b*) Specify the quantum numbers for each of these wave functions. SSM

38 •• For the ground state of the hydrogen atom, calculate the probability of finding the electron in the region between r and $r + \Delta r$, where $\Delta r = 0.03a_0$ and (*a*) $r = a_0$ and (*b*) $r = 2a_0$.

39 •• The value of the constant C_{200} in the equation

$$\psi_{200} = C_{200}\left(2 - \frac{Zr}{a_0}\right)e^{-Zr/(2a_0)}$$

(Equation 36-35) is given by

$$C_{200} = \frac{1}{4\sqrt{2\pi}}\left(\frac{Z}{a_0}\right)^{3/2}$$

Find the values of (*a*) $\psi(r)$ at $r = a_0$, (*b*) $\psi^2(r)$ at $r = a_0$, and (*c*) the radial probability density $P(r)$ at $r = a_0$ for the state $n = 2$, $\ell = 0$, and $m_\ell = 0$ of a hydrogen atom. Give your answers in terms of a_0.

40 ••• Show that the radial probability density for the $n = 2$, $\ell = 1$, and $m_\ell = 0$ state of a one-electron atom can be written as $P(r) = A\cos^2\theta\, r^4 e^{-Zr/a_0}$, where A is a constant.

41 ••• Calculate the probability of finding the electron in the region between r and $r + \Delta r$, where $\Delta r = 0.02a_0$ and (*a*) $r = a_0$ and (*b*) $r = 2a_0$ for the state $n = 2$, $\ell = 0$, and $m_\ell = 0$ in hydrogen. (See Problem 39 for the value of C_{200}.)

42 •• Show that the ground-state hydrogen atom wave function $\psi_{100} = \pi^{-1/2}(Z/a_0)^{3/2}e^{-Zr/a_0}$ (Equation 36-32) is a solution to Schrödinger's equation in spherical coordinates:

$$\frac{-\hbar}{2mr^2}\left\{\frac{\partial}{\partial r}\left(r^2\frac{\partial\psi}{\partial r}\right) + \left[\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial\psi}{\partial\theta}\right) + \frac{1}{\sin^2\theta}\frac{\partial^2\psi}{\partial\phi^2}\right]\right\} + U(r)\psi = E\psi$$

where $U(r) = kZe^2/r$ (Equation 36-25).

43 •• Show by dimensional analysis that the expression for the hydrogen atom ground-state energy given by $E_0 = \frac{1}{2}mk^2e^4/\hbar^2$ (Equation 36-27) has the dimensions of energy.

44 •• By dimensional analysis, show that the expression for the first Bohr radius given by $a_0 = \hbar^2/(mke^2)$ (Equation 36-12) has the dimensions of length.

45 •• The radial probability distribution function for a one-electron atom in its ground state can be written $P(r) = Cr^2e^{-2Zr/a_0}$, where C is a constant. Show that $P(r)$ has its maximum value at $r = a_0/Z$.

46 ••• Show that the number of states in the hydrogen atom for a given n is $2n^2$.

47 ••• Calculate the probability that the electron in the ground state of a hydrogen atom is in the region $0 < r < a_0$.

THE SPIN–ORBIT EFFECT AND FINE STRUCTURE

48 • The potential energy of a magnetic moment in an external magnetic field is given by $U = -\vec{\mu}\cdot\vec{B}$. (*a*) Calculate the difference in energy between the two possible orientations of an electron in a magnetic field $\vec{B} = 1.50\text{ T}\hat{k}$. (*b*) If the electrons are bombarded with photons of energy equal to that energy difference, "spin flip" transitions can be induced. Find the wavelength of the photons needed for such transitions. This phenomenon is called *electron spin resonance*.

49 • The total angular momentum of a hydrogen atom in a certain excited state has the quantum number $j = \frac{1}{2}$. What can you say about the value of the orbital angular-momentum quantum number ℓ?

50 • A hydrogen atom is in the state $n = 3$, $\ell = 2$. What are the possible values of j?

51 • Using a scaled vector diagram, show how the orbital angular momentum $\vec{L}$ combines with the spin angular momentum $\vec{S}$ to produce the two possible values of total angular momentum $\vec{J}$ for the $\ell = 3$ state of the hydrogen atom.

THE PERIODIC TABLE

52 • The total number of states of a hydrogen atom that has principal quantum number $n = 4$ is (*a*) 4, (*b*) 16, (*c*) 32, (*d*) 36, (*e*) 48

53 • How many of the eight electrons in an oxygen atom in the ground state are in a p state? (*a*) 0, (*b*) 2, (*c*) 4, (*d*) 6, (*e*) 8

54 • Write the ground-state electron configuration of (*a*) an atom of carbon and (*b*) an atom of oxygen.

55 • Give the possible values of the z component of the orbital angular momentum of (*a*) a d electron and (*b*) an f electron.

OPTICAL SPECTRA AND X-RAY SPECTRA

56 • The optical spectra of atoms that have two electrons in the same highest energy shell are similar, but they are quite different from the spectra of atoms that have just one electron in the highest energy shell because of the interaction of the two electrons. Group the elements according to similar spectra: lithium, beryllium, sodium, magnesium, potassium, calcium, chromium, nickel, cesium, and barium.

57 • Write down the possible electron configurations for the first excited state of (*a*) a hydrogen atom, (*b*) a sodium atom, and (*c*) a helium atom.

58 • Indicate which of the following atoms should have optical spectra similar to a hydrogen atom and which of the following atoms should have optical spectra similar to a helium atom: Li, Ca, Ti, Rb, Hg, Ag, Cd, Ba, Fr, and Ra.

59 • (*a*) Calculate the next two longest wavelengths in the K series (after the K_α line) of molybdenum. (*b*) What is the wavelength of the shortest wavelength in this series?

60 • The wavelength of the K_α line for a certain element is 0.3368 nm. What is the element?

61 • Calculate the wavelength of the K_α line in (*a*) a magnesium ($Z = 12$) atom and (*b*) a copper ($Z = 29$) atom.

GENERAL PROBLEMS

62 • What is the energy of the shortest wavelength photon emitted by the hydrogen atom?

63 • The wavelength of a spectral line of hydrogen is 97.254 nm. Identify the transition that results in this line, assuming that the transition is to the ground state.

64 •• The wavelength of a spectral line of hydrogen is 1093.8 nm. Identify the transition that results in this line.

65 •• Spectral lines of the following wavelengths are emitted by a singly ionized helium atom: 164 nm, 230.6 nm, and 541 nm. Identify the transitions that result in those spectral lines.

66 •• The combination of physical constants $\alpha = e^2k/\hbar c$, where k is the Coulomb constant, is known as the *fine-structure constant*. It appears in numerous relations in atomic physics. (*a*) Show that α is dimensionless. (*b*) Show that in the Bohr model of the hydrogen atom $v_n = c\alpha/n$, where v_n is the speed of the electron in the state of quantum number n.

67 •• The wavelengths of the photons emitted by a potassium atom corresponding to transitions from the $4P_{3/2}$ and $4P_{1/2}$ states to the ground state are 766.41 nm and 769.90 nm. (*a*) Calculate the energies of the photons in electron volts. (*b*) The difference in the energies of the photons equals the difference in energy ΔE between the $4P_{3/2}$ and $4P_{1/2}$ states in potassium. Calculate ΔE. (*c*) Estimate the magnetic field that the 4p electron in potassium experiences.

68 •• To observe the characteristic K lines of the X-ray spectrum, one of the $n = 1$ electrons must be ejected from the atom. This is generally accomplished by bombarding the target material with electrons of sufficient energy to eject this tightly bound electron. What is the minimum energy required to observe the K lines of (*a*) a tungsten atom, (*b*) a molybdenum atom, and (*c*) a copper atom?

69 •• We are often interested in finding the quantity ke^2/r in electron volts when r is given in nanometers. Show that $ke^2 = 1.44\ \text{eV} \cdot \text{nm}$. SSM

70 •• The *positron* is a particle that has the same mass as the electron and carries a charge equal to $+e$. *Positronium* is a bound state of an electron–positron combination. (*a*) Calculate the energies of the five lowest energy states of positronium using the reduced mass, as given in Problem 27. (*b*) Do transitions between any of the levels found in Part (*a*) fall in the visible range of wavelengths? If so, which transitions are they?

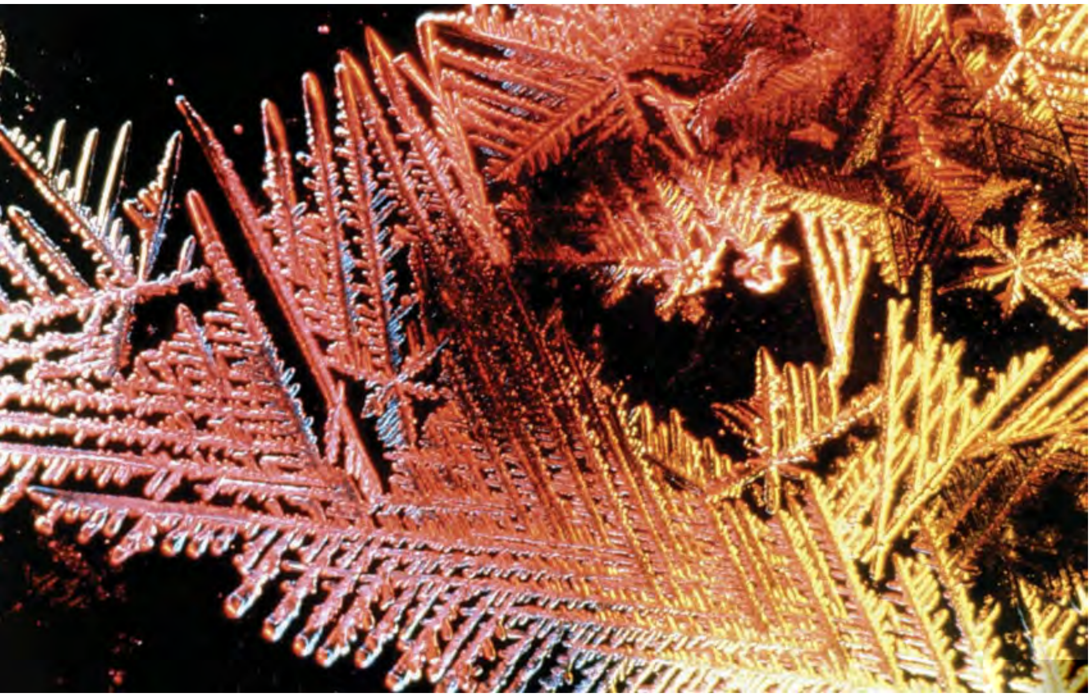
71 • In 1947, Lamb and Retherford showed that there is a very small energy difference between the $2S_{1/2}$ and the $2P_{1/2}$ states of the hydrogen atom. They measured this difference essentially by causing transitions between the two states using very long wavelength electromagnetic radiation. The energy difference (the Lamb shift) is 4.372×10^{-6} eV and is explained by quantum electrodynamics as being due to fluctuations in the energy level of the vacuum. (*a*) What is the frequency of a photon whose energy is equal to the Lamb shift energy? (*b*) What is the wavelength of that photon? In what spectral region does it belong?

72 • A Rydberg atom is one in which an electron is in a *very* high excited state ($n \approx 40$ or higher). Such atoms are useful for experiments that probe the transition from quantum-mechanical behavior to classical. Furthermore, these excited states have extremely long lifetimes (i.e., the electron will stay in this high excited state for a very long time). A hydrogen atom is in the $n = 45$ state. (*a*) What is the ionization energy of the atom when it is in that state? (*b*) What is the energy level separation (in electron volts) between that state and the $n = 44$ state? (*c*) What is the wavelength of a photon resonant with the transition between these two states? (*d*) What is the radius of the atom when it is in the $n = 45$ state?

73 •• The deuteron, the nucleus of deuterium (heavy hydrogen), was first recognized from the spectrum of hydrogen. The deuteron has a mass that is approximately twice the mass of the proton. (*a*) Calculate the Rydberg constant for hydrogen and for deuterium using the reduced mass as given in Problem 27. (*b*) Using the result obtained in Part (*a*), determine the difference between the longest wavelength Balmer line of hydrogen (protium) and the longest wavelength Balmer line of deuterium.

74 •• The muonium atom is a hydrogen atom that has the electron replaced by a μ^- particle. The μ^- has a mass 207 times as great as the electron. (*a*) Calculate the energies of the five lowest energy levels of muonium using the reduced mass as given in Problem 27. (*b*) Do transitions between any of the levels found in Part (*a*) fall in the visible range of wavelengths (for example, between $\lambda = 700$ nm and $\lambda = 400$ nm)? If so, which transitions are they?

75 •• The triton, a nucleus consisting of a proton and two neutrons, is unstable and has a half-life of approximately 12 years. Tritium is an atom consisting of an electron and a triton. (*a*) Calculate the Rydberg constant of tritium using the reduced mass as given in Problem 27. (*b*) Determine the difference between the longest wavelength of the Balmer lines of tritium and the longest wavelength of the Balmer lines of deuterium (see Problem 73). In addition, (*c*) determine the difference between the longest wavelength of the Balmer lines of tritium and the longest wavelength of the Balmer lines of hydrogen (protium).



CHAPTER 37

A MICROGRAPH OF SODIUM FLUORIDE CRYSTALS. SODIUM FLUORIDE IS OFTEN ADDED TO PUBLIC WATER SUPPLIES AS A TOOTH-DECAY PREVENTATIVE. *(National Institutes of Health/Photo Researchers.)*

Molecules

? How much energy is needed to form sodium fluoride? (See Example 37-1).

Most atoms bond together to form molecules or solids. Molecules may exist as separate entities, as in gaseous O_2 or N_2, or they may bond together to form liquids or solids. A molecule is the smallest constituent of a substance that retains its chemical properties.

In this chapter, we use our understanding of quantum mechanics to discuss bonding and the energy levels and spectra of diatomic molecules. Much of our discussion will be qualitative because, as in atomic physics, the quantum-mechanical calculations are very difficult.

37-1 BONDING

Consider a hydrogen molecule (H_2). We can think of H_2 either as two H atoms joined together or as a quantum-mechanical system of two protons and two electrons. The latter picture is more useful in this case because neither of the electrons in the H_2 molecule is confined to the region surrounding either one of the two protons. Instead, each electron is equally shared by both protons. For more complicated molecules, however, an intermediate picture is useful. For example, the fluorine molecule F_2 consists of 18 protons and 18 electrons, but only two of the electrons take part in the bonding. We therefore can consider this molecule as two F^+ ions and two electrons that belong to the molecule as a whole. The molecular wave functions for the bonding electrons are called **molecular orbitals.** In many cases, these molecular wave functions can be constructed from combinations of the atomic wave functions with which we are familiar.

The two principal types of bonds responsible for the formation of solids and molecules are the ionic bond and the covalent bond. Other types of bonds that are important in the bonding of liquids and solids are van der Waals bonds, metallic bonds, and hydrogen bonds. In many cases, bonding is a mixture of these mechanisms.

THE IONIC BOND

The simplest type of bond is the **ionic bond,** which is found in salts such as sodium chloride (NaCl). The sodium atom has one 3s electron outside a stable ten-electron core. The first ionization energy of sodium is the energy needed to remove the 3s electron from an isolated sodium atom. This energy is just 5.14 eV (see Figure 36-18). The removal of this electron results in an isolated positive ion that has its $n = 1$ and $n = 2$ electron shells filled. A chlorine atom has 17 electrons, and so is one electron short of having its first three shells filled. A measure of the energy released when an isolated atom gains one electron is called its **electron affinity;** a chlorine atom releases 3.62 eV of energy when it acquires an electron to form a Cl^- ion. Thus, the chlorine atom is said to have an electron affinity of -3.62 eV. The acquisition of one electron by chlorine results in a negative ion that has a filled outer electron shell. Thus, the formation of a Na^+ ion and a Cl^- ion by the donation of one electron of sodium to chlorine requires only 5.14 eV $-$ 3.62 eV $=$ 1.52 eV at infinite separation. The electrostatic potential energy U_e of the two ions when they are a distance r apart is $-ke^2/r$. When the separation of the ions is less than approximately 0.95 nm, the negative potential energy of attraction is of greater magnitude than the 1.52 eV of energy needed to create the ions. Thus, at separation distances less than 0.95 nm, it is energetically favorable (the total energy of the system is reduced) for the sodium atom to donate an electron to the chlorine atom to form NaCl.

Because the electrostatic attraction increases as the ions get closer together, it might seem that equilibrium could not exist. However, when the separation of the ions is very small, there is a strong repulsion that can be described by quantum mechanics and the exclusion principle. This repulsion is also responsible for the repulsion of the atoms in all molecules and ions (except H_2).* We can understand it qualitatively as follows. When the ions are very far apart, the probability distribution for a core electron in one of the ions does not overlap the probability distribution of any electron in the other ion. We can distinguish the electrons by the ion to which they belong. This means that electrons in the two ions can have the same quantum numbers because they occupy different regions of space. However, as the distance between the ions decreases, the probability distributions of the core electrons begin to overlap; that is, the electrons in the two ions begin to occupy the same region of space. Some of these electrons must go into higher energy quantum states as described by the exclusion principle.† But energy is required to shift the electrons into higher energy quantum states. This increase in energy when the ions are pushed closer together is equivalent to the repulsion energy of the ions. It is not a sudden process. The energy states of the electrons change gradually as the ions are brought together. A sketch of the potential energy $U(r)$ of the Na^+ and Cl^- ions versus separation distance r is shown in Figure 37-1. The energy is lowest at an

* In H_2, the repulsion is simply that of the two positively charged protons.

† Recall from our discussion in Chapter 35 that the exclusion principle is related to the fact that the wave function for two identical electrons is antisymmetric on the exchange of the electrons and that an antisymmetric wave function for two electrons with the same quantum numbers is zero if the space coordinates of the electrons are the same.

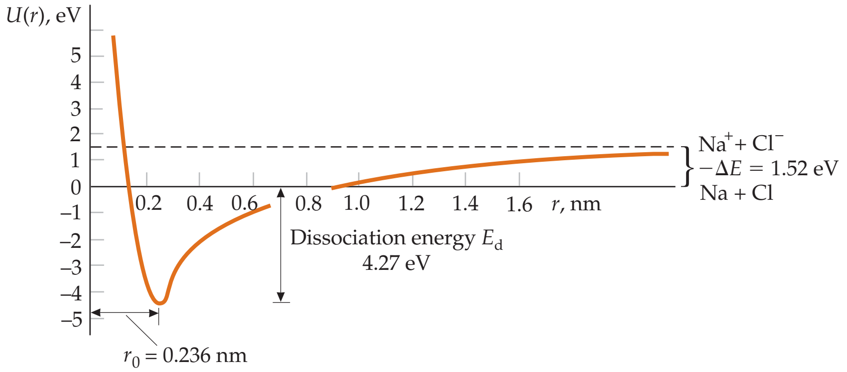


FIGURE 37-1 Potential energy for Na^+ and Cl^- ions as a function of separation distance r. The energy at infinite separation is chosen to be 1.52 eV, corresponding to the energy $-\Delta E$ needed to form the ions from atoms. The minimum energy is at the equilibrium separation $r_0 = 0.236$ nm for the ions.

equilibrium separation r_0 of approximately 0.236 nm. At smaller separations, the energy increases steeply. The energy required to separate the ions and form sodium and chlorine atoms is called the **dissociation energy** E_d, which is approximately 4.27 eV for NaCl.

The equilibrium separation distance of the gaseous NaCl, which can be obtained by evaporating solid NaCl, is 0.236 nm. Normally, NaCl exists as a solid in a cubic crystal structure, where the Na^+ and Cl^- ions are at the alternate corners of a cube. The separation of the Na^+ and Cl^- ions in a crystal is approximately 0.28 nm, which is somewhat larger than the 0.236 nm separation for the gaseous NaCl. Because of the presence of neighboring ions of opposite charge, the electrostatic energy per ion pair is lower when the ions are in a crystal.

Example 37-1 The Energy of Sodium Fluoride

The electron affinity of fluorine is −3.40 eV and the equilibrium separation of sodium fluoride (NaF) is 0.193 nm. (*a*) How much energy is needed to form Na^+ and F^- ions from sodium and fluorine atoms? (*b*) What is the electrostatic potential energy of the Na^+ and F^- ions at their equilibrium separation? (*c*) The dissociation energy of NaF is 5.38 eV. What is the energy due to repulsion of the ions at the equilibrium separation?

PICTURE (*a*) The energy ΔE needed to form Na^+ and F^- ions from the sodium and fluorine atoms is the sum of the first ionization energy of sodium (5.14 eV) and the electron affinity of fluorine. (*b*) The electrostatic potential energy, where $U = 0$ at infinity, is $U_e = -ke^2/r$. (*c*) If we choose the potential energy at infinity to be ΔE, the total potential energy is $U_{tot} = U_e + \Delta E + U_{rep}$, where U_{rep} is the energy of repulsion, which is found by setting the dissociation energy equal to $-U_{tot}$.

SOLVE

(*a*) Calculate the energy needed to form Na^+ and F^- ions from the sodium and fluorine atoms (see the Picture section):

$$\Delta E = 5.14\text{ eV} - 3.40\text{ eV} = \boxed{1.74\text{ eV}}$$

(*b*) Calculate the electrostatic potential energy at the equilibrium separation of $r = 0.193$ nm:

$$U_e = -\frac{ke^2}{r}$$
$$= -\frac{(8.99 \times 10^9\text{ N}\cdot\text{m}^2/\text{C}^2)(1.60 \times 10^{-19}\text{ C})^2}{1.93 \times 10^{-10}\text{ m}}$$
$$= -1.19 \times 10^{-18}\text{ J} = \boxed{-7.45\text{ eV}}$$

(*c*) The dissociation energy equals the negative of the total potential energy:

$$E_d = -U_{tot} = -(U_e + \Delta E + U_{rep})$$

so

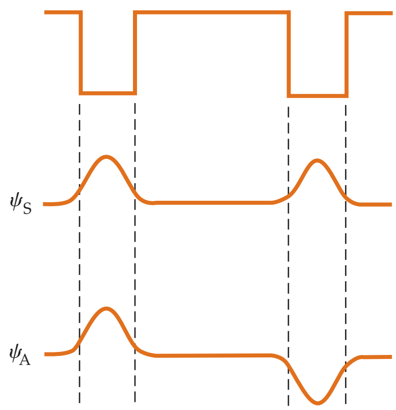
$$U_{rep} = -(E_d + \Delta E + U_e)$$
$$= -(5.38\text{ eV} + 1.74\text{ eV} - 7.45\text{ eV}) = \boxed{0.33\text{ eV}}$$

CHECK The Part (*c*) result is greater than zero as expected.

THE COVALENT BOND

A completely different mechanism, the **covalent bond,** is responsible for the bonding of identical or similar atoms to form molecules such as gaseous hydrogen (H_2), nitrogen (N_2), and carbon monoxide (CO). If we calculate the energy needed to form H^+ and H^- ions by the transfer of an electron from one atom to the other and then add this energy to the electrostatic potential energy, we find that there is no separation distance for which the total energy is negative. The bond thus cannot be ionic. Instead, the attraction of two hydrogen atoms can only be explained quantum-mechanically. The decrease in energy when two hydrogen atoms approach each other is due to the sharing of the two electrons by both atoms, which can be explained using the symmetry properties of the wave functions of electrons.

We can gain some insight into covalent bonding by considering a simple, one-dimensional quantum-mechanics problem of two identical finite square wells. We first consider a single electron that is equally likely to be in either well. Because the wells are identical, the probability distribution, which is proportional to $|\psi^2|$, must be symmetric about the midpoint between the wells. Then ψ must be either symmetric or antisymmetric with respect to the two wells. The two possibilities for the ground state are shown in Figure 37-2*a* for the case in which the wells are far apart and in Figure 37-2*b* for the case in which the wells are close together. An important feature of Figure 37-2*b* is that in the region between the wells the symmetric wave function is large and the antisymmetric wave function is small.



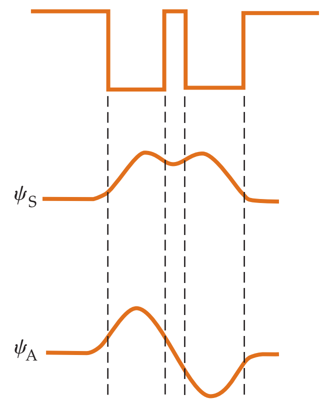


FIGURE 37-2 (*a*) Two square wells far apart. The electron wave function can be either symmetric (ψ_S) or antisymmetric (ψ_A) in space. The probability distributions and energies are the same for the two wave functions when the wells are far apart. (*b*) Two square wells that are close together. Between the wells, the antisymmetric space wave function is approximately zero, whereas the symmetric space wave function is quite large.

Now consider adding a second electron to the two wells. We saw in Section 6 of Chapter 35 that the wave functions for particles that obey the exclusion principle are antisymmetric on exchange of the particles. Thus, the total wave function for the two electrons must be antisymmetric on exchange of the electrons. Note that exchanging the electrons while keeping the wells in place is equivalent to keeping the electrons in place and exchanging the wells. The total wave function for two electrons can be written as a spatial expression and an expression for spin. So, an antisymmetric wave function can be the product of a symmetric spatial expression and an antisymmetric expression for spin or of a symmetric expression for spin and an antisymmetric spatial expression.

To understand the symmetry of the total wave function, we must therefore understand the symmetry of the expression for spin of the wave function. The spin of a single electron can have two possible values for its quantum number m_S: $m_S = +\frac{1}{2}$, which we call spin up, or $m_S = -\frac{1}{2}$, which we call spin down. We will use arrows to designate the spin wave function for a single electron: $\uparrow_1$ or $\uparrow_2$ for electron 1 or electron 2 that both are spin up and $\downarrow_1$ or $\downarrow_2$ for electron 1 or electron 2 that are both spin down. The total spin quantum number for two electrons can be $S = 1$, where $m_S = +1, 0,$ or -1; or $S = 0$, where $m_S = 0$. We use $\phi_{S\,m_S}$ to denote the spin wave function for two electrons. The spin state $\phi_{1\,+1}$, corresponding to $S = 1$ and $m_S = +1$, can be written

$$\phi_{1\,+1} = \uparrow_1\uparrow_2 \qquad S = 1, m_S = +1 \tag{37-1}$$

Similarly, the spin state for $S = 1$, $m_S = -1$ is

$$\phi_{1\,-1} = \downarrow_1\downarrow_2 \qquad S = 1, m_S = -1 \tag{37-2}$$

Note that both of these states are symmetric upon exchange of the electrons. The spin state corresponding to $S = 1$ and $m_S = 0$ is not quite so obvious. It turns out to be proportional to

$$\phi_{10} = \uparrow_1\downarrow_2 + \uparrow_2\downarrow_1 \qquad S = 1, m_S = 0 \tag{37-3}$$

This spin state is also symmetric upon exchange of the electrons. The spin state for two electrons with antiparallel spins ($S = 0$) is

$$\phi_{00} = \uparrow_1\downarrow_2 - \uparrow_2\downarrow_1 \qquad S = 0, m_S = 0 \qquad 37\text{-}4$$

This spin state is antisymmetric upon exchange of electrons.

We thus have the important result that the spin part of the wave function is symmetric for parallel spins ($S = 1$) and antisymmetric for antiparallel spins ($S = 0$). Because the total wave function is the product of the spatial expression and the expression for spin, we have the following important result:

> For the total wave function of two electrons to be antisymmetric, the spatial part of the wave function must be antisymmetric for parallel spins ($S = 1$) and symmetric for antiparallel spins ($S = 0$).
>
> SPIN ALIGNMENT AND WAVE-FUNCTION SYMMETRY

We can now consider the problem of two hydrogen atoms. Figure 37-3*a* shows a spatially symmetric wave function ψ_S and a spatially antisymmetric wave function ψ_A for two hydrogen atoms that are far apart, and Figure 37-3*b* shows the same two wave functions for two hydrogen atoms that are close together. The squares of these two wave functions are shown in Figure 37-3*c.* Note that the probability distribution $|\psi|^2$ in the region between the protons is large for the symmetric wave function and small for the antisymmetric wave function. Thus, when the spatial part of the wave function is symmetric ($S = 0$), the electrons are often found in the region between the protons. The electron cloud, as shown in the upper part of Figure 37-3*c,* is concentrated in the space between the protons and the protons are bound together by this negatively charged cloud. Conversely, when the spatial part of the wave function is antisymmetric ($S = 1$), the electrons spend little time between the protons and the atoms do not bond together to form a molecule. In this case, the electron cloud is not concentrated in the space between the protons, as shown in the lower part of Figure 37-3*c.*

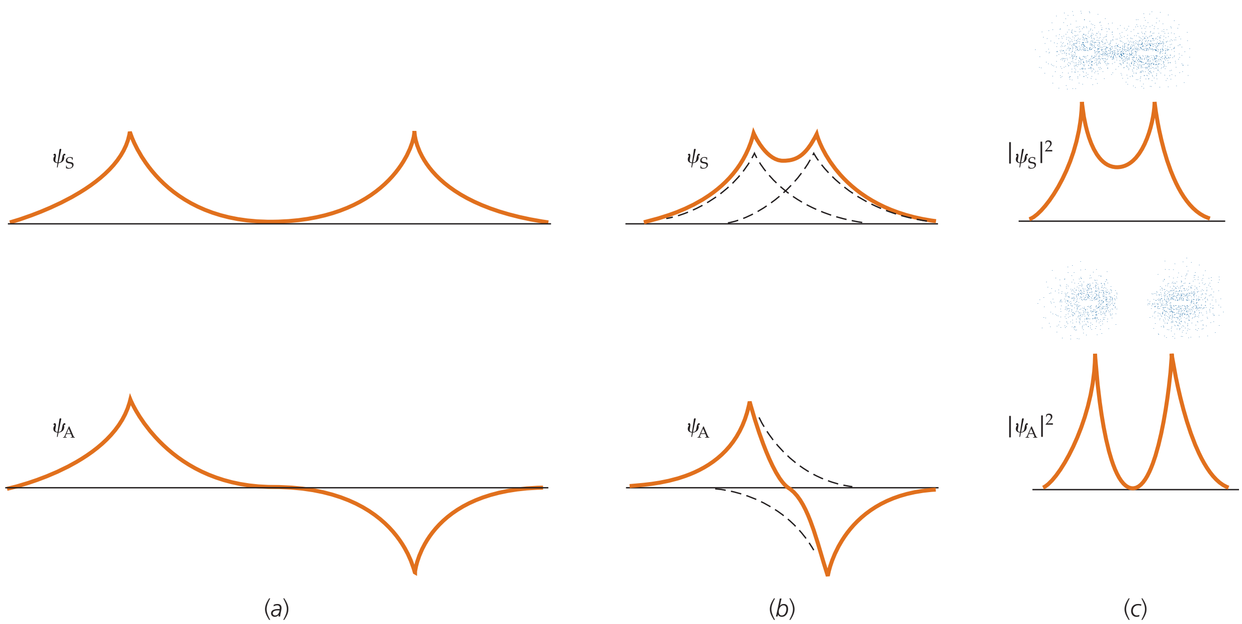

FIGURE 37-3 One-dimensional symmetric and antisymmetric wave functions for two hydrogen atoms (*a*) far apart and (*b*) close together. (*c*) Electron probability distributions ($|\psi|^2$) for the wave functions in Figure 37-3*b*. For the symmetric wave function, the electron charge density is large between the protons. This negative charge density holds the protons together in the hydrogen molecule H_2. For the antisymmetric wave function, the electron charge density is not large between the protons.

The total electrostatic potential energy for the H_2 molecule consists of the positive energy of repulsion of the two electrons and the negative potential energy of attraction of each electron for each proton. Figure 37-4 shows the electrostatic potential energy function U_S for two hydrogen atoms versus separation for the case in which the spatial part of the electron wave function is symmetric, and the electrostatic potential energy function U_A for the case in which the spatial part of the wave function is antisymmetric. We can see that the potential energy for the symmetric state is lower than the potential energy for the antisymmetric state and that the shape of the potential energy curve for the symmetric state is similar to the shape of the potential energy curve for ionic bonding (Figure 37-1). The equilibrium separation for H_2 is $r_0 = 0.074$ nm, and the binding energy is 4.52 eV. For the antisymmetric state, the potential energy is never negative and there is no bonding.

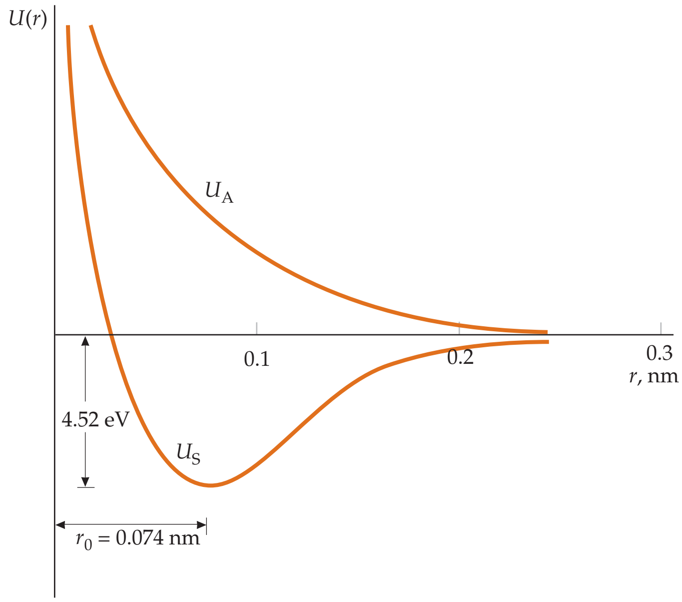

FIGURE 37-4 Potential energy versus separation for two hydrogen atoms. The curve labeled U_S is for a wave function that has a symmetric expression for the spatial part and the curve labeled U_A is for a wave function that has an antisymmetric expression for the spatial part.

We can now see why three hydrogen atoms do not bond to form H_3. If a third hydrogen atom is brought near an H_2 molecule, the third electron cannot be in a 1s state and have its spin antiparallel to the spin of both of the other electrons. If that electron is in an antisymmetric spatial state with respect to exchange with one of the electrons, the repulsion of this atom is greater than the attraction of the other. As the three atoms are pushed together, the third electron is, in effect, forced into a higher quantum-energy state according to the exclusion principle. The bond between two hydrogen atoms is called a **saturated bond** because there is no room for another electron. The two shared electrons essentially fill the 1s states of both atoms.

We can also see why two helium atoms do not normally bond together to form the He_2 molecule. There are no valence electrons that can be shared. The electrons in the filled shells are forced into higher energy states when the two atoms are brought together. At low temperatures or high pressures, helium atoms do bond together due to van der Waals forces, which we will discuss next. This bonding is so weak that at atmospheric pressure helium boils at 4 K, and it does not form a solid at any temperature unless the pressure is greater than about 20 atm.

! Don't think all bonds between atoms are partly ionic. They are not. Bonds between two identical atoms are always 100 percent covalent.

When two identical atoms bond, as in O_2 or N_2, the bonding is purely covalent. However, the bonding of two dissimilar atoms is often a mixture of covalent and ionic bonding. Even in NaCl, the electron donated by sodium to chlorine has some probability of being at the sodium atom because its wave function in the vicinity of the sodium atom, while small, is not zero. Thus, this electron is partially shared in a covalent bond, although this bonding is only a small part of the total bond, which is mainly ionic.

A measure of the degree to which a bond is ionic or covalent can be obtained from the electric dipole moment of the molecule or ionic unit. For example, if the bonding in NaCl were purely ionic, the center of positive charge would be at the Na^+ ion and the center of negative charge would be at the Cl^- ion. The electric dipole moment would have the magnitude

$$p_{\text{ionic}} = er_0 \qquad 37\text{-}5$$

where $r_0 = 2.36 \times 10^{-10}$ m is the equilibrium separation of the ions. Thus, the dipole moment of NaCl would be (from Figure 37-1)

$$\begin{aligned} p_{\text{ionic}} &= er_0 \\ &= (1.60 \times 10^{-19}\ \text{C})(2.36 \times 10^{-10}\ \text{m}) = 3.78 \times 10^{-29}\ \text{C}\cdot\text{m} \end{aligned}$$

The actual measured electric dipole moment of NaCl is

$$p_{\text{measured}} = 3.00 \times 10^{-29}\ \text{C}\cdot\text{m}$$

We can define the ratio of p_{measured} to p_{ionic} as the fractional amount of ionic bonding. For NaCl, this ratio is $3.00/3.78 = 0.79$. Thus, the bonding in NaCl is about 79 percent ionic.

PRACTICE PROBLEM 37-1

The equilibrium separation of HCl is 0.128 nm and its measured electric dipole moment is $3.60 \times 10^{-30}\ \text{C}\cdot\text{m}$. What is the percentage of ionic bonding in HCl?

OTHER BONDING TYPES

The van der Waals Bond Any two separated molecules will be attracted to one another by electrostatic forces called *van der Waals forces.* So will any two atoms that do not form ionic or covalent bonds. The **van der Waals bonds** due to these forces are much weaker than the bonds already discussed. At high enough temperatures, these forces are not strong enough to overcome the motion of the atoms or molecules due to thermal energy. At sufficiently low temperatures, these motions become negligible and the van der Waals forces will cause virtually all substances to condense into a liquid and then a solid form.* The van der Waals forces arise from the interaction of the instantaneous electric dipole moments of the molecules.

Figure 37-5 shows how two polar molecules—molecules that have *permanent* electric dipole moments, such as H_2O—can bond. The electric field due to the dipole moment of one molecule orients the other molecule so that the two dipole moments attract. Nonpolar molecules also attract other nonpolar molecules by the van der Waals forces. Although nonpolar molecules have zero electric dipole moments on the average, they have instantaneous dipole moments that are generally not zero because of fluctuations in the positions of the charges. When two nonpolar molecules are near each other, the fluctuations in the instantaneous dipole moments tend to become correlated so as to produce attraction. This is illustrated in Figure 37-6.

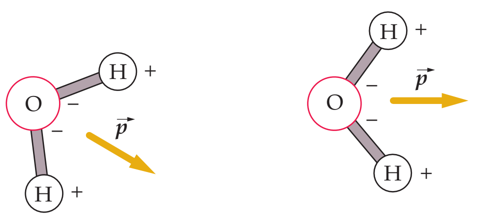

FIGURE 37-5 Bonding of H_2O molecules due to the attraction of the electric dipoles. The dipole moment of each molecule is indicated by $\vec{p}$. The electric field of one dipole orients the other dipole so the two dipole moments tend to be parallel. When the dipole moments are approximately parallel, the center of negative charge of one molecule is closer to the center of positive charge of the other molecule than it is to the center of the negative charge, so the molecules attract.

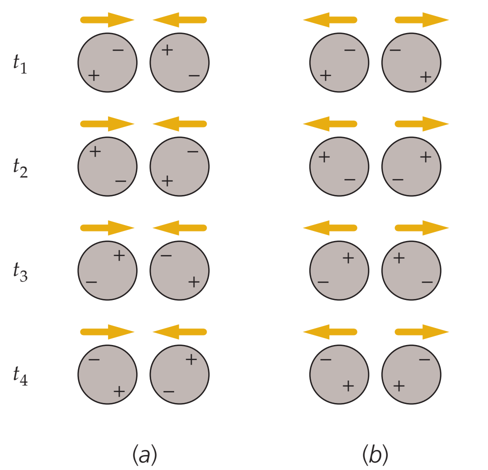

FIGURE 37-6 van der Waals attraction of molecules that have zero permanent dipole moments. (*a*) Possible orientations of instantaneous dipole moments at different times leading to attraction. (*b*) Possible orientations leading to repulsion. The electric field of the instantaneous dipole moment of one molecule tends to polarize the other molecule; thus the orientations leading to attraction (Figure 37-6*a*) are much more likely than those leading to repulsion (Figure 37-6*b*).

* Helium is the only element that does not solidify at any temperature at atmospheric pressure.

The hydrogen bond Another bonding mechanism of great importance is the hydrogen bond, which is formed by the sharing of a proton (the nucleus of the hydrogen atom) between two atoms, frequently two oxygen atoms. This sharing of a proton is similar to the sharing of electrons responsible for the covalent bond already discussed. It is facilitated by the small mass of the proton and by the absence of core electrons in hydrogen. The hydrogen bond often holds groups of molecules together and is responsible for the cross-linking that allows giant biological molecules and polymers to hold their fixed shapes. The well-known helical structure of DNA is due to hydrogen-bond linkages across turns of the helix (Figure 37-7).

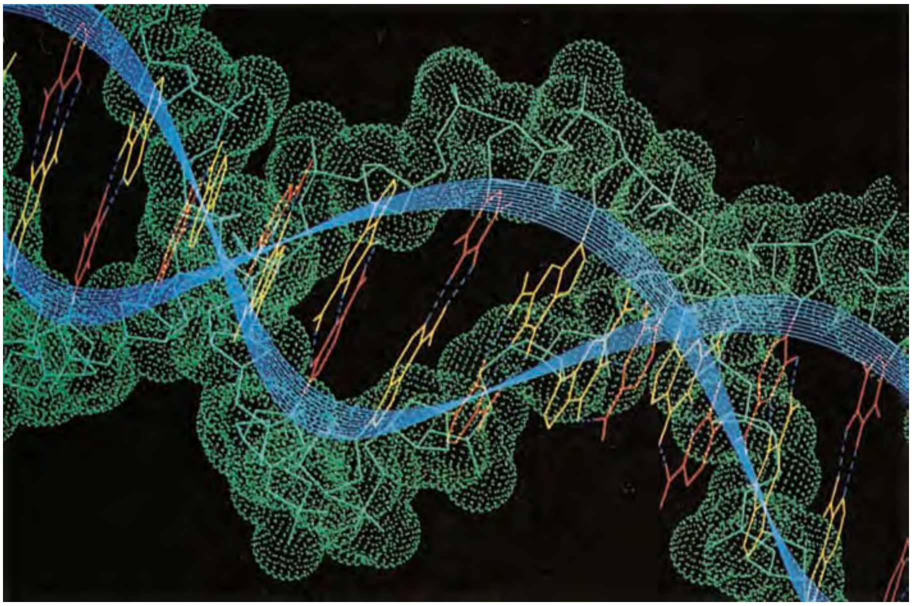

FIGURE 37-7 The DNA molecule. *(© Will and Demi McIntire/Photo Researchers.)*

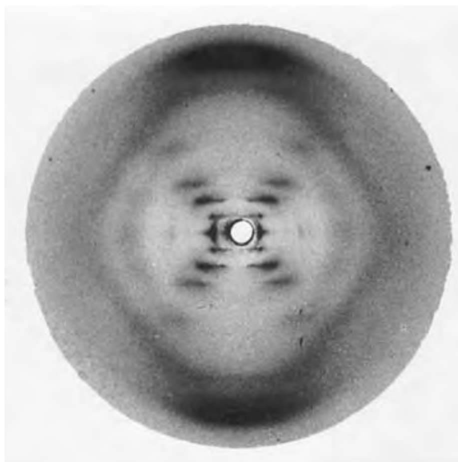
(*a*) The discoverers of the structure of DNA. James Watson at left and Francis Crick are shown with their model of part of a DNA molecule in 1953. Crick and Watson met at the Cavendish Laboratory, Cambridge, in 1951. Their work on the structure of DNA was performed with a knowledge of Chargaff's ratios of the bases in DNA and some access to the X-ray crystallography of Maurice Wilkins and Rosalind Franklin at King's College London. Combining all of this work led to the deduction that DNA exists as a double helix, thus to its structure. Crick, Watson, and Wilkins shared the 1962 Nobel Prize for Physiology or Medicine; Franklin died from cancer in 1958. *((a) Norman Collection for the History of Molecular Biology.)*



(*b*) X-ray diffraction pattern of the B form of DNA. Rosalind Franklin's colleague Maurice Wilkins, without obtaining her permission, made available to Watson and Crick her then unpublished X-ray diffraction pattern of the B form of DNA, which was crucial evidence for the helical structure. In his account of this discovery, Watson wrote: "The instant I saw the picture, my mouth fell open and pulse began to race. . . . The black cross of reflections which dominated the picture could arise only from a helical structure. . . . Mere inspection of the X-ray picture gave several of the vital helical parameters" (from Stent, Gunther, *The Double Helix*, New York: Norton, 1980). *((b) © A. Barrington Brown/Photo Researchers, NY.)*

The metallic bond In a metal, two atoms do not bond together by exchanging or sharing an electron to form a molecule. Instead, each valence electron is shared by many atoms. The bonding is thus distributed throughout the entire metal. A metal can be thought of as a lattice of positive ions held together by essentially free electrons that roam throughout the solid. In the quantum-mechanical picture, these free electrons form a cloud of negative charge density between the positively charged lattice ions that holds the ions together. In this respect, the metallic bond is somewhat similar to the covalent bond. However, with the metallic bond, there are far more than just two atoms involved, and the negative charge is distributed uniformly throughout the volume of the metal. The number of free electrons per lattice ion varies from metal to metal but is of the order of one free electron per ion.

* 37-2 POLYATOMIC MOLECULES

Molecules that have more than two atoms range from relatively simple molecules such as water, which has a molecular mass number of 18, to such giants as proteins and DNA, which can have molecular mass numbers of hundreds of thousands up to many millions. As with diatomic molecules, the structure of polyatomic molecules can be understood by applying basic quantum mechanics to the bonding of individual atoms. The bonding mechanisms for most polyatomic molecules are the covalent bond and the hydrogen bond. We will discuss only some of the simplest polyatomic molecules—H_2O, NH_3, and CH_4—to illustrate both the simplicity and complexity of the application of quantum mechanics to molecular bonding.

The basic requirement for the sharing of electrons in a covalent bond is that the wave functions of the valence electrons in the individual atoms must overlap as much as possible. As our first example, we will consider the water molecule. The ground-state configuration of the oxygen atom is $1s^2 2s^2 2p^4$. The 1s and 2s electrons are in filled shells and do not contribute to the bonding. The 2p shell has room for six electrons, two in each of the three spatial states (orbitals) corresponding to $\ell = 1$. In an isolated atom, we describe these spatial states by the hydrogen-like wave functions corresponding to $\ell = 1$ and $m_\ell = +1, 0,$ and -1. Because the energy is the same for these three spatial states, we could equally well use any linear combination of these wave functions. When an atom participates in molecular bonding, certain combinations of these atomic wave functions are important. These combinations are called **p_x, p_y, and p_z atomic orbitals.** The angular dependence of these orbitals is

$$p_x \propto \sin\theta \cos\phi \tag{37-6}$$

$$p_y \propto \cos\theta \cos\phi \tag{37-7}$$

$$p_z \propto \cos\phi \tag{37-8}$$

The electron charge distribution for these orbitals is maximum along the x, y, or z axis, respectively, as shown in Figure 37-8.

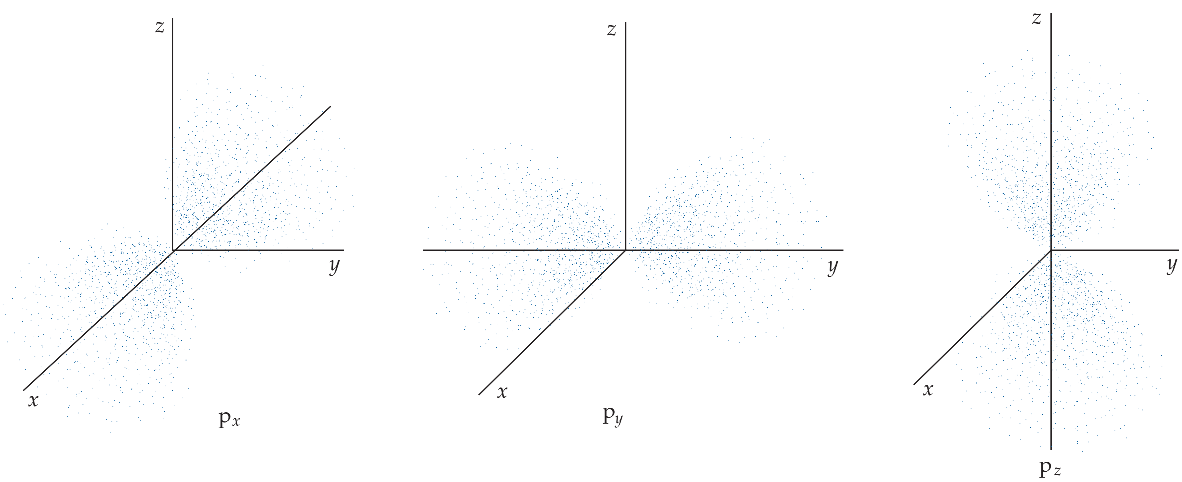


FIGURE 37-8 Computer-generated dot plot illustrating the spatial dependence of the electron charge distribution in the p_x, p_y, and p_z atomic orbitals.

For the oxygen in an H_2O molecule, maximum overlap of the electron wave functions occurs when two of the four 2p electrons are in one of the atomic orbitals (for this example, assume the p_z orbital) with their spins antiparallel, the third 2p electron is in a second orbital (the p_x orbital), and the fourth 2p electron is in the third orbital (the p_y orbital). Each of the unpaired electrons (in the p_x and p_y orbitals for this example) forms a bond with the electron of a hydrogen atom, as shown in Figure 37-9. Because of the repulsion of the two hydrogen atoms, the angle between the O—H bonds is actually greater than 90°. The effect of this repulsion can be calculated, and the result is in agreement with the measured angle of 104.5°.

Similar reasoning leads to an understanding of the bonding in NH_3 (not shown). In the ground state, nitrogen has three electrons in the 2p state. When these three electrons are in the p_x, p_y, and p_z atomic orbitals, they bond to the electrons of hydrogen atoms. Again, because of the repulsion of the hydrogen atoms, the angles between the bonds are somewhat larger than 90°.

The bonding of carbon atoms is somewhat more complicated. Carbon forms single, double and triple bonds, leading to a great diversity in the kinds of organic molecules. The ground-state configuration of carbon is $1s^22s^22p^2$. From our previous discussion, we might expect carbon to be divalent–that is, bonding only through its two 2p electrons–with the two bonds forming at approximately 90°. However, one of the most important features of the chemistry of carbon is that tetravalent carbon compounds, such as CH_4, are overwhelmingly favored.

The observed valence of 4 for carbon comes about in an interesting way. One of the first excited states of carbon occurs when a 2s electron is excited to a 2p state, giving a configuration of $1s^22s^12p^3$. In this excited state, we can have four unpaired electrons, one each in the 2s, $2p_x$, $2p_y$, and $2p_z$ atomic orbitals. We might expect there to be three similar bonds corresponding to the three p orbitals and one different bond corresponding to the s orbital. However, when carbon forms tetravalent bonds, these four atomic orbitals become mixed and form four new *equivalent* molecular orbitals called **hybrid orbitals.** This mixing of atomic orbitals, called hybridization, is among the most important features involved in the physics of complex molecular bonds. Figure 37-10 shows the tetrahedral structure of the methane molecule (CH_4), and Figure 37-11 shows the structure of the ethane molecule (CH_3—CH_3), which is similar to two joined methane molecules in which one of the C—H bonds is replaced with a C—C bond.

Carbon orbitals can also hybridize such that the s, p_x, and p_y orbitals combine to form three hybrid orbitals that are in the *xy* plane and form bonds that are 120° apart (the p_z orbital does not participate in bonding). An example of this configuration is graphite, in which the bonds in the *xy* plane provide the strongly layered structure characteristic of the material.

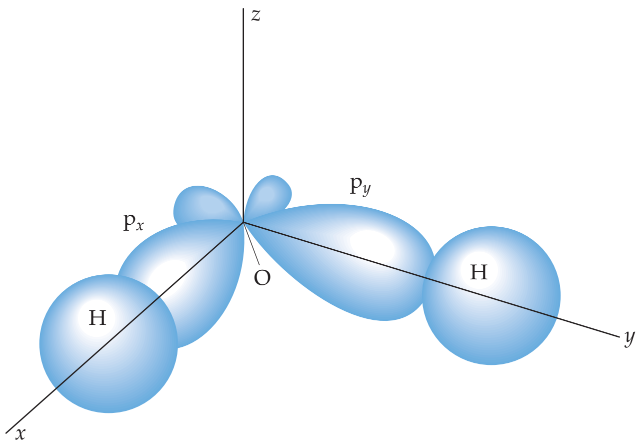

FIGURE 37-9 Electron charge distribution in the H_2O molecule.

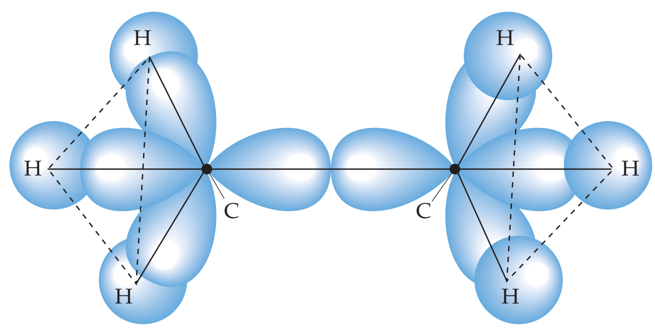

FIGURE 37-11 Electron charge distribution in the CH_3—CH_3 (ethane) molecule.

37-3 ENERGY LEVELS AND SPECTRA OF DIATOMIC MOLECULES

As is the case with an atom, a molecule often emits electromagnetic radiation when it makes a transition from an excited energy state to a state of lower energy. Conversely, a molecule can absorb radiation and make a transition from a lower energy state to a higher energy state. The study of molecular emission and absorption spectra thus provides us with information about the energy states of molecules. For simplicity, we will consider only diatomic molecules here.

The internal energy of a molecule can be conveniently separated into three parts: electronic, due to the excitation of the electrons of the molecule; vibrational, due to the oscillations of the atoms of the molecule; and rotational, due to the rotation of the molecule about its center of mass. The magnitudes of these energies are sufficiently different that they can be treated separately. The energies due to the electronic excitations of a molecule are typically of the order of magnitude of 1 eV, the same as for the electronic excitations of an atom. The energies of the vibrations of the atoms and of the rotation of the molecule are much smaller than the electronic excitation energy.

ROTATIONAL ENERGY LEVELS

Figure 37-12 shows a simple schematic model of a diatomic molecule consisting of particles that have masses of m_1 and m_2, are separated by a distance r and are rotating about the center of mass. Classically, the kinetic energy of rotation (Equation 9-11) is

$$E = \frac{1}{2} I\omega^2 \qquad \text{37-9}$$

where I is the moment of inertia and ω is the angular speed of the rotation motion. If we write this in terms of the angular momentum $L = I\omega$, we have

$$E = \frac{(I\omega)^2}{2I} = \frac{L^2}{2I} \qquad \text{37-10}$$

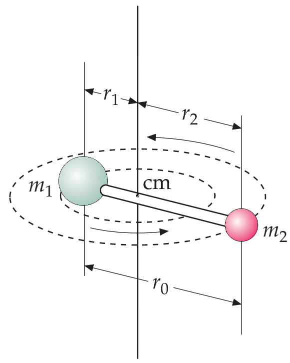

FIGURE 37-12 Diatomic molecule rotating about an axis through its center of mass.

The solution of the Schrödinger equation for rotation leads to quantization of the angular momentum with values given by

$$L^2 = \ell(\ell + 1)\hbar^2 \qquad \ell = 0, 1, 2, \ldots \qquad \text{37-11}$$

where ℓ is the **rotational quantum number.** This is the same quantum condition on angular momentum that holds for the orbital angular momentum of an electron in an atom. Note, however, that L in Equation 37-10 refers to the angular momentum of the entire molecule rotating about its center of mass. The energy levels of a rotating molecule are therefore given by

$$E_\ell = \frac{\ell(\ell + 1)\hbar^2}{2I} = \ell(\ell + 1)E_{0r} \qquad \ell = 0, 1, 2, \ldots \qquad \text{37-12}$$

ROTATIONAL ENERGY LEVELS

where E_{0r} is the characteristic rotational energy of a particular molecule, which is inversely proportional to its moment of inertia:

$$E_{0r} = \frac{\hbar^2}{2I} \qquad \text{37-13}$$

CHARACTERISTIC ROTATIONAL ENERGY

A measurement of the rotational energy of a molecule from its rotational spectrum can be used to determine the moment of inertia of the molecule, which can then be used to find the separation of the atoms in the molecule. The moment of inertia about an axis through the center of mass of a diatomic molecule (see Figure 37-12) is

$$I = m_1 r_1^2 + m_2 r_2^2$$

Using $m_1 r_1 = m_2 r_2$, where r_1 is the distance of atom 1 from the center of mass, r_2 is the distance of atom 2 from the center of mass, and $r_0 = r_1 + r_2$, we can write the moment of inertia (see Problem 26) as

$$I = \mu r_0^2 \qquad \text{37-14}$$

where μ, called the **reduced mass,** is

$$\mu = \frac{m_1 m_2}{m_1 + m_2} \qquad \text{37-15}$$

DEFINITION—REDUCED MASS

If the masses are equal ($m_1 = m_2 = m$), as in H_2 and O_2, the reduced mass is $\mu = \frac{1}{2}m$ and

$$I = \tfrac{1}{2} m r_0^2 \qquad \text{37-16}$$

A unit of mass convenient for discussing atomic and molecular masses is the **unified atomic mass unit,** u, which is defined as one-twelfth the mass of the carbon-12 (^{12}C) atom. The mass of one ^{12}C atom is thus 12 u. The mass of an atom in unified mass units is therefore numerically equal to the molar mass of the atom in grams. The unified mass unit is related to the gram and kilogram by

$$1\ \text{u} = \frac{1\ \text{g}}{N_A} = \frac{10^{-3}\ \text{kg}}{6.0221 \times 10^{23}} = 1.6606 \times 10^{-27}\ \text{kg} \qquad \text{37-17}$$

where N_A is Avogadro's number.

Example 37-2 The Reduced Mass of a Diatomic Molecule

Find the reduced mass of the HCl molecule.

PICTURE We find the masses of the hydrogen and chlorine atoms in Appendix C* and use the definition of reduced mass (Equation 37-15).

SOLVE

1. The reduced mass μ is related to the individual masses m_H and m_{Cl}: $\quad \mu = \dfrac{m_H m_{Cl}}{m_H + m_{Cl}}$
2. Find the masses in the periodic table: $\quad m_H = 1.01\ \text{u}, \qquad m_{Cl} = 35.5\ \text{u}$
3. Substitute to calculate the reduced mass: $\quad \mu = \dfrac{m_H m_{Cl}}{m_H + m_{Cl}} = \dfrac{(1.01\ \text{u})(35.5\ \text{u})}{1.01\ \text{u} + 35.5\ \text{u}} = \boxed{0.982\ \text{u}}$

CHECK The formula for reduced mass is identical to the formula for the equivalent resistance for two resistors in parallel. As expected, the reduced mass is less than either mass.

TAKING IT FURTHER When one atom of a diatomic molecule is much more massive than the other, the center of mass of the molecule is approximately at the center of the more massive atom and the reduced mass is approximately equal to the mass of the lighter atom.

* The masses in the tables are weighted according to the natural isotopic distribution. Thus, the mass of carbon is given as 12.011 rather than 12.000 because natural carbon consists of about 98.9 percent ^{12}C and 1.1 percent ^{13}C. Similarly, natural chlorine consists of about 76 percent ^{35}Cl and 24 percent ^{37}Cl.

Example 37-3 Rotational Kinetic Energy of a Molecule

Estimate the characteristic rotational kinetic energy of an O_2 molecule, assuming that the separation of the atoms is 0.100 nm.

PICTURE The characteristic rotational kinetic energy is given by $E_{0r} = \hbar/(2I)$ (Equation 37-13), where I is the moment of inertia. The moment of inertia is given by $I = \mu r_0^2$ (Equation 37-14), where μ is the reduced mass and r_0 is the average center-to-center separation of the atomic nuclei.

SOLVE

1. The characteristic rotational energy is inversely proportional to the moment of inertia:

$$E_{0r} = \frac{\hbar^2}{2I}$$

2. Calculate the moment of inertia:

$$I = \mu r_0^2 = \tfrac{1}{2} m r_0^2$$

3. Substitute this expression for I into the expression for E_{0r}:

$$E_{0r} = \frac{\hbar^2}{m r_0^2}$$

4. Use $m = 16$ u for the mass of oxygen to calculate E_{0r}:

$$E_{0r} = \frac{\hbar^2}{m r_0^2} = \frac{(1.055 \times 10^{-34}\ \text{J}\cdot\text{s})^2}{(16\ \text{u})(10^{-10}\ \text{m})^2} \times \left(\frac{1\ \text{u}}{1.66 \times 10^{-27}\ \text{kg}}\right)$$

$$= 4.19 \times 10^{-23}\ \text{J} = \boxed{2.62 \times 10^{-4}\ \text{eV}}$$

CHECK As expected, the characteristic rotational kinetic energy is small compared with 1 eV (a typical electronic excitation energy).

We can see from Example 37-3 that the rotational energy levels are several orders of magnitude smaller than energy levels due to electron excitation. Transitions within a given set of rotational energy levels yield photons in the microwave region of the electromagnetic spectrum. The rotational energies are also small compared with the typical thermal energy kT at normal temperatures. For $T = 300$ K, for example, kT is about 2.6×10^{-2} eV, which is approximately 100 times the characteristic rotational energy as calculated in Example 37-3 and approximately 1 percent of the typical electronic energy. Thus, at ordinary temperatures, a molecule can be easily excited to the lower rotational energy levels by collisions with other molecules. But such collisions cannot excite the molecule to its electronic energy levels above the ground state.

CONCEPT CHECK 37-1

At room temperature, the molecules of a diatomic gas undergo transitions between rotational states, but the atoms of a monatomic gas do not. Why?

VIBRATIONAL ENERGY LEVELS

The quantization of energy in a simple harmonic oscillator was one of the first problems solved by Schrödinger in his paper proposing his wave equation. Solving the Schrödinger equation for a simple harmonic oscillator gives

$$E_\nu = (\nu + \tfrac{1}{2})hf \qquad \nu = 0, 1, 2, \ldots \tag{37-18}$$

VIBRATIONAL ENERGY LEVELS

where f is the frequency of the oscillator and ν (lowercase Greek nu) is the **vibrational quantum number.*** An interesting feature of this result is that the energy levels are equally spaced with intervals equal to hf. The frequency of vibration of a diatomic molecule can be related to the force exerted by one atom on the other. Consider two objects of mass m_1 and m_2 connected by a spring of force constant k_F.

* We use ν here rather than n so as not to confuse the vibrational quantum number with the principal quantum number n for electronic energy levels.

The frequency of oscillation of this system (see Problem 32) can be shown to be

$$f = \frac{1}{2\pi}\sqrt{\frac{k_F}{\mu}} \qquad 37\text{-}19$$

where μ is the reduced mass given by Equation 37-15. The effective force constant k_F of a diatomic molecule can thus be determined from a measurement of the frequency of oscillation of the molecule.

A selection rule on transitions between vibrational states (of the same electronic state) requires that the vibrational quantum number ν can change only by ± 1, so the energy of a photon emitted by such a transition is hf and the frequency of the photon is f, the same as the frequency of vibration. There is a similar selection rule that ℓ must change by ± 1 for transitions between rotational states.

A typical measured frequency of a transition between vibrational states is 5×10^{13} Hz, which gives

$$E \approx hf = (4.14 \times 10^{-15}\ \mathrm{eV \cdot s})(5.0 \times 10^{13}\ \mathrm{s^{-1}}) = 0.2\ \mathrm{eV}$$

and is an estimate for the order of magnitude of vibrational energies. This typical vibrational energy is approximately 1000 times greater than the typical rotational energy E_{0r} of the O_2 molecule we found in Example 37-3 and about 8 times greater than the typical thermal energy $kT = 0.026$ eV at $T = 300$ K. Thus, the vibrational levels are almost never excited by molecular collisions at ordinary temperatures.

Example 37-4 Determining the Force Constant

The frequency of vibration of the CO molecule is 6.42×10^{13} Hz. What is the effective force constant for this molecule?

PICTURE We use $2\pi f = \sqrt{k_F/\mu}$ (Equation 37-19) to relate k_F to the frequency and the reduced mass, and calculate μ from its definition.

SOLVE

1. The effective force constant is related to the frequency and reduced mass by Equation 37-19:

$$f = \frac{1}{2\pi}\sqrt{\frac{k_F}{\mu}}$$

$$k_F = (2\pi f)^2\mu$$

2. Calculate the reduced mass using 12 u for the mass of the carbon atom and 16 u for the mass of the oxygen atom:

$$\mu = \frac{m_1 m_2}{m_1 + m_2} = \frac{(12\ \mathrm{u})(16\ \mathrm{u})}{12\ \mathrm{u} + 16\ \mathrm{u}} = 6.86\ \mathrm{u}$$

3. Substitute this value of μ into the equation for k_F in step 1 and convert to SI units:

$$\begin{aligned} k_F &= (2\pi f)^2\mu \\ &= 4\pi^2(6.42 \times 10^{13}\ \mathrm{Hz})^2(6.86\ \mathrm{u}) \\ &= 1.12 \times 10^{30}\ \mathrm{u/s^2} \times \left(\frac{1.66 \times 10^{-27}\ \mathrm{kg}}{1\ \mathrm{u}}\right) \\ &= \boxed{1.85 \times 10^3\ \mathrm{N/m}} \end{aligned}$$

CHECK From Newton's second law we know that 1 kg m/s^2 = 1 N, so the units of kg/s^2 that remain after canceling out the u's in step 3 are equal to N/m, which is what is expected for the force constant of a "spring."

EMISSION SPECTRA

Figure 37-13 shows schematically some electronic, vibrational, and rotational energy levels of a diatomic molecule. The vibrational levels are labeled with the quantum number ν and the rotational levels are labeled with ℓ. The lower vibrational levels are evenly spaced, with $\Delta E = hf$. For higher vibrational levels, the approximation that the vibration is simple harmonic is not valid and the levels are not quite evenly spaced.

Note that the potential energy curves representing the force between the two atoms in the molecule do not have exactly the same shape for the electronic ground and excited states. This implies that the fundamental frequency of vibration f is different for different electronic states. For transitions between vibrational states of different electronic states, the selection rule $\Delta\nu = \pm 1$ does not hold. Such transitions result in the emission of photons of wavelengths in or near the visible spectrum, so the emission spectrum of a molecule for electronic transitions is also sometimes called the optical spectrum.

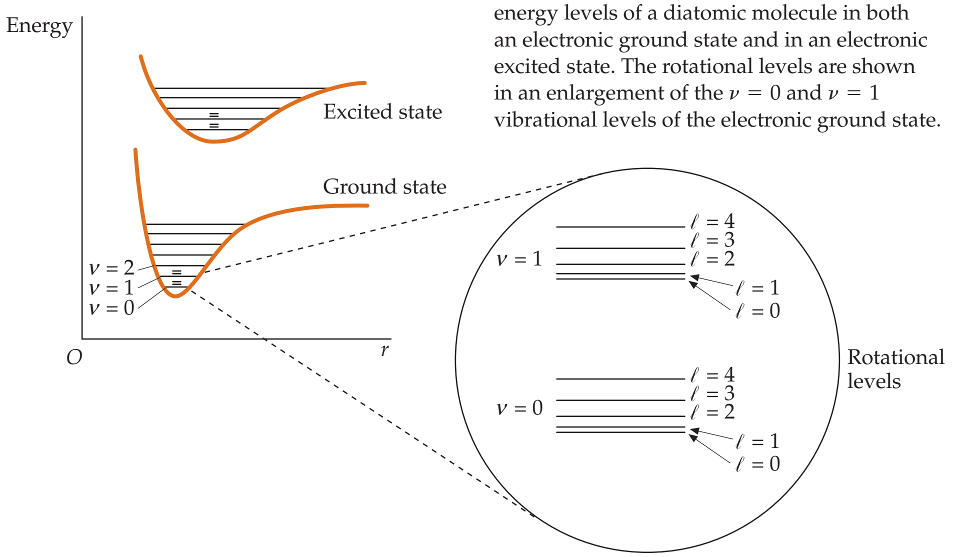

FIGURE 37-13 Vibrational and rotational energy levels of a diatomic molecule in both an electronic ground state and in an electronic excited state. The rotational levels are shown in an enlargement of the $\nu = 0$ and $\nu = 1$ vibrational levels of the electronic ground state.

The spacing of the rotational levels increases with increasing values of ℓ. Because the energies of rotation are so much smaller than those of vibrational excitation or electronic excitation of a molecule, molecular rotation shows up in optical spectra as a fine splitting of the spectral lines. When this fine structure is not resolved, the spectrum appears as bands, as shown in Figure 37-14*a.* Close inspection of these bands reveals that they have a fine structure due to the rotational energy levels, as shown in the enlargement in Figure 37-14*c.*

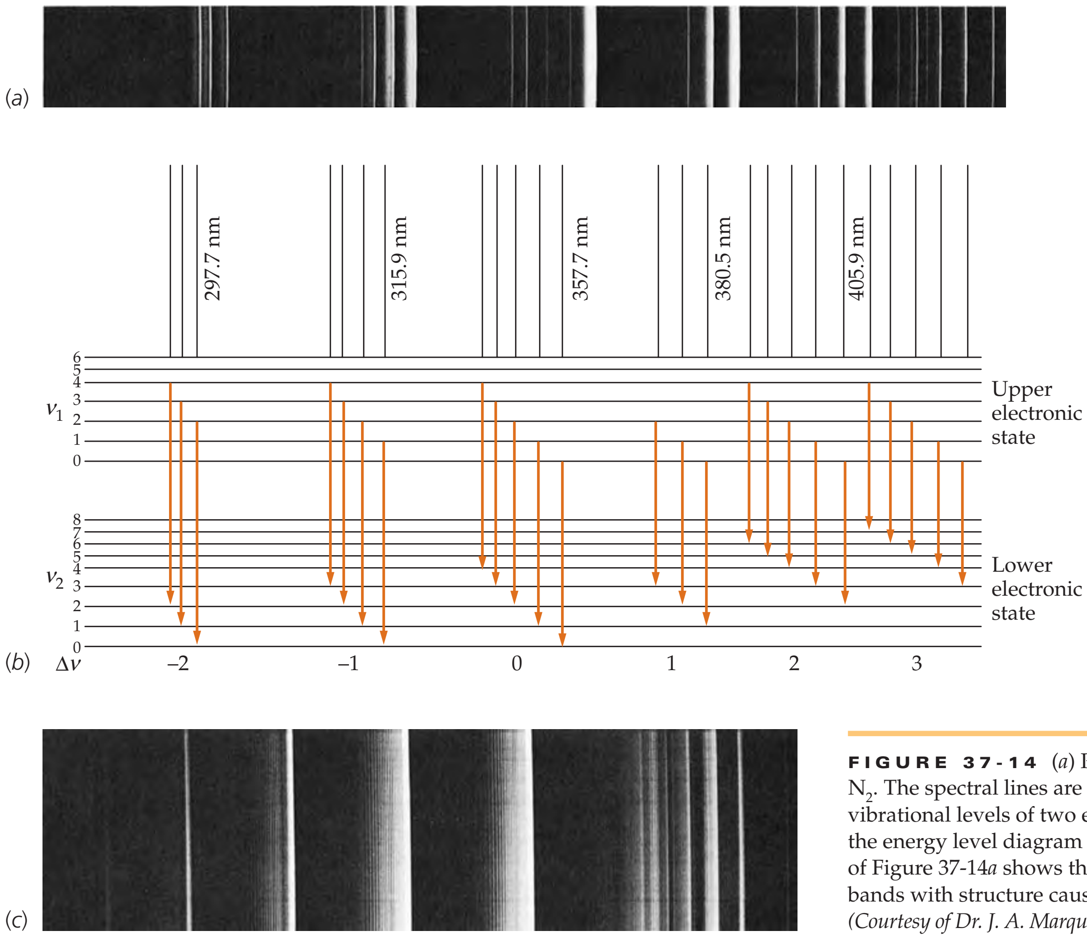

FIGURE 37-14 (*a*) Part of the emission spectrum of N_2. The spectral lines are due to transitions between the vibrational levels of two electronic states, as indicated in the energy level diagram (*b*). (*c*) An enlargement of part of Figure 37-14*a* shows that the apparent lines are in fact bands with structure caused by rotational levels. *(Courtesy of Dr. J. A. Marquissee.)*

ABSORPTION SPECTRA

Much molecular spectroscopy is done using infrared absorption techniques in which only the vibrational and rotational energy levels of the ground-state electronic level are excited. For ordinary temperatures, the vibrational energies are sufficiently large in comparison with the thermal energy kT that most of the molecules are in the lowest vibrational state $\nu = 0$, for which the energy is $E_0 = \frac{1}{2}hf$. The transition from $\nu = 0$ to $\nu = 1$ is the predominant transition in absorption. However, at room temperature the rotational energies are much less than the thermal energy kT. Thus, a number of the rotational energy states are occupied. If the molecule is originally in a vibrational state characterized by $\nu = 0$ and a rotational state characterized by the quantum number ℓ, the molecule's initial energy is

$$E_\ell = \tfrac{1}{2}hf + \ell(\ell + 1)E_{0\mathrm{r}} \qquad \text{37-20}$$

where $E_{0\mathrm{r}}$ is given by Equation 37-13. From this state, two transitions are permitted by the selection rules. For a transition to the next higher vibrational state $\nu = 1$ and a rotational state characterized by $\ell + 1$, the final energy is

$$E_{\ell+1} = \tfrac{3}{2}hf + (\ell + 1)(\ell + 2)E_{0\mathrm{r}} \qquad \text{37-21}$$

For a transition to the next higher vibrational state and to a rotational state characterized by $\ell - 1$, the final energy is

$$E_{\ell-1} = \tfrac{3}{2}hf + (\ell - 1)\ell E_{0\mathrm{r}} \qquad \text{37-22}$$

The energy differences therefore are

$$\Delta E_{\ell\to\ell+1} = E_{\ell+1} - E_\ell = hf + 2(\ell + 1)E_{0\mathrm{r}} \qquad \ell = 0, 1, 2, \ldots \qquad \text{37-23}$$

and

$$\Delta E_{\ell\to\ell-1} = E_{\ell-1} - E_\ell = hf - 2\ell E_{0\mathrm{r}} \qquad \ell = 1, 2, 3, \ldots \qquad \text{37-24}$$

(In Equation 37-24, ℓ begins at $\ell = 1$ rather than at $\ell = 0$ because from $\ell = 0$ only the transition $\ell \to \ell + 1$ can occur.) Figure 37-15 illustrates these transitions. The frequencies of these transitions are given by

$$f_{\ell\to\ell+1} = \frac{\Delta E_{\ell\to\ell+1}}{h} = f + \frac{2(\ell + 1)E_{0\mathrm{r}}}{h} \qquad \ell = 0, 1, 2, \ldots \qquad \text{37-25}$$

and

$$f_{\ell\to\ell-1} = \frac{\Delta E_{\ell\to\ell-1}}{h} = f - \frac{2\ell E_{0\mathrm{r}}}{h} \qquad \ell = 1, 2, 3, \ldots \qquad \text{37-26}$$

The frequencies for the transitions $\ell \to \ell + 1$ are thus $f + 2(E_{0\mathrm{r}}/h)$, $f + 4(E_{0\mathrm{r}}/h)$, $f + 6(E_{0\mathrm{r}}/h)$, and so forth; those corresponding to the transition $\ell \to \ell - 1$ are $f - 2(E_{0\mathrm{r}}/h)$, $f - 4(E_{0\mathrm{r}}/h)$, $f - 6(E_{0\mathrm{r}}/h)$, and so forth. We thus expect the absorption spectrum to contain frequencies equally spaced by $2E_{0\mathrm{r}}/h$ except for a gap of $4E_{0\mathrm{r}}/h$ at the vibrational frequency f, as shown in Figure 37-16. A measurement of the position of the gap gives f and a measurement of the spacing of the absorption peaks gives $E_{0\mathrm{r}}$, which is inversely proportional to the moment of inertia of the molecule.

Figure 37-17 shows the absorption spectrum of HCl. The double-peak structure results from the fact that chlorine occurs naturally in two isotopes, ^{35}Cl and ^{37}Cl, which gives HCl with two different moments of inertia. If all the rotational levels were equally populated initially, we would expect the intensities of each absorption line to be equal. However, the population of a rotational level is proportional to the degeneracy of the level, that is, to the number of states with the same value of ℓ, which is $2\ell + 1$, and to the Boltzmann factor $e^{-E/kT}$, where E is the energy of

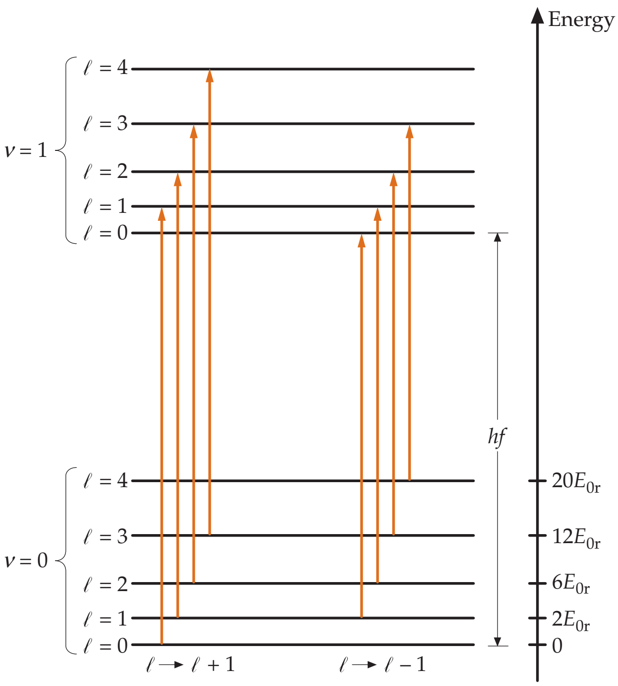

FIGURE 37-15 Absorptive transitions between the lowest vibrational states $\nu = 0$ and $\nu = 1$ in a diatomic molecule. These transitions obey the selection rule $\Delta\ell \pm 1$ and fall into two bands. The energies of the $\ell \rightarrow \ell + 1$ band are $hf + 2E_{0r}$, $hf + 4E_{0r}$, $hf + 6E_{0r}$, and so forth; whereas the energies of the $\ell \rightarrow \ell - 1$ band are $hf - 2E_{0r}$, $hf - 4E_{0r}$, $hf - 6E_{0r}$, and so forth.

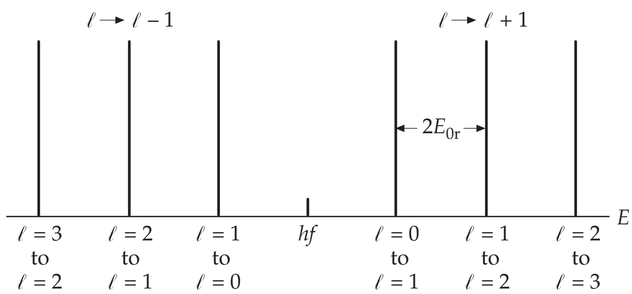

FIGURE 37-16 Expected absorption spectrum of a diatomic molecule. The right branch corresponds to transitions $\ell \rightarrow \ell + 1$ and the left branch corresponds to the transitions $\ell \rightarrow \ell - 1$. The lines are equally spaced by $2E_{0r}$. The energy midway between the branches is hf, where f is the frequency of vibration of the molecule.

the state. (The Boltzmann factor is presented in Chapter 17.) For low values of ℓ, the population increases slightly because of the degeneracy factor, whereas for higher values of ℓ, the population decreases because of the Boltzmann factor. The intensities of the absorption lines therefore increase with ℓ for low values of ℓ and then decrease with ℓ for high values of ℓ, as can be seen from the figure.

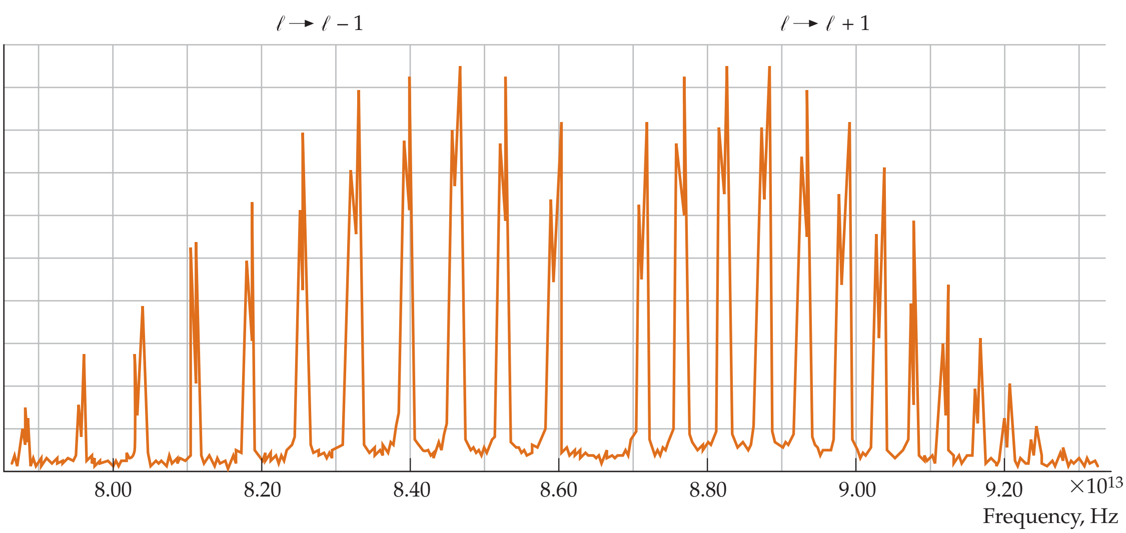

FIGURE 37-17 Absorption spectrum of the diatomic molecule HCl. The double-peak structure results from the two isotopes of chlorine, ^{35}Cl (abundance 75.5 percent) and ^{37}Cl (abundance 24.5 percent). The intensities of the peaks vary because the population of the initial state depends on ℓ.

Summary

1. Atoms are usually found in nature bonded to form molecules or in the lattices of crystalline solids.
2. Ionic bonnds and covalent bonds are the principal mechanisms responsible for forming molecules. Metallic bonds and van der Waals bonds are important in the formation of solids and liquids. Hydrogen bonds enable large biological molecules to maintain their shape.
3. Like atoms, molecules emit electromagnetic radiation when making a transition from a higher energy state to a lower energy state. The internal energy of a molecule can be separated into three parts: electronic, vibrational, and rotational energy.

TOPIC	RELEVANT EQUATIONS AND REMARKS	
1. Molecular Bonding		
Ionic	Ionic bonds result when an electron is transferred from one atom to another, resulting in a positive ion and a negative ion that bond together.	
Covalent	The covalent bond is the sharing of one or more electrons by atoms.	
van der Waals	The van der Waals bonds are weak bonds that result from the interaction of the instantaneous electric dipole moments of molecules.	
Hydrogen	The hydrogen bond results from the sharing of a proton of the hydrogen atom by other atoms.	
Metallic	In the metallic bond, the positive lattice ions of the metal are held together by a cloud of negative charge composed of free electrons.	
Mixed	A diatomic molecule formed from two identical atoms, such as O_2, must bond by covalent bonding. The bonding of two nonidentical atoms is often a mixture of covalent and ionic bonding. The percentage of ionic bonding can be found from the ratio of the magnitude of the measured electric dipole moment to the magnitude of the ionic electric dipole moment defined by $p_{\text{ionic}} = er_0$ where r_0 is the equilibrium separation of the ions.	37-5
2. *Polyatomic Molecules	The shapes of such polyatomic molecules as H_2O and NH_3 can be understood from the spatial distribution of the atomic-orbital or molecular-orbital wave functions. The tetravalent nature of the carbon atom is a result of the hybridization of the 2s and 2p atomic orbitals.	
3. Diatomic Molecules		
Moment of inertia	$I = \mu r_0^2$	37-14
	where $\mu = \dfrac{m_1 m_2}{m_1 + m_2}$	37-15
	r_0 is the equilibrium separation, and μ is the reduced mass.	
Rotational energy levels	$E_\ell = \ell(\ell + 1)E_{0r}$ where $E_{0r} = \hbar/2\pi$ and $\ell = 0, 1, 2, \ldots$	37-12
Vibrational energy levels	$E_\nu = \left(\nu + \frac{1}{2}\right)hf \qquad \nu = 0, 1, 2, \ldots$	37-18
Effective force constant k_F	$f = \dfrac{1}{2\pi}\sqrt{\dfrac{k_F}{\mu}}$	37-19
4. Molecular Spectra	The optical spectra of molecules have a band structure due to transitions between rotational levels. Information about the structure and bonding of a molecule can be found from its rotational and vibrational absorption spectrum involving transitions from one vibrational-rotational level to another. These transitions obey the selection rules $\Delta\nu = \pm 1 \qquad \Delta\ell = \pm 1$	

Answers to Practice Problems

37-1 17.6 percent

Answers to Concept Check

37-1 The moment of inertia of an atom is much much less than the moment of inertia of a diatomic molecule, so the amount of energy needed to change the rotational state of a single atom is much much larger than the amount needed for a diatomic molecule. At 300 K, the required energy is not available by way of collisions between atoms.

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • Would you expect NaCl to be polar or nonpolar? SSM

2 • Would you expect N_2 to be polar or nonpolar?

3 • Does neon naturally occur as Ne or Ne_2? Explain your answer.

4 • What type of bonding mechanism would you expect for atoms of (*a*) HF, (*b*) KBr, (*c*) N_2, (*d*) Ag in solid silver?

5 •• The elements in the far right column of the periodic table are sometimes called noble gases, both because they are gases under a wide range of conditions and because atoms of these elements almost never react with other atoms to form molecules or ionic compounds. However, atoms of noble gases can react if the resulting molecule is formed in an electronic excited state. An example is ArF. When it is formed in the excited state, it is written ArF* and is called an excimer (for *ex*cited d*imer*). Refer to Figure 37-13 and discuss how a diagram for the electronic, vibrational, and rotation energy levels of ArF and ArF* would look in which the ArF ground state is unstable and the ArF* excited state is stable. (Note: Excimers are used in certain kinds of lasers.) SSM

6 • Find other atoms that have the same subshell electron configurations in their two highest energy orbitals as carbon atoms do. Would you expect the same type of hybridization for these orbitals as for carbon?

7 • How does the value of the effective force constant calculated for a CO molecule in Example 37-4 compare with the value of the force constant of the suspension springs on a typical automobile, which is about 1.5 kN/m?

8 • Explain why the moment of inertia of a diatomic molecule increases slightly with increasing angular momentum.

9 • Why would you expect the separation distance between the two protons to be larger in a H_2^+ ion than in a H_2 molecule?

10 • At room temperature an atom typically absorb radiation only from the ground state, whereas a diatomic molecule typically absorbs radiation from many different rotational states. Why?

11 •• The vibrational energy levels of diatomic molecules are described by a single vibrational frequency f that is the frequency of vibration of the two atoms of the molecule along the line through their centers. Would you expect to see one or more than one vibrational frequency in molecules that have three or more atoms? Consider in particular a water molecule H_2O (Figure 37-9).

ESTIMATION AND APPROXIMATION

12 •• The potential energy for a diatomic molecule has a minimum as shown in Figure 37-13. Near this minimum, the graph for the energy as a function of distance between the atoms may be approximated as a parabola, leading to the harmonic oscillator model for the vibrating molecule. An improved approximation is called the anharmonic oscillator and leads to a modification of the expression for the energy $E_\nu = (\nu + \frac{1}{2})hf$, where $\nu = 0, 1, 2, \ldots$ (Equation 37-18). The modified expression for energy is $E_\nu = (\nu + \frac{1}{2})hf - (\nu + \frac{1}{2})^2 hf\alpha$, where $\nu = 0, 1, 2, \ldots$. For an O_2 molecule, the constants have the values $f = 4.74 \times 10^{13}\ \mathrm{s^{-1}}$ and $\alpha = 7.6 \times 10^{-3}$. Use this formula to estimate the smallest value of the quantum number ν for which the modified expression differs from the original expression by 10 percent.

13 •• To understand why quantum mechanics is not needed to describe many macroscopic systems, estimate the rotational energy quantum number ℓ and spacing between adjacent energy levels for a baseball ($m \sim 300$ g, $r \sim 3$ cm) spinning about its own axis at 20 rev/min. *Hint: Pick ℓ so the quantum energy formula $E_\ell = \ell(\ell + 1)\hbar^2/(2I)$, where $\ell = 0, 1, 2, \ldots$ (Equation 37-12) gives the correct energy for the given system. Then find the energy increase for the next highest energy level.*

14 •• Estimate the quantum number ν and spacing between adjacent energy levels for a 1.0-kg mass attached to spring. The spring has a force constant equal to 1200 N/m and the mass-spring system is vibrating with an amplitude of 3.0 cm. *Hint: Pick ν so that the quantum energy formula $E_\nu = (\nu + \frac{1}{2})hf$, where $\nu = 0, 1, 2, \ldots$ (Equation 37-18) gives the correct energy for the given system. Then find the energy increase for the next highest energy level.*

MOLECULAR BONDING

15 • Calculate the separation of Na^+ and Cl^- ions for which the potential energy of a single ionic unit (one Na^+ ion and one Cl^- ion) is -1.52 eV.

16 • The equilibrium separation of the atoms in a HF molecule is 0.0917 nm and the measured electric dipole moment of the molecule is $6.40 \times 10^{-30}\ \mathrm{C \cdot m}$. What percentage of the HF bond is ionic?

17 •• The dissociation energy of RbF is 5.12 eV, and the equilibrium separation of RbF is 0.227 nm. The electron affinity of a fluorine atom is -3.40 eV and the ionization energy of rubidium is 4.18 eV. Determine the core-repulsion energy of RbF.

18 •• The equilibrium separation of the K^+ and Cl^- ions in KCl is about 0.267 nm. (*a*) Calculate the potential energy of attraction of the ions. Assume that the ions are point charges at this separation. (*b*) The ionization energy of potassium is 4.34 eV and the electron affinity of chlorine is -3.62 eV. Calculate a value for the dissociation energy using the assumption that the energy of repulsion is negligible. (See Figure 37-1.) (*c*) The measured dissociation energy is 4.49 eV. What is the energy due to repulsion of the ions at the equilibrium separation?

19 •• Indicate an approximate value for the average value of the separation distance r for two vibrational levels on the potential energy curve for a diatomic molecule (one of the curves in Figure 37-13). Your teacher claims that the increase in r_{av} with increases in vibration energy explains why solids expand when heated. Do you agree? If so, give an argument supporting this claim. If not, give an argument opposing this claim.

20 •• Calculate the potential energy of attraction between the Na^+ and Cl^- ions at the equilibrium separation $r_0 = 0.236$ nm. Compare this result with the dissociation energy given in Figure 37-1. What is the energy due to repulsion of the ions at the equilibrium separation?

21 •• The equilibrium separation of the K^+ and F^- ions in KF is about 0.217 nm. (*a*) Calculate the potential energy of attraction of these ions. Assume that the ions are point charges at this separation. (*b*) The ionization energy of potassium is 4.34 eV and the electron affinity of fluorine is -3.40 eV. Find the dissociation energy by neglecting any energy of repulsion. (*c*) The measured dissociation energy is 5.07 eV. Calculate the energy due to repulsion of the ions at the equilibrium separation.

ENERGY LEVELS OF SPECTRA OF DIATOMIC MOLECULES

22 • The characteristic rotational energy E_{0r} for the rotation of a N_2 molecule is 2.48×10^{-4} eV. Using this value, find the separation distance of the 2 nitrogen atoms.

23 • The separation of the two oxygen atoms in a molecule of O_2 is actually slightly greater than the 0.100 nm used in Example 37-3. Furthermore, the characteristic energy of rotation E_{0r} for O_2 is 1.78×10^{-4} eV rather than the result obtained in that example. Use this value to calculate the separation distance of the two oxygen atoms. SSM

24 •• Show that the reduced mass of a diatomic molecule is always smaller than the mass of the molecule. Calculate the reduced mass for (*a*) H_2, (*b*) N_2, (*c*) CO, and (*d*) HCl. Express your answers in unified atomic mass units.

25 •• A CO molecule has a binding energy of approximately 11 eV. Find the vibrational quantum number ν that corresponds to 11 eV. (If a CO molecule actually had this much vibrational energy, it would "shake" apart.)

26 •• Derive the equation $I = \mu r_0^2$ (Equation 37-14) for the moment of inertia in terms of the reduced mass of a diatomic molecule.

27 •• The equilibrium separation between the atoms of a LiH molecule is 0.16 nm. Determine the energy separation between the $\ell = 3$ and $\ell = 2$ rotational levels of the diatomic molecule. SSM

28 •• The equilibrium separation of the K^+ and Cl^- ions in KCl is about 0.267 nm. Use this value together with the reduced mass of KCl to calculate the characteristic rotational energy E_{0r} (Equation 37-13) of KCl.

29 •• The central frequency for the absorption band of HCl shown in Figure 37-17 is at 8.66×10^{13} Hz, and the absorption peaks to either side of the central frequency are separated by about 6×10^{11} Hz. Use this information to find (*a*) the lowest (zero-point) vibrational energy for HCl, (*b*) the moment of inertia of HCl, and (*c*) the equilibrium separation of the two atoms.

30 •• Calculate the effective force constant for HCl from its reduced mass and from the fundamental vibrational frequency obtained from Figure 37-17.

31 •• The equilibrium separation between the atoms of a CO molecule is 0.113 nm. For a molecule, such as CO, that has a permanent electric dipole moment, radiative transitions obeying the selection rule $\Delta\ell = \pm 1$ between two rotational energy levels of the same vibrational level are allowed. (That is, the selection rule $\Delta\nu = \pm 1$ does not hold.) (*a*) Find the moment of inertia of CO and calculate the characteristic rotational energy E_{0r} (in eV). (*b*) Make an energy-level diagram for the rotational levels from $\ell = 0$ to $\ell = 5$ for some vibrational level. Label the energies in electron volts, starting with $E = 0$ for $\ell = 0$. Indicate on your diagram the transitions that obey $\Delta\ell = -1$, and calculate the energies of the photons emitted. (*c*) Find the wavelength of the photons emitted during each transition in (*b*). In what region of the electromagnetic spectrum are those photons? SSM

32 •• Two objects, one of mass m_1 and the other of mass m_2, are connected to opposite ends of a spring of force constant k_F. The objects are released from rest with the spring compressed. (*a*) Show that when the spring is extended and the object of mass m_1 is a distance Δr_1 from its equilibrium position in the center-of-mass reference frame, the force exerted by the spring is given by $F = -k_F(m_1/\mu)\Delta r_1$, where μ is the reduced mass. (*b*) Show that the frequency of oscillation f is related to k_F and μ by $2\pi f = \sqrt{k_F/\mu}$.

33 ••• Calculate the reduced masses μ for $H^{35}Cl$ and $H^{37}Cl$ molecules and the fractional difference $\Delta\mu/\mu$. Show that the mixture of isotopes in HCl leads to a fractional difference in the frequency of a transition from one rotational state to another given by $\Delta f/f = -\Delta\mu/\mu$. Compute $\Delta f/f$ and compare your result with Figure 37-17.

GENERAL PROBLEMS

34 • Show that when one atom of a diatomic molecule is much more massive than the other the reduced mass is approximately equal to the mass of the lighter atom.

35 •• The equilibrium separation between the nuclei of a CO molecule is 0.113 nm. Determine the energy difference between the $\ell = 2$ and $\ell = 1$ rotational energy levels of the molecule.

36 •• The effective force constant for a HF molecule is 970 N/m. Find the frequency of vibration for the molecule.

37 •• The frequency of vibration of a NO molecule is 5.63×10^{13} Hz. Find the effective force constant for NO.

38 •• The effective force constant of the hydrogen bond in a H_2 molecule is 580 N/m. Obtain the energies of the four lowest vibrational levels of the H_2, HD, and D_2 molecules, where H is protium and D is deuterium, and find the wavelengths of photons resulting from transitions between adjacent vibrational levels for each of the molecules.

39 •• The potential energy between two atoms in a molecule separated by a distance r can often be described rather well by the Lenard-Jones (or 6-12) potential function, which can be written as

$$U = U_0\left[\left(\frac{a}{r}\right)^{12} - 2\left(\frac{a}{r}\right)^{6}\right]$$

where U_0 and a are constants. Find the equilibrium separation r_0 in terms of a. *Hint: At the equilibrium separation the potential energy is a minimum.* Find U_{min}, the value of U when $r = r_0$. Use Figure 37-4 to obtain numerical values of r_0 and U_0 for a H_2 molecule, and express your answers in nanometers and electron volts.

40 •• In this problem, you are to determine how the van der Waals force between a polar molecule and a nonpolar molecule depends on the distance between the molecules. Let the polar molecule be at the origin and let its dipole moment be in the $+x$ direction. In addition, let the nonpolar molecule be on the x axis a distance x away. (*a*) How does the electric field strength due to an electric dipole vary with the distance from the dipole in a given direction? (*b*) Use (1) that the potential energy U of an electric dipole of dipole moment $\vec{p}$ in an electric field $\vec{E}$ can be expressed as $U = -\vec{p}\cdot\vec{E}$, and (2) that the induced dipole moment $\vec{p}\,'$ of the nonpolar molecule is in the direction of $\vec{E}$, and that p' is proportional to E, to determine how the potential energy of interaction of the two molecules depends on the separation distance x. (*c*) Using $F_x = -dU/dx$, determine how the force between the two molecules depends on distance.

41 •• Find the dependence of the force on separation distance between the two polar molecules described in Problem 40.

42 •• Use the infrared absorption spectrum of HCl in Figure 37-17 to obtain (*a*) the characteristic rotational energy E_{0r} (in eV) and (*b*) the vibrational frequency f and the vibrational energy hf (in eV).

43 • The dissociation energy is sometimes expressed in kilocalories per mole (kcal/mol). (*a*) Find the relation between the units eV/molecule and kcal/mol. (*b*) Find the dissociation energy of NaCl in kcal/mol.

CHAPTER 38

IT IS WELL KNOWN THAT ARSENIC IS A POISON. IT IS LESS WELL KNOWN THAT SILICON CRYSTALS THAT HAVE SMALL CONCENTRATIONS OF ARSENIC ATOMS HAVE A MUCH LOWER RESISTIVITY THAN DO CRYSTALS THAT ARE 100 PERCENT SILICON. *(The Natural History Museum/Alamy.)*

? Do you know how many atoms of arsenic it takes to increase the charge-carrier density by a factor of 5 million? (See Example 38-7.)

Solids

The first microscopic model of electric conduction in metals was proposed by Paul K. Drude in 1900 and developed by Hendrik A. Lorentz about 1909. This model successfully predicts that the current is proportional to the potential drop (Ohm's law) and relates the resistivity of conductors to the mean speed and the mean free path* of the free electrons within the conductor. However, when mean speed and mean free path are interpreted classically, there is a disagreement between the calculated values and the measured values of the resistivity, and a similar disagreement between the predicted temperature dependence and the observed temperature dependence that resistivity values have. Thus, the classical theory fails to adequately describe the resistivity of metals. Furthermore, the classical theory says nothing about the most striking

* The mean free path is the average distance traveled between collisions.

property of solids, namely, that some substances are conductors, others are insulators, and still others are semiconductors, which are substances whose resistivity falls between that of conductors and insulators.

When mean speed and mean free path are interpreted using quantum theory, both the magnitude and the temperature dependence of the resistivity are correctly predicted. In addition, quantum theory allows us to determine if a substance will be a conductor, an insulator, or a semiconductor.

In this chapter, we use our understanding of quantum mechanics to discuss the structure of solids and solid-state semiconducting devices. Much of our discussion will be qualitative because, as in atomic physics, the quantum-mechanical calculations are mathematically sophisticated.

38-1 THE STRUCTURE OF SOLIDS

The three phases of matter we observe everyday—gas, liquid, and solid—result from the relative strengths of the attractive forces between atoms and molecules and the thermal energies of the particles. Molecules and atoms in the gas phase have relatively large thermal kinetic energies, and such particles have little influence on one another except during their frequent but brief collisions. (By using the term thermal kinetic energies, we mean the kinetic energies of the molecules and atoms in the center-of-mass reference frame of the gas.) At sufficiently low temperatures, van der Waals forces will cause practically every substance to condense into a liquid and then into a solid. In liquids, the molecules or atoms are close enough—and their thermal kinetic energies are low enough—that they can develop a temporary **short-range order.** As their thermal kinetic energies are further reduced, the molecules or atoms form solids, which are characterized by a lasting order.

If a liquid is cooled slowly so that the kinetic energy of its molecules is reduced slowly, the molecules (or atoms or ions) may arrange themselves in a regular crystalline array, producing the maximum number of bonds and leading to a minimum potential energy. However, if the liquid is cooled rapidly so that its internal energy is removed before the molecules have a chance to arrange themselves, the solid formed is often not crystalline or the arrangement is not regular. Such a solid is called an **amorphous solid.** It displays short-range order but not the long-range order (the order over many molecular, atomic, or ionic diameters) that is characteristic of a crystal. Glass is a typical amorphous solid. A characteristic result of the long-range ordering of a crystal is that it has a well-defined melting point, whereas an amorphous solid merely softens as its temperature is increased. Many substances may solidify into either an amorphous state or a crystalline state depending on how the substances are prepared; others exist only in one such state or the other.

Most common solids are polycrystalline; that is, they consist of many single crystals that meet at *grain boundaries.* The size of a single crystal is typically a fraction of a millimeter. However, large single crystals do occur naturally and can be produced artificially. The most important property of a single crystal is the symmetry and regularity of its structure. It can be thought of as having a single unit structure that is repeated throughout the crystal. This smallest unit of a crystal is called the **unit cell;** its structure depends on the type of bonding—ionic, covalent, metallic, hydrogen, van der Waals—between the atoms, ions, or molecules. If more than one kind of atom is present, the structure will also depend on the relative sizes of the atoms.

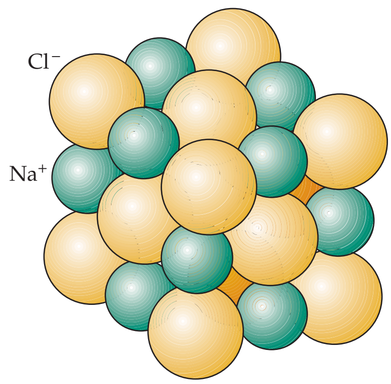

FIGURE 38-1 Face-centered-cubic structure of the NaCl crystal.

Figure 38-1 shows the structure unit cell of crystalline sodium chloride (NaCl). The Na^+ and Cl^- ions are spherically symmetric, and the Cl^- ion is approximately twice as large as the Na^+ ion. The minimum potential energy for this crystal occurs when an ion of either kind has six nearest neighbors of the other kind. This structure is called *face-centered-cubic* (fcc). Note that the Na^+ and Cl^- ions in solid NaCl are *not* paired into NaCl molecules.

The net attractive part of the potential energy of an ion in a crystal can be written

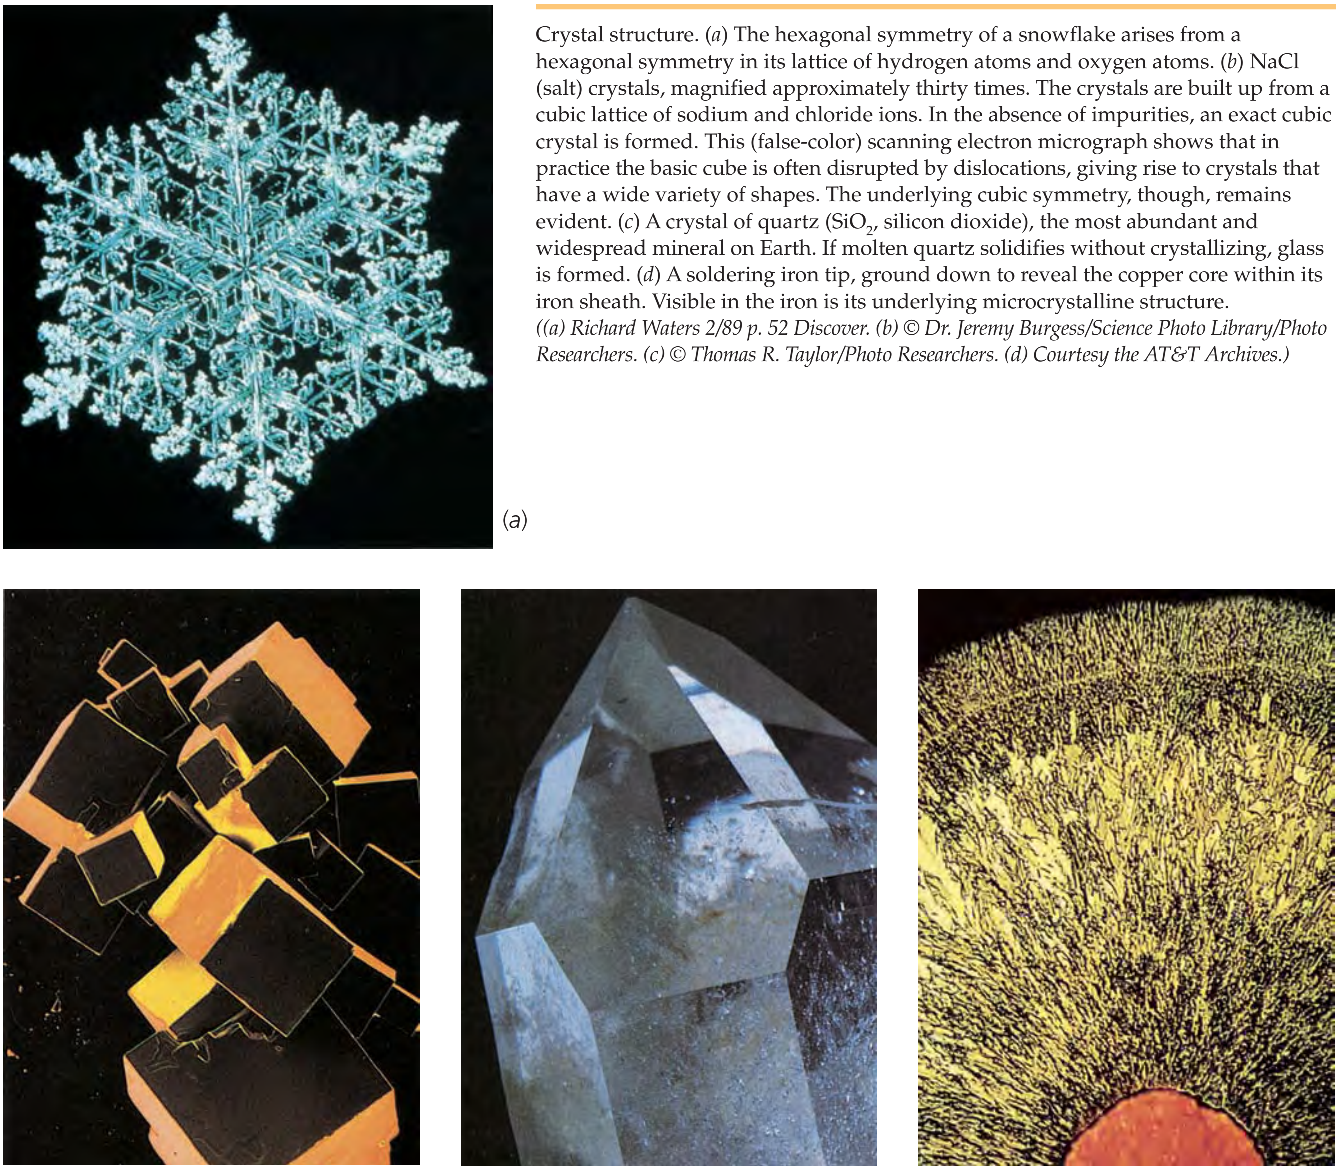
$$U_{\text{att}} = -\alpha \frac{ke^2}{r} \qquad \text{38-1}$$

where r is the (center-to-center) separation distance between neighboring ions (0.281 nm for the Na^+ and Cl^- ions in crystalline NaCl) and α, called the **Madelung constant,** depends on the geometry of the crystal. If only the six nearest neighbors of each ion in a face-centered-cubic crystalline structure were important, α would be six. However, in addition to the six neighbors of the opposite charge at a distance r, there are twelve ions of the same charge at a distance $\sqrt{2}r$, eight ions of opposite charge at a distance $\sqrt{3}r$, and so on. The Madelung constant is thus an infinite sum:

$$\alpha = 6 - \frac{12}{\sqrt{2}} + \frac{8}{\sqrt{3}} - \ldots \qquad \text{38-2}$$

The value of the Madelung constant for face-centered-cubic structures is $\alpha = 1.7476$.*

* A large number of terms are needed to calculate the Madelung constant accurately because the sum converges very slowly.



(a) (b) (c) (d)

Crystal structure. (*a*) The hexagonal symmetry of a snowflake arises from a hexagonal symmetry in its lattice of hydrogen atoms and oxygen atoms. (*b*) NaCl (salt) crystals, magnified approximately thirty times. The crystals are built up from a cubic lattice of sodium and chloride ions. In the absence of impurities, an exact cubic crystal is formed. This (false-color) scanning electron micrograph shows that in practice the basic cube is often disrupted by dislocations, giving rise to crystals that have a wide variety of shapes. The underlying cubic symmetry, though, remains evident. (*c*) A crystal of quartz (SiO_2, silicon dioxide), the most abundant and widespread mineral on Earth. If molten quartz solidifies without crystallizing, glass is formed. (*d*) A soldering iron tip, ground down to reveal the copper core within its iron sheath. Visible in the iron is its underlying microcrystalline structure.

When Na^+ and Cl^- ions are very close together, they repel each other because of the overlap of their electron orbitals and the exclusion-principle repulsion discussed in Section 37-1. A simple empirical expression for the potential energy associated with this repulsion that works fairly well is

$$U_{rep} = \frac{A}{r^n}$$

where A and n are constants. The total potential energy of an ion is then

$$U = -\alpha\frac{ke^2}{r} + \frac{A}{r^n} \qquad 38\text{-}3$$

The equilibrium separation $r = r_0$ is that at which the force $F = -dU/dr$ is zero. Differentiating and setting $dU/dr = 0$ at $r = r_0$, we obtain

$$A = \frac{\alpha ke^2 r_0^{n-1}}{n} \qquad 38\text{-}4$$

Substituting for A in Equation 38-3 gives

$$U = -\alpha\frac{ke^2}{r_0}\left[\frac{r_0}{r} - \frac{1}{n}\left(\frac{r_0}{r}\right)^n\right] \qquad 38\text{-}5$$

At $r = r_0$, we have

$$U(r_0) = -\alpha\frac{ke^2}{r_0}\left(1 - \frac{1}{n}\right) \qquad 38\text{-}6$$

If we know the equilibrium separation r_0, the value of n can be found approximately from the *dissociation energy* of the crystal, which is the energy needed to break up the crystal into atoms.

Example 38-1 Separation Distance between Na^+ and Cl^- in NaCl

Calculate the equilibrium separation r_0 for NaCl from the measured density of NaCl, which is $\rho = 2.16\ \mathrm{g/cm^3}$.

PICTURE We consider each ion to occupy a cubic volume of side r_0. The mass of 1 mol of NaCl is 58.4 g, which is the sum of the molar masses of sodium and chlorine. There are $2N_A$ ions in 1 mol of NaCl, where $N_A = 6.02 \times 10^{23}$ is Avogadro's number.

SOLVE

1. We consider each ion to occupy a cubic volume of side r_0. The volume v of one mole of NaCl equals the number of ions multiplied by the volume per ion:
$$v = 2N_A r_0^3$$

2. Relate r_0 to the density ρ and the molar mass M of NaCl:
$$\rho = \frac{M}{v} = \frac{M}{2N_A r_0^3}$$

3. Solve for r_0^3 and substitute the known values:
$$r_0^3 = \frac{M}{2N_A\rho} = \frac{58.4\ \mathrm{g}}{2(6.02 \times 10^{23})(2.16\ \mathrm{g/cm^3})}$$
$$= 2.25 \times 10^{-23}\ \mathrm{cm^3}$$
so
$$r_0 = 2.82 \times 10^{-8}\ \mathrm{cm} = \boxed{0.282\ \mathrm{nm}}$$

CHECK In Chapter 36, we found the diameter of the hydrogen atom in the ground state to be about 0.11 nm. Our step 3 result is less than three times larger. Thus, $r_0 = 0.282$ nm is plausible.

The measured dissociation energy of NaCl is 770 kJ/mol. Using $1\ \mathrm{eV} = 1.602 \times 10^{-19}$ J and the fact that 1 mol of NaCl has N_A pairs of ions, we can express the dissociation energy in electron volts per ion pair. The conversion between electron volts per ion pair and kilojoules per mole is

$$1\frac{\mathrm{eV}}{\text{ion pair}} \times \frac{6.022 \times 10^{23}\ \text{ion pairs}}{1\ \mathrm{mol}} \times \frac{1.602 \times 10^{-19}\ \mathrm{J}}{1\ \mathrm{eV}}$$

The result is

$$1\,\frac{\text{eV}}{\text{ion pair}} = 96.47\,\frac{\text{kJ}}{\text{mol}} \qquad 38\text{-}7$$

Thus, 770 kJ/mol = 7.98 eV per ion pair. Substituting −7.98 eV for $U(r_0)$, 0.282 nm for r_0, and 1.75 for α in Equation 38-6, we can solve for n. The result is $n = 9.35 \approx 9$.

Most ionic crystals, such as LiF, KF, KCl, KI, and AgCl, have a face-centered-cubic structure. Some elemental solids that have fcc structure are silver, aluminum, gold, calcium, copper, nickel, and lead.

Figure 38-2 shows the structure of CsCl, which is called the *body-centered-cubic* (bcc) structure. In this structure, each ion has eight nearest neighbor ions of the opposite charge. The Madelung constant for these crystals is 1.7627. Elemental solids that have bcc structure include barium, cesium, iron, potassium, lithium, molybdenum, and sodium.

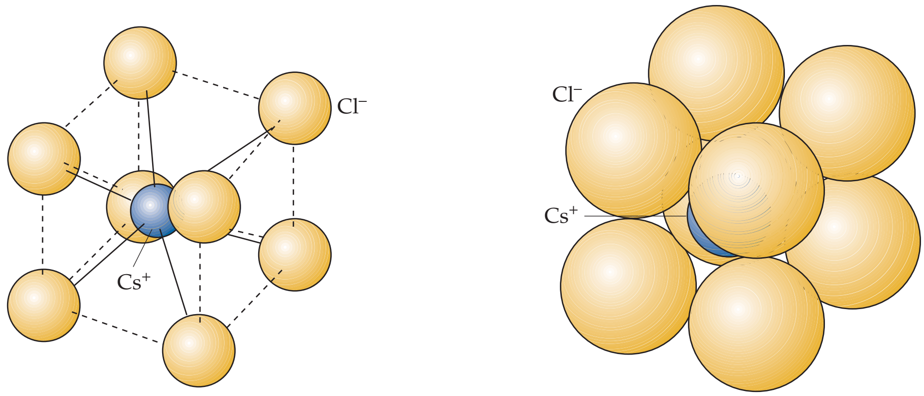

FIGURE 38-2 Body-centered-cubic structure of the CsCl crystal.

Figure 38-3 shows another important crystal structure: the *hexagonal close-packed* (hcp) structure. This structure is obtained by stacking identical spheres, such as bowling balls. In the first layer, each ball touches six others; thus, the name *hexagonal.* In the next layer, each ball fits into a triangular depression of the first layer. In the third layer, each ball fits into a triangular depression of the second layer, so it lies directly over a ball in the first layer. Elemental solids that have hcp structure include beryllium, cadmium, cerium, magnesium, osmium, and zinc.

For solids that have covalent bonding, the crystal structure is determined by the configuration of the bonds. Figure 38-4 illustrates the diamond structure of carbon, in which each atom is bonded to four other atoms as a result of hybridization, which is discussed in Section 37-2. This configuration is also the structure of germanium and silicon.

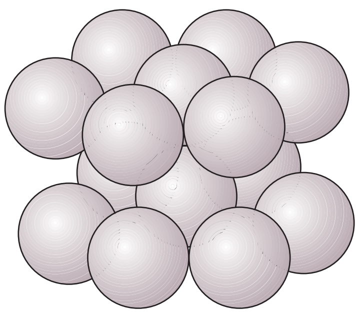

FIGURE 38-3 Hexagonal close-packed crystal structure.

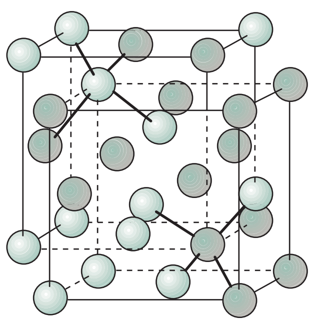

FIGURE 38-4 Diamond crystal structure. This structure can be considered to be a combination of two interpenetrating face-centered-cubic structures.

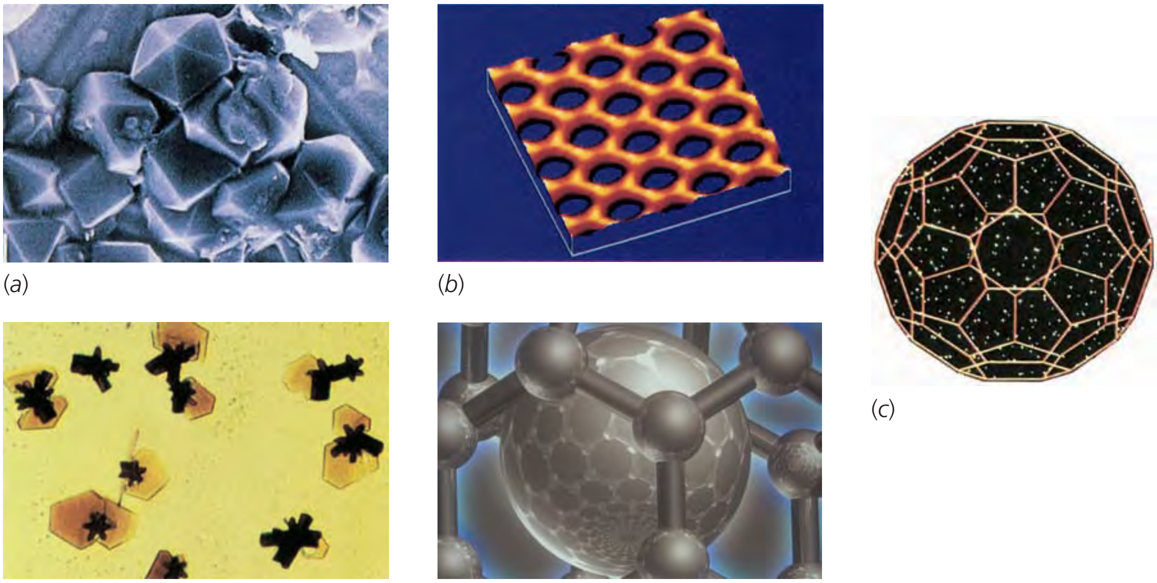

(a) (b) (c) (d) (e)

Carbon exists in three well-defined crystalline forms: diamond, graphite, and fullerenes (short for "buckminsterfullerenes"). Fullerenes were discovered in 1985. The forms differ in how the carbon atoms are packed together in a lattice. A fourth form of carbon, in which no well-defined crystalline form exists, is common charcoal. (*a*) Synthetic diamonds, magnified approximately 75,000 times. In diamond, each carbon atom is centered in a tetrahedron of four other carbon atoms. The strength of these bonds accounts for the hardness of a diamond. (*b*) An atomic-force micrograph of graphite. In graphite, carbon atoms are arranged in sheets, where each sheet is made up of atoms in hexagonal rings. The sheets slide easily across one another, a property that allows graphite to function as a lubricant. (*c*) A single sheet of carbon rings can be closed on itself if certain rings are allowed to be pentagonal, instead of hexagonal. A computer-generated image of the smallest such structure, C_{60}, is shown here. Each of the sixty vertices corresponds to a carbon atom; twenty of the faces are hexagons and twelve of the faces are pentagons. The same geometric pattern is encountered in a soccer ball. (*d*) Fullerene crystals, in which C_{60} molecules are close-packed. The smaller crystals tend to form thin brownish platelets; larger crystals are usually rodlike in shape. Fullerenes exist in which more than sixty carbon atoms appear. In the crystals shown here, about one-sixth of the molecules are C_{70}. (*e*) Carbon nanotubes have very interesting electrical properties. A single graphite sheet is a semimetal, which means that it has properties intermediate between those of semiconductors and those of metals. When a graphite sheet is rolled into a nanotube, not only do the carbon atoms have to line up around the circumference of the tube, but the wave functions of the electrons must also match up. This boundary-matching requirement places restrictions on these wave functions, which affects the motion of the electrons. Depending on exactly how the tube is rolled up, the nanotube can be either a semiconductor or a metal. *((a) Chris Kovach 3/91 p. 69 Discover. 38-2 A MICROSCOPIC PICTURE OF CONDUCTION

We consider a metal as a regular three-dimensional lattice of ions filling some volume V and having a large number N of electrons that are free to move throughout the whole metal. The number of free electrons in a metal is approximately one to four electrons per atom. In the absence of an electric field, the free electrons move about the metal randomly, much the way gas molecules move about in a container.

The current in a conducting wire segment is proportional to the voltage drop across the segment:

$$I = \frac{V}{R} \qquad (\text{or } V = IR)$$

The resistance R is proportional to the length L of the wire segment and inversely proportional to the cross-sectional area A:

$$R = \rho\frac{L}{A}$$

where ρ is the resistivity. Substituting $\rho L/A$ for R, and EL for V, we can write the current in terms of the electric field strength E and the resistivity. We have

$$I = \frac{V}{R} = \frac{EL}{\rho L/A} = \frac{1}{\rho}EA$$

Dividing both sides by the area A gives $I/A = (1/\rho)E$, or $J = (1/\rho)E$, where $J = I/A$ is the magnitude of the **current density** vector $\vec{J}$. The current density vector is defined as

$$\vec{J} = qn\vec{v}_d \qquad 38\text{-}8$$

DEFINITION—CURRENT DENSITY

where q, n, and $\vec{v}_d$ are the charge, the number density, and the drift velocity of the charge carrier. (This follows from Equation 25-3.) In vector form, the relation between the current density and the electric field is

$$\vec{J} = \frac{1}{\rho}\vec{E} \qquad 38\text{-}9$$

This relation is the point form of Ohm's law. The reciprocal of the resistivity is called the **conductivity.**

According to Ohm's law, the resistivity is independent of both the current density and the electric field $\vec{E}$. Combining Equations 38-8 and 38-9 gives

$$-en_e\vec{v}_d = \frac{1}{\rho}\vec{E} \qquad 38\text{-}10$$

where $-e$ and n_e have been substituted for q and n, respectively. According to Equation 38-10, the drift velocity $\vec{v}_d$ is proportional to $\vec{E}$.

In the presence of an electric field, a free electron experiences a force $-e\vec{E}$. If this were the only force acting, the electron would have a constant acceleration $-e\vec{E}/m_e$. However, Equation 38-10 implies a steady-state situation with a constant drift velocity that is proportional to the field $\vec{E}$. In the microscopic model, it is assumed that a free electron is accelerated for a short time and then makes a collision with a lattice ion. The velocity of the electron immediately after the collision is completely unrelated to the drift velocity. The justification for this assumption is that the magnitude of the drift velocity is extremely small compared with the speeds associated with the thermal kinetic energies of the free electrons.

For a typical free electron, its velocity a time t after its last collision is $\vec{v}_0 - (-e\vec{E}/m_e)t$, where $\vec{v}_0$ is its velocity immediately after that collision. Because the direction of $\vec{v}_0$ is random, it does not contribute to the average velocity of the electrons. Thus, the average velocity or drift velocity of the electrons is

$$\vec{v}_d = -\frac{e\vec{E}}{m_e}\tau \qquad 38\text{-}11$$

where τ is the average time since the last collision. Substituting for $\vec{v}_d$ in Equation 38-10, we obtain

$$-n_e e\left(\frac{e\vec{E}}{m_e}\tau\right) = \frac{1}{\rho}\vec{E}$$

so

$$\rho = \frac{m_e}{n_e e^2\tau} \qquad 38\text{-}12$$

The time τ, called the **collision time,** is also the average time between collisions.*

* It is tempting but incorrect to think that if τ is the average time between collisions, the average time since its last collision is $\frac{1}{2}\tau$ rather than τ. If you find this confusing, you may take comfort in the fact that Drude used the incorrect result $\frac{1}{2}\tau$ in his original work.

The average distance an electron travels between collisions is $v_{av}\tau$, which is called the mean free path λ:

$$\lambda = v_{av}\tau \tag{38-13}$$

where v_{av} is the mean speed of the electrons. (The mean speed is many orders of magnitude greater than the drift speed.) In terms of the mean free path and the mean speed, the resistivity is

$$\rho = \frac{m_e v_{av}}{n_e e^2 \lambda} \tag{38-14}$$

RESISTIVITY IN TERMS OF v_{AV} AND λ

According to Ohm's law, the resistivity ρ is independent of the electric field $\vec{E}$. Because m_e, n_e, and e are constants, the only quantities that could possibly depend on $\vec{E}$ are the mean speed v_{av} and the mean free path λ. Let us examine these quantities to see if they can possibly depend on the applied field $\vec{E}$.

CLASSICAL INTERPRETATION OF v_{av} AND λ

Classically, at $T = 0$ all the free electrons in a conductor should have zero kinetic energy. As the conductor is heated, the lattice ions acquire an average kinetic energy of $\frac{3}{2}kT$, which is imparted to the free electrons by the collisions between the electrons and the ions. (This is a result of the equipartition theorem studied in Chapters 17 and 18.) The free electrons would then have a Maxwell–Boltzmann distribution just like a gas of molecules. In equilibrium, the electrons would be expected to have a mean kinetic energy of $\frac{3}{2}kT$, which at ordinary temperatures (~300 K) is approximately 0.04 eV. At $T = 300$ K, their root-mean-square (rms) speed,* which is slightly greater than the mean speed, is

$$v_{av} \approx v_{rms} = \sqrt{\frac{3kT}{m_e}} = \sqrt{\frac{3(1.38 \times 10^{-23}\text{ J/K})(300\text{ K})}{9.11 \times 10^{-31}\text{kg}}} = 1.17 \times 10^5 \text{ m/s} \tag{38-15}$$

Note that this is about nine orders of magnitude greater than the typical drift speed of 3.5×10^{-5} m/s, which was calculated in Example 25-1. The very small drift speed caused by the electric field therefore has essentially no effect on the very large mean speed of the electrons, so v_{av} in Equation 38-14 cannot depend on the electric field $\vec{E}$.

The mean free path is related classically to the size of the lattice ions in the conductor and to the number of ions per unit volume. Consider one electron moving with speed v through a region of stationary ions that are assumed to be hard spheres (Figure 38-5). Assume the size of the electron is negligible. The electron will collide with an ion if it comes within a distance r from the center of the ion, where r is the radius of the ion. During some time interval Δt_1, the electron moves a distance vt_1. If there is an ion whose center is in the cylindrical volume $\pi r^2 v\Delta t_1$, the electron will collide with the ion. The electron will then change directions and collide with another ion in time Δt_2 if the center of the ion is in the volume $\pi r^2 vt_2$. Thus, in the total time $\Delta t = \Delta t_1 + \Delta t_2 + \ldots$, the electron will collide with the number of ions whose centers are in the volume $\pi r^2 v\Delta t$. The number of ions in this volume is $n_{ion}\pi r^2 v\Delta t$, where n_{ion} is the number of ions per unit volume.

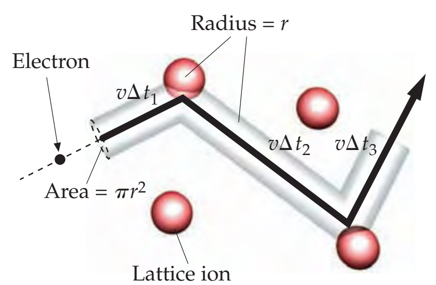

FIGURE 38-5 Model of an electron moving through the lattice ions of a conductor. The electron, which is considered to be a point particle, collides with an ion if it comes within a distance r of the center of the ion, where r is the radius of the ion. If the electron speed is v, it collides in time Δt with all the ions whose centers are in the volume $\pi r^2 v\Delta t$. While this picture is in accord with the classical Drude model for conduction in metals, it is in conflict with the current quantum-mechanical model presented later in this chapter.

* See Equation 17–21.

The total path length divided by the number of collisions is the mean free path:

$$\lambda = \frac{v\Delta t}{n_{\text{ion}}\pi r^2 v\Delta t} = \frac{1}{n_{\text{ion}}\pi r^2} = \frac{1}{n_{\text{ion}}A} \qquad \text{38-16}$$

where $A = \pi r^2$ is the cross-sectional area of a lattice ion.

SUCCESSES AND FAILURES OF THE CLASSICAL MODEL

Neither n_{ion} nor r depends on the electric field $\vec{E}$, so λ also does not depend on $\vec{E}$. v_{av} and λ do not depend on $\vec{E}$ according to their classical interpretations, so the resistivity ρ does not depend on $\vec{E}$ in accordance with Ohm's law. However, the classical theory gives an incorrect temperature dependence for the resistivity. Because λ depends only on the radius and the number density of the lattice ions, the only quantity in Equation 38-14 that depends on temperature in the classical theory is v_{av}, which is proportional to $\sqrt{T}$. But experiments show that ρ varies linearly with temperature. Furthermore, when ρ is calculated at $T = 300$ K using the Maxwell–Boltzmann distribution for v_{av} and Equation 38-16 for λ, the calculated result is about six times greater than the measured value.

The classical theory of conduction fails because electrons are not classical particles. The wave nature of the electrons must be considered. Because of the wave properties of electrons and the constraints described by the exclusion principle (to be discussed in the following section), the energy distribution of the free electrons in a metal is not even approximately given by the Maxwell–Boltzmann distribution. Furthermore, the collision of an electron with a lattice ion is not similar to the collision of a baseball with a tree. Instead, it involves the scattering of electron waves by the lattice. To understand the quantum theory of conduction, we need a qualitative understanding of the energy distribution of free electrons in a metal. This will also help us understand the origin of contact potentials between two dissimilar metals in contact and the contribution of free electrons to the heat capacity of metals.

38-3 FREE ELECTRONS IN A SOLID

One may want to consider free electrons in a metal to be an *electron gas* in a metal. However, molecules in an ordinary gas, such as air, obey the classical Maxwell–Boltzmann energy distribution, but the free electrons in a metal do not. Instead, they obey a quantum energy distribution called the *Fermi–Dirac distribution.* The main features of a free electron can be understood by considering the electron in a metal to be a particle in a box, a problem whose one-dimensional version we studied extensively in Chapter 34. We discuss the main features of a free electron semiquantitatively in this section and leave the details of the Fermi–Dirac distribution to Section 38-9.

ENERGY QUANTIZATION IN A BOX

In Chapter 34, we found that the wavelength associated with an electron of momentum p is given by the de Broglie relation:

$$\lambda = \frac{h}{p} \qquad \text{38-17}$$

where h is Planck's constant. When a particle is confined to a finite region of space, such as a box, only certain wavelengths λ_n, where $n = 1, 2, \ldots$, that are specified by standing-wave conditions are allowed. For a one-dimensional box of length L, the standing-wave condition is

$$n\frac{\lambda_n}{2} = L \qquad n = 1, 2, \ldots \qquad \text{38-18}$$

This results in the quantization of energy:

$$E_n = \frac{p_n^2}{2m} = \frac{(h/\lambda_n)^2}{2m} = \frac{h^2}{2m}\frac{1}{\lambda_n^2} = \frac{h^2}{2m}\frac{1}{(2L/n)^2}$$

or

$$E_n = n^2 E_1 \qquad \text{38-19}$$

where $E_1 = h^2/(8mL^2)$. The spatial wave function for the nth state is given by

$$\psi_n(x) = \sqrt{\frac{2}{L}}\sin(n\pi x/L) \qquad \text{38-20}$$

The quantum number n characterizes the wave function for a particular state and the energy of that state. In three-dimensional problems, three quantum numbers arise, one associated with each dimension.

THE EXCLUSION PRINCIPLE

The distribution of electrons among the possible energy states is described by the exclusion principle, which states that no two electrons in an atom can be in the same quantum state; that is, they cannot have the same set of values for their quantum numbers. The exclusion principle applies to all "spin one-half" particles (fermions), which include electrons, protons, and neutrons. These particles have a *spin* quantum number m_s which has two possible values, $+\frac{1}{2}$ and $-\frac{1}{2}$. The quantum state of a particle is characterized by the spin quantum number m_s and the quantum numbers associated with the spatial part of the wave function. Because the spin quantum numbers have just two possible values, the exclusion principle can be stated in terms of the spatial states:

> There can be at most two electrons with the same set of values for their *spatial* quantum numbers.
>
> EXCLUSION PRINCIPLE IN TERMS OF SPATIAL STATES

When there are more than two electrons in a system, such as an atom, only two can be in the lowest energy state. The third and fourth electrons must go into the second-lowest state, and so on.

Example 38-2 Boson-System Energy versus Fermion-System Energy

Compare the total energy of the ground state of five identical bosons of mass m in a one-dimensional box with the total energy of the ground state of five identical fermions of mass m in the same box.

PICTURE The ground state is the lowest possible energy state. The energy levels in a one-dimensional box are given by $E_n = n^2E_1$, where $E_1 = h^2/(8mL^2)$. (This is in accord with Equation 38-19.) The lowest energy for five bosons occurs when all the bosons are in the state $n = 1$, as shown in Figure 38-6*a*. For fermions, the lowest state occurs when two fermions are in the state $n = 1$, two fermions are in the state $n = 2$, and one fermion is in the state $n = 3$, as shown in Figure 38-6*b*.

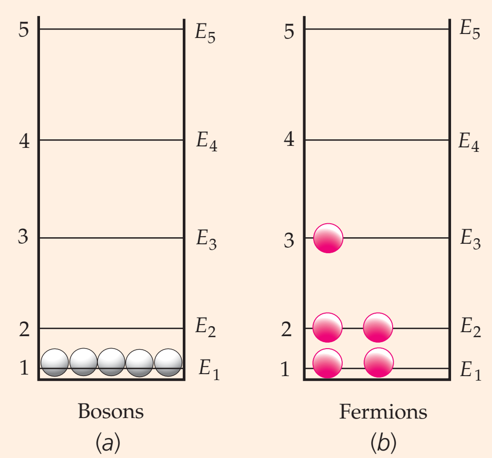

FIGURE 38-6

SOLVE

1. The energy of five bosons in the state $n = 1$ is: $E = 5E_1$

2. The energy of two fermions in the state $n = 1$, two fermions in the state $n = 2$, and one fermion in the state $n = 3$ is: $E = 2E_1 + 2E_2 + 1E_3 = 2E_1 + 2(2)^2E_1 + 1(3)^2E_1$ $= 2E_1 + 8E_1 + 9E_1 = 19E_1$

3. Compare the total energies: $\boxed{\text{The five identical fermions have 3.8 times the total energy of the five identical bosons.}}$

CHECK The fact that fermions must have different quantum states has a large effect on the total energy of a multiple-particle system, as expected.

THE FERMI ENERGY

When there are many electrons in a box, at $T = 0$ the electrons will occupy the lowest energy states consistent with the exclusion principle. If we have N electrons, we can put two electrons in the lowest energy level, two electrons in the next lowest energy level, and so on. The N electrons thus fill the lowest $N/2$ energy levels (Figure 38-7). The energy of the last filled (or half-filled) level at $T = 0$ is called the Fermi energy E_F. If the electrons moved in a one-dimensional box, the Fermi energy would be given by Equation 38-19, with $n = N/2$:

$$E_F = \left(\frac{N}{2}\right)^2 \frac{h^2}{8m_eL^2} = \frac{h^2}{32m_e}\left(\frac{N}{L}\right)^2 \qquad 38\text{-}21$$

FERMI ENERGY AT $T = 0$ IN ONE DIMENSION

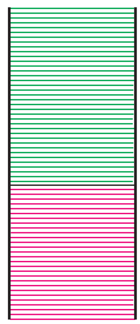

FIGURE 38-7 At $T = 0$ the electrons fill up the allowed energy states to the Fermi energy E_F. The levels are so closely spaced that they can be assumed to be continuous.

In a one-dimensional box, the Fermi energy depends on the number of free electrons per unit length of the box.

PRACTICE PROBLEM 38-1

Suppose there is an ion, and therefore a free electron, every 0.100 nm in a one-dimensional box. Calculate the Fermi energy. *Hint: Write Equation* 38-21 *as*

$$E_F = \frac{(hc)^2}{32m_ec^2}\left(\frac{N}{L}\right)^2 = \frac{(1240\ \text{eV}\cdot\text{nm})^2}{32(0.511\ \text{MeV})}\left(\frac{N}{L}\right)^2$$

In our model of conduction, the free electrons move in a *three-dimensional* box of volume V. The derivation of the Fermi energy in three dimensions is somewhat difficult, so we will just give the result. In three dimensions, the Fermi energy at $T = 0$ is

$$E_F = \frac{h^2}{8m_e}\left(\frac{3N}{\pi V}\right)^{2/3} \qquad 38\text{-}22a$$

FERMI ENERGY AT $T = 0$ IN THREE DIMENSIONS

The Fermi energy depends on the number density of free electrons N/V. Substituting numerical values for the constants gives

$$E_F = (0.3646\ \text{eV}\cdot\text{nm}^2)\left(\frac{N}{V}\right)^{2/3} \qquad 38\text{-}22b$$

FERMI ENERGY AT $T = 0$ IN THREE DIMENSIONS

Example 38-3 The Fermi Energy for Copper

The number density for electrons in copper was calculated in Example 25-1 and found to be $84.7/\text{nm}^3$. Calculate the Fermi energy at $T = 0$ for copper.

PICTURE The Fermi energy is given by Equations 38-22.

SOLVE

1. The Fermi energy is given by Equation 38-22*b*:

$$E_F = (0.3646\ \text{eV}\cdot\text{nm}^2)\left(\frac{N}{V}\right)^{2/3}$$

2. Substitute the given number density for copper:

$$E_F = (0.3646\ \text{eV}\cdot\text{nm}^2)(84.7/\text{nm}^3)^{2/3}$$
$$= \boxed{7.03\ \text{eV}}$$

CHECK The Fermi energy (the step-2 result) is much greater than kT at room temperatures as expected. For example, at $T = 300$ K, kT is only about 0.026 eV.

PRACTICE PROBLEM 38-2 Use Equation 38-22*b* to calculate the Fermi energy at $T = 0$ for gold, which has a free-electron number density of $59.0/\text{nm}^3$.

Table 38-1 lists the free-electron number densities and Fermi energies at $T = 0$ for several metals.

The free electrons in a metal are sometimes referred to as a Fermi gas. (They constitute a gas of fermions.) The average energy of a free electron can be calculated from the complete energy distribution of the electrons, which is discussed in Section 38-9. At $T = 0$, the average energy turns out to be

$$E_{av} = \tfrac{3}{5}E_F \qquad 38\text{-}23$$

AVERAGE ENERGY OF ELECTRONS IN A FERMI GAS AT $T = 0$

Table 38-1 Free-Electron Number Densities* and Fermi Energies at $T = 0$ for Selected Elements

	Element	N/V, electrons/nm^3	E_F, eV
Al	Aluminum	181	11.7
Ag	Silver	58.6	5.50
Au	Gold	59.0	5.53
Cu	Copper	84.7	7.03
Fe	Iron	170	11.2
K	Potassium	14.0	2.11
Li	Lithium	47.0	4.75
Mg	Magnesium	86.0	7.11
Mn	Manganese	165	11.0
Na	Sodium	26.5	3.24
Sn	Tin	148	10.2
Zn	Zinc	132	9.46

* Number densities are measured using the Hall effect, discussed in Section 26-4.

For copper, E_{av} is approximately 4 eV. This average energy is huge compared with thermal energies of about $kT \approx 0.026$ eV at a temperature of $T = 300$ K. This result is very different from the classical Maxwell–Boltzmann distribution result that at $T = 0$, $E = 0$, and that at some temperature T, E is of the same order as kT.

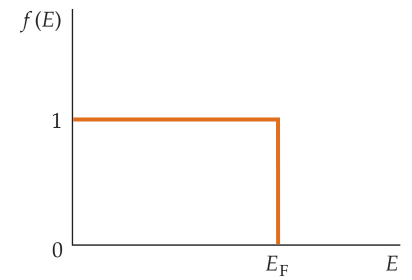

FIGURE 38-8 Fermi factor versus energy at $T = 0$.

THE FERMI FACTOR AT $T = 0$

The probability of an energy state being occupied is called the **Fermi factor,** $f(E)$. At $T = 0$ all the states below E_F are filled, whereas all those above that energy are empty, as shown in Figure 38-8. Thus, at $T = 0$ the Fermi factor is simply

$$f(E) = \begin{cases} 1 & E < E_F \\ 0 & E > E_F \end{cases} \qquad 38\text{-}24$$

THE FERMI FACTOR FOR $T > 0$

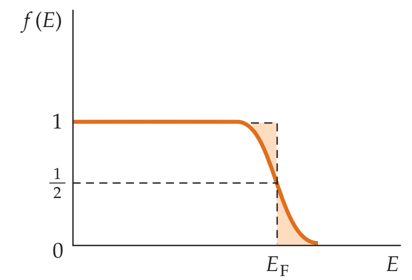

FIGURE 38-9 The Fermi factor for some temperature T. Some electrons that have energies near the Fermi energy are excited, as indicated by the shaded regions. The Fermi energy E_F is that value of E for which $f(E) = \frac{1}{2}$.

At temperatures greater than $T = 0$, some electrons will occupy higher energy states because of thermal energy gained during collisions with the lattice. However, an electron cannot move to a higher or lower state unless it is unoccupied. Because the kinetic energy of the lattice ions is of the order of kT, electrons cannot gain much more energy than kT in collisions with the lattice ions. Therefore, only those electrons that have energies within about kT of the Fermi energy can gain energy as the temperature is increased. At 300 K, kT is only 0.026 eV, so the exclusion principle prevents all but a very few electrons near the top of the energy distribution from gaining energy through random collisions with the lattice ions. Figure 38-9 shows a plot of the Fermi factor for some temperature T. Because for $T > 0$ there is no distinct energy that separates filled levels from unfilled levels, the definition of the Fermi energy must be slightly modified. At temperature T, the Fermi energy is defined to be the energy of the energy state for which the probability of being occupied is $\frac{1}{2}$. For all but extremely high temperatures, the difference between the Fermi energy at temperature T and the Fermi energy at temperature $T = 0$ is very small.

The **Fermi temperature** T_F is defined by

$$kT_F = E_F \qquad 38\text{-}25$$

For temperatures much lower than the Fermi temperature, the average energy of the lattice ions will be much less than the Fermi energy, and the electron energy distribution will not differ greatly from that at $T = 0$.

Example 38-4 The Fermi Temperature for Copper

Find the Fermi temperature for copper.

PICTURE We use Equation 38-25 to find the Fermi temperature. The Fermi energy for copper at $T = 0$, calculated in Example 38-3, is 7.03 eV.

SOLVE

Use $E_F = 7.03$ eV and $k = 8.617 \times 10^{-5}$ eV/K in Equation 38-25:

$$T_F = \frac{E_F}{k} = \frac{7.03 \text{ eV}}{8.617 \times 10^{-5} \text{ eV/K}} = \boxed{81\,600 \text{ K}}$$

CHECK The Fermi temperature is very high, as expected.

TAKING IT FURTHER We can see from this example that the Fermi temperature of copper is much greater than any temperature T for which copper remains a solid.

Because an electric field in a conductor accelerates all of the conduction electrons together, the exclusion principle does not prevent the free electrons in filled states from participating in conduction. Figure 38-10 shows the Fermi factor in one dimension versus *velocity* for an ordinary temperature. The factor is approximately 1 for velocities v_x in the range $-u_F < v_x < u_F$, where the Fermi speed u_F is related to the Fermi energy by $E_F = \frac{1}{2}mu_F^2$. Then

$$u_F = \sqrt{\frac{2E_F}{m_e}} \qquad 38\text{-}26$$

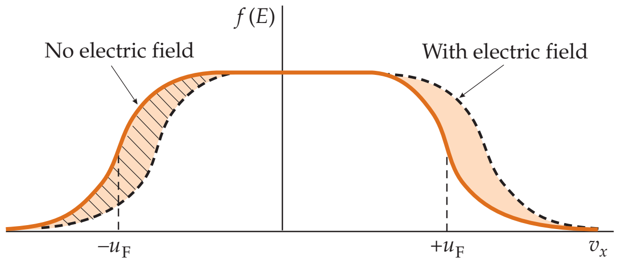

FIGURE 38-10 Fermi factor versus velocity in one dimension with no electric field (solid) and with an electric field in the $-x$ direction (dashed). The difference is greatly exaggerated.

Example 38-5 The Fermi Speed for Copper

Calculate the Fermi speed for copper.

PICTURE We use Equation 38-26 to find the Fermi speed. The Fermi energy for copper at $T = 0$, calculated in Example 38-3, is 7.03 eV.

SOLVE

Use Equation 38-26 with $E_F = 7.03$ eV:

$$u_F = \sqrt{\frac{2(7.03\text{ eV})}{9.11 \times 10^{-31}\text{ kg}}\left(\frac{1.60 \times 10^{-19}\text{ J}}{1\text{ eV}}\right)} = \boxed{1.57 \times 10^6\text{ m/s.}}$$

CHECK As expected, the result (the Fermi speed for copper) is high, but less than the speed of light.

The dashed curve in Figure 38-10 shows the Fermi factor after the electric field has been acting for some time t. Although all of the free electrons have their velocities shifted in the direction opposite to the electric field, the net effect is equivalent to shifting only the electrons near the Fermi energy.

CONTACT POTENTIAL

When two different metals are placed in contact, a potential difference $V_{contact}$ called the **contact potential** develops between them. The contact potential depends on both the work functions of the two metals, ϕ_1 and ϕ_2 (we encountered work functions when the photoelectric effect was introduced in Chapter 34), and the Fermi energies of the two metals. When the metals are in contact, the total energy of the system is lowered if electrons near the boundary move from the metal that has the higher Fermi energy into the metal that has the lower Fermi energy until the Fermi energies of the two metals are the same, as shown in Figure 38-11. When equilibrium is established, the metal that has the lower initial Fermi energy is negatively charged and the other metal is positively charged, so that between them there is a potential difference $V_{contact}$ given by

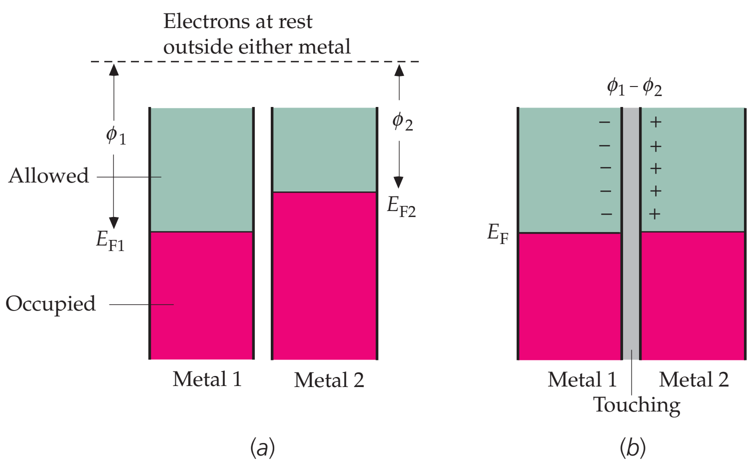

FIGURE 38-11 (*a*) Energy levels for two different metals that have different Fermi energies E_F and work functions ϕ. The work function is the difference between the energy of an electron at rest outside the metal and the Fermi energy within the metal. (*b*) When the metals are in contact, electrons flow from the metal that initially has the higher Fermi energy to the metal that initially has the lower Fermi energy until the Fermi energies are equal.

$$V_{contact} = \frac{\phi_1 - \phi_2}{e} \qquad 38\text{-}27$$

Table 38-2 lists the work functions for several metals.

Table 38-2 Work Functions for Some Metals

	Metal	ϕ, eV		Metal	ϕ, eV
Ag	Silver	4.7	K	Potassium	2.1
Au	Gold	4.8	Mn	Manganese	3.8
Ca	Calcium	3.2	Na	Sodium	2.3
Cu	Copper	4.1	Ni	Nickel	5.2

Example 38-6 Contact Potential between Silver and Tungsten

The threshold wavelength for the photoelectric effect is 271 nm for tungsten and 262 nm for silver. What is the contact potential developed when silver and tungsten are placed in contact?

PICTURE The contact potential is proportional to the difference in the work functions for the two metals (Equation 38-27). The work function ϕ can be found from the given threshold wavelengths using $\phi = hc/\lambda_t$ (Equation 34-4).

SOLVE

1. The contact potential is given by Equation 38-27:
$$V_{\text{contact}} = \frac{\phi_1 - \phi_2}{e}$$

2. The work function is related to the threshold wavelength (Equation 34-4):
$$\phi = \frac{hc}{\lambda_t}$$

3. Substitute $\lambda_t = 271$ nm for tungsten (the symbol for tungsten is W):
$$\phi_W = \frac{hc}{\lambda_t} = \frac{1240\ \text{eV}\cdot\text{nm}}{271\ \text{nm}} = 4.58\ \text{eV}$$

4. Substitute $\lambda_t = 262$ nm for silver:
$$\phi_{Ag} = \frac{1240\ \text{eV}\cdot\text{nm}}{262\ \text{nm}} = 4.73\ \text{eV}$$

5. The contact potential is thus:
$$V_{\text{contact}} = \frac{\phi_{Ag} - \phi_W}{e} = 4.73\ \text{V} - 4.58\ \text{V} = \boxed{0.15\ \text{V}}$$

CHECK As expected, the contact potential is small (less than one volt). You do not get large potential differences just by putting two metals in contact.

HEAT CAPACITY DUE TO ELECTRONS IN A METAL

The quantum-mechanical description of the electron distribution in metals allows us to understand why the contribution of the free electrons to the heat capacity of a metal is much less that of the ions. According to the classical equipartition theorem, the energy of the lattice ions in n moles of a solid is $3nRT$, and thus the molar specific heat is $c' = 3R$, where R is the universal gas constant (see Section 18-7). In a metal, the number of free electrons is approximately equal to the number of lattice ions. If these electrons obey the classical equipartition theorem, they should have an energy of $\frac{3}{2}nRT$ and contribute an additional $\frac{3}{2}R$ to the molar specific heat. But measured heat capacities of metals are just slightly greater than those of insulators. We can understand this result because at some temperature T, only those electrons that have energies near the Fermi energy can be excited by random collisions with the lattice ions. The number of those electrons is of the order of $(kT/E_F)N$, where N is the total number of free electrons. The energy of those electrons is increased from that at $T = 0$ by an amount that is of the order of kT. So the total increase in thermal energy is of the order of $(kT/E_F)N \times kT$.

We can thus express the energy of N electrons at temperature T as

$$E = NE_{\text{av}}(0) + \alpha N \frac{kT}{E_{\text{F}}} kT \qquad 38\text{-}28$$

where $E_{\text{av}}(0)$ is the average energy at $T = 0$ and α is a constant that we expect to be of the order of 1 if our reasoning is correct. The calculation of α is quite challenging. The result is $\alpha = \pi^2/4$. Using this result and writing E_{F} in terms of the Fermi temperature, $E_{\text{F}} = kT_{\text{F}}$, we obtain the following for the contribution of the free electrons to the heat capacity at constant volume:

$$C_{\text{V}} = \frac{dE}{dT} = 2\alpha Nk \frac{kT}{E_{\text{F}}} = \frac{1}{2}\pi^2 nR \frac{T}{T_{\text{F}}}$$

where we have written Nk in terms of the gas constant R ($R = Nk/n$). The molar specific heat at constant volume is then

$$c'_{\text{V}} = \frac{1}{2}\pi^2 R \frac{T}{T_{\text{F}}} \qquad 38\text{-}29$$

We can see that because of the large value of T_{F}, the contribution of the free electrons is a small fraction of R at ordinary temperatures. Because $T_{\text{F}} = 81\,600$ K for copper, the molar specific heat of the free electrons at $T = 300$ K is

$$c'_{\text{V}} = \frac{1}{2}\pi^2 \frac{300 \text{ K}}{81\,600 \text{ K}} R \approx 0.02R$$

which is in good agreement with the experiment.

38-4 QUANTUM THEORY OF ELECTRICAL CONDUCTION

We can use Equation 38-14 for the resistivity if we use the Fermi speed u_{F} (Equation 38-26) in place of v_{av}:

$$\rho = \frac{m_{\text{e}} u_{\text{F}}}{n_{\text{e}} e^2 \lambda} \qquad 38\text{-}30$$

We now have two problems. First, because the Fermi speed u_{F} is approximately independent of temperature, the resistivity given by Equation 38-30 is independent of temperature unless the mean free path should depend on the temperature. The second problem concerns magnitudes. As mentioned earlier, the classical expression for resistivity using v_{av} calculated from the Maxwell–Boltzmann distribution gives values that are about 6 times too large at $T = 300$ K. Because the Fermi speed u_{F} is about 16 times the Maxwell-Boltzmann value of v_{av}, the magnitude of ρ predicted by Equation 38-30 will be approximately 100 times greater than the experimentally determined value. The resolution of both of these problems lies in the calculation of the mean free path λ.

THE SCATTERING OF ELECTRON WAVES

In Equation 38-16 for the classical mean free path $\lambda = 1/(n_{\text{ion}}A)$, the quantity $A = \pi r^2$ is the cross-sectional area of the lattice ion as seen by an electron. In the quantum calculation, the mean free path is related to the scattering of electron waves by the crystal lattice. Detailed calculations show that, for a *perfectly* ordered crystal, $\lambda = \infty$; that is, there is no scattering of the electron waves. The scattering of electron waves arises because of *imperfections* in the crystal lattice, which have nothing to do with the actual cross-sectional area A of the lattice ions.

According to the quantum theory of electron scattering, A depends merely on *deviations* of the lattice ions from a perfectly ordered array and not on the size of the ions. The most common causes of such deviations are thermal vibrations of the lattice ions or impurities.

We can use $\lambda = 1/(n_{\text{ion}}A)$ for the mean free path if we reinterpret the area A. Figure 38-12 compares the classical picture and the quantum picture of this area. In the quantum picture, the lattice ions are points that have no size but present an area $A = \pi r_0^2$, where r_0 is the amplitude of thermal vibrations. In Chapter 14, we saw that the energy of vibration in simple harmonic motion is proportional to the square of the amplitude, which is πr_0^2. Thus, the effective area A is proportional to the energy of vibration of the lattice ions. From the equipartition theorem,* we know that the average energy of vibration is proportional to kT. Thus, A is proportional to T, and λ is proportional to $1/T$. Then the resistivity given by Equation 38-14 is proportional to T, in agreement with experiment.

The effective area A due to thermal vibrations can be calculated, and the results give values for the resistivity that are in agreement with experiments. At $T = 300$ K, for example, the effective area turns out to be about 100 times smaller than the actual cross-sectional area of a lattice ion. We see, therefore, that the free-electron model of metals gives a good account of electrical conduction if the classical mean speed v_{av} is replaced by the Fermi speed u_{F} and if the collisions between electrons and the lattice ions are interpreted in terms of the scattering of electron waves, for which only deviations from a perfectly ordered lattice are important.

The presence of impurities in a metal also causes deviations from perfect regularity in the crystal lattice. The effects of impurities on resistivity are approximately independent of temperature. The resistivity of a metal containing impurities can be written $\rho = \rho_{\text{t}} + \rho_{\text{i}}$, where ρ_{t} is the resistivity due to the thermal motion of the lattice ions and ρ_{i} is the resistivity due to impurities. Figure 38-13 shows typical resistance versus temperature curves for metals with impurities. As the absolute temperature approaches zero, the resistivity due to thermal motion approaches zero, and the total resistivity approaches the resistivity due to impurities, which is constant.

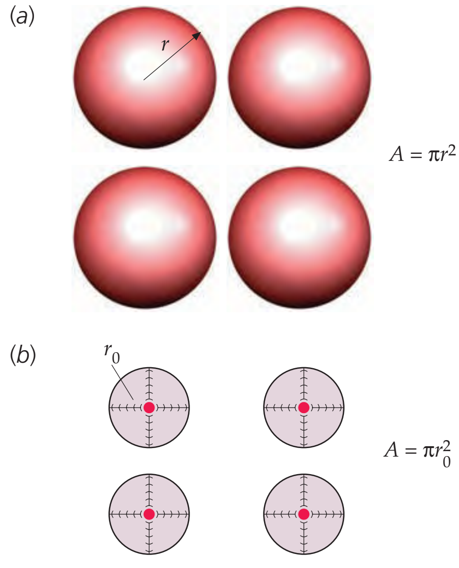

FIGURE 38-12 (*a*) Classical picture of the lattice ions as spherical balls of radius r that each present an area πr^2 to the electrons. (*b*) Quantum-mechanical picture of the lattice ions as points that are vibrating in three dimensions. The area presented to the electrons is πr_0^2, where r_0 is the amplitude of oscillation of the ions.

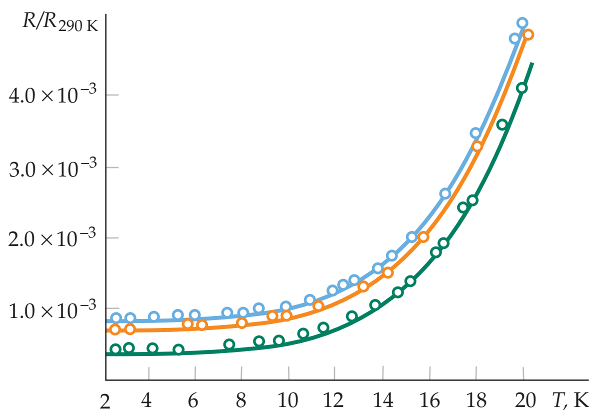

FIGURE 38-13 Relative resistance versus temperature for three samples of sodium. The three curves have the same temperature dependence but different magnitudes because of differing amounts of impurities in the samples.

38-5 BAND THEORY OF SOLIDS

Resistivities vary enormously between insulators and conductors. For a typical insulator, such as quartz, $\rho \sim 10^{16}\ \Omega\cdot\text{m}$, whereas for a typical conductor, $\rho \sim 10^{-8}\ \Omega\cdot\text{m}$. The reason for this enormous variation is the variation in the number density of free electrons n_{e}. To understand this variation, we consider the effect of the lattice on the electron energy levels.

We begin by considering the energy levels of the individual atoms as they are brought together. The allowed energy levels in an isolated atom are often far apart. For example, in hydrogen, the lowest allowed energy $E_1 = -13.6$ eV is 10.2 eV below the next lowest allowed energy $E_2 = (-13.6\text{ eV})/4 = -3.4$ eV.† Let us consider two identical atoms and focus our attention on one particular energy level. When the atoms are far apart, the energy of a particular level is the same for each atom. As the atoms are brought closer together, the energy level for each atom changes because of the influence of the other atom. As a result, the level splits into two levels of slightly different energies for the two-atom system. If we bring three atoms close together,

* The equipartition theorem does hold for the lattice ions, which obey the Maxwell–Boltzmann energy distribution.

† The energy levels in hydrogen are discussed in Chapter 36.

a particular energy level splits into three separate levels of slightly different energies. Figure 38-14 shows the energy splitting of two energy levels for six atoms as a function of the separation of the atoms.

If we have N identical atoms, a particular energy level in the isolated atom splits into N different, closely spaced energy levels when the atoms are close together. In a macroscopic solid, N is very large—of the order of 10^{23}—so each energy level splits into a very large number of levels called a **band.** The levels are spaced almost continuously within the band. There is a separate band of levels for each particular energy level of the isolated atom. The bands may be widely separated in energy, they may be close together, or they may even overlap, depending on the kind of atom and the type of bonding in the solid.

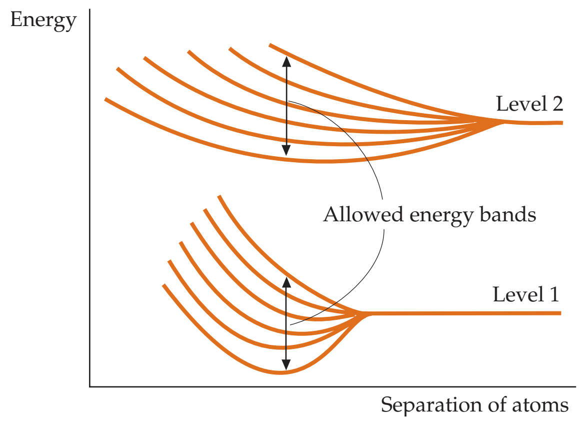

FIGURE 38-14 Energy splitting of two energy levels for six atoms as a function of the separation of the atoms. When there are many atoms, each level splits into a near-continuum of levels called a band.

The lowest energy bands, corresponding to the lowest energy levels of the atoms in the lattice, are filled with electrons that are bound to the individual atoms. The electrons that can take part in conduction occupy the higher energy bands. The highest energy band that contains electrons is called the **valence band.** The valence band may be completely filled with electrons or only partially filled, depending on the kind of atom and the type of bonding in the solid.

We can now understand why some solids are conductors and why others are insulators. If the valence band is only partially filled, there are many available empty energy states in the band, and the electrons in the band can easily be raised to a higher energy state by an electric field. Accordingly, this substance is a good conductor. If the valence band is filled and there is a large energy gap between it and the next available band, an applied electric field may be too weak to excite an electron from the upper energy levels of the filled band across the large gap into the energy levels of the empty band, so the substance is an insulator. The lowest band in which there are unoccupied states is called the **conduction band.** In a conductor, the valence band is only partially filled, so the valence band is also the conduction band. An energy gap between allowed bands is called a **forbidden energy band.**

The band structure for a conductor, such as copper, is shown in Figure 38-15*a.* The lower bands (not shown) are filled with the lower energy electrons of the atoms. The valence band is only about half-filled. When an electric field is established in the conductor, the electrons in the conduction band are accelerated, which means that their energies are increased. This is consistent with the exclusion principle because there are many empty energy states just above those occupied by electrons in this band. These electrons are thus the conduction electrons.

Figure 38-15*b* shows the band structure for magnesium, which is also a conductor. In this case, the highest occupied band is completely filled, but there is an empty band above it that overlaps it. The two bands thus form a combined valence–conduction band that is only partially filled.

Figure 38-15*c* shows the band structure for a typical insulator. At $T = 0$ K, the valence band is completely filled. The next energy band having empty energy states, the conduction band, is separated from the valence band by a large energy gap.

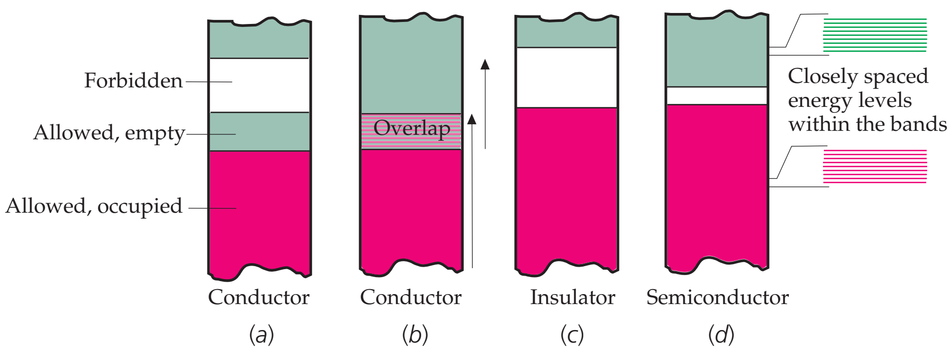

FIGURE 38-15 Four possible band structures for a solid. (*a*) A typical conductor. The valence band is also the conduction band. It is only partially filled, so electrons can be easily excited to nearby energy states. (*b*) A conductor in which the valence band overlaps a conduction band above it. (*c*) A typical insulator. There is a forbidden band that has a large energy gap between the filled valence band and the conduction band. (*d*) A semiconductor. The energy gap between the filled valence band and the conduction band is very small, so some electrons are excited to the conduction band at normal temperatures, leaving holes in the valence band.

At $T = 0$, the conduction band is empty. At ordinary temperatures, a few electrons can be excited to states in that band, but most cannot be excited to states because the energy gap is large compared with the energy an electron might obtain by thermal excitation. Very few electrons can be thermally excited to the nearly empty conduction band, even at fairly high temperatures. When an electric field of ordinary magnitude is established in the solid, electrons cannot be accelerated because there are no empty energy states at nearby energies. We describe this by saying that there are no free electrons. The small conductivity that is observed is due to the very few electrons that are thermally excited into the nearly empty conduction band. When an electric field applied to an insulator is sufficiently strong to cause an electron to be excited across the energy gap to the empty band, dielectric breakdown occurs.

In some substances, the energy gap between the filled valence band and the empty conduction band is very small, as shown in Figure 38-15*d*. At $T = 0$, there are no electrons in the conduction band and the material is an insulator. At ordinary temperatures, however, there are an appreciable number of electrons in the conduction band due to thermal excitation. Such a material is called an **intrinsic semiconductor.** For typical intrinsic semiconductors, such as silicon and germanium, the energy gap is only about 1 eV. In the presence of an electric field, the electrons in the conduction band can be accelerated because there are empty states nearby. Also, for each electron in the conduction band there is a vacancy, or **hole,** in the nearly filled valence band. In the presence of an electric field, electrons in this band can also be excited to a vacant energy level. This contributes to the electric current and is most easily described as the motion of a hole in the direction of the field and opposite to the motion of the electrons. The hole thus acts like a positive charge. To visualize the conduction of holes, think of a two-lane, one-way road that has one lane completely filled with parked cars and the other lane empty. If a car moves out of the completely filled lane into the empty lane, it can move ahead freely. As the other cars move up to occupy the vacated space, the vacated space propagates backward in the direction opposite the motion of the cars. Both the forward motion of the car in the nearly empty lane and the backward propagation of the empty space contribute to a net forward propagation of the cars.

An interesting characteristic of semiconductors is that the resistivity of the substance decreases as the temperature increases, which is contrary to the case for normal conductors. The reason is that as the temperature increases, the number of free electrons increases because there are more electrons in the conduction band. The number of holes in the valence band also increases, of course. In semiconductors, the effect of the increase in the number of charge carriers, both electrons and holes, exceeds the effect of the increase in resistivity due to the increased scattering of the electrons by the lattice ions due to thermal vibrations. Semiconductors therefore have a negative temperature coefficient of resistivity.

38-6 SEMICONDUCTORS

The semiconducting property of intrinsic semiconductors makes them useful as a basis for electronic circuit components whose resistivity can be controlled by application of an external voltage or current. Most such *solid-state devices,* however, such as the semiconductor diode and the transistor, make use of **impurity semiconductors,** which are created through the controlled addition of certain impurities to intrinsic semiconductors. This process is called **doping.** Figure 38-16*a* is a schematic illustration of silicon doped with a small amount of arsenic so that the arsenic atoms replace a few of the silicon atoms in the crystal lattice. The conduction band of pure silicon is virtually empty at ordinary temperatures, so pure silicon is a poor conductor of electricity. However, arsenic has five valence electrons rather than the four valence electrons of silicon. Four of these electrons take part in bonds with the four neighboring silicon atoms, and the fifth electron is very

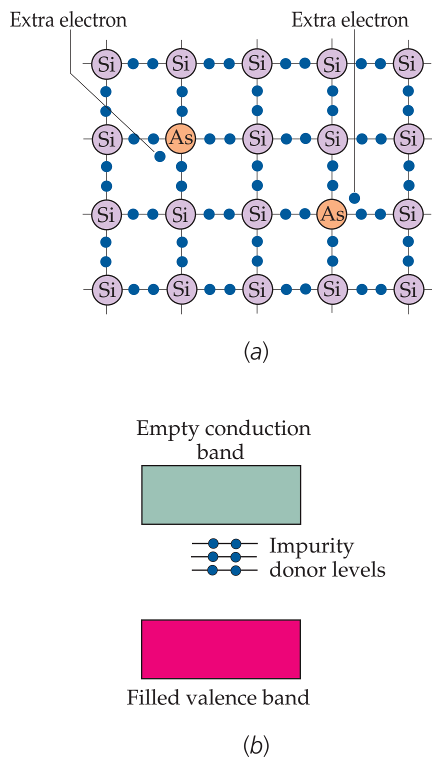

FIGURE 38-16 (*a*) A two-dimensional schematic illustration of silicon doped with arsenic. Because arsenic has five valence electrons, there is an extra, weakly bound electron that is easily excited to the conduction band, where it can contribute to electrical conduction. (*b*) Band structure of an *n*-type semiconductor, such as silicon doped with arsenic. The impurity atoms provide filled energy levels that are just below the conduction band. These levels donate electrons to the conduction band.

loosely bound to the atom. This extra electron occupies an energy level that is just slightly below the conduction band in the solid, and it is easily excited into the conduction band, where it can contribute to electrical conduction.

The effect on the band structure of a silicon crystal achieved by doping it with arsenic is shown in Figure 38-16*b*. The levels shown just below the conduction band are due to the extra electrons of the arsenic atoms. These levels are called **donor levels** because they donate electrons to the conduction band without leaving holes in the valence band. Such a semiconductor is called an ***n*-type semiconductor** because the major charge carriers are negatively charged electrons. The conductivity of a doped semiconductor can be controlled by controlling the amount of impurity added. The addition of just one part per million can increase the conductivity by several orders of magnitude.

Another type of impurity semiconductor can be made by replacing a silicon atom with a gallium atom, which has three valence electrons (Figure 38-17*a*). The gallium atom accepts electrons from the valence band to complete its four covalent bonds, thus creating a hole in the valence band. The effect on the band structure of silicon achieved by doping it with gallium is shown in Figure 38-17*b*. The empty levels shown just above the valence band are due to the holes from the ionized gallium atoms. These levels are called **acceptor levels** because they accept electrons from the filled valence band when those electrons are thermally excited to a higher energy state. This creates holes in the valence band that are free to propagate in the direction of an electric field. Such a semiconductor is called a ***p*-type semiconductor** because the charge carriers are positively charged holes. The fact that conduction is due to the motion of positively charged holes can be verified by the Hall effect. (The Hall effect is discussed in Chapter 26.)

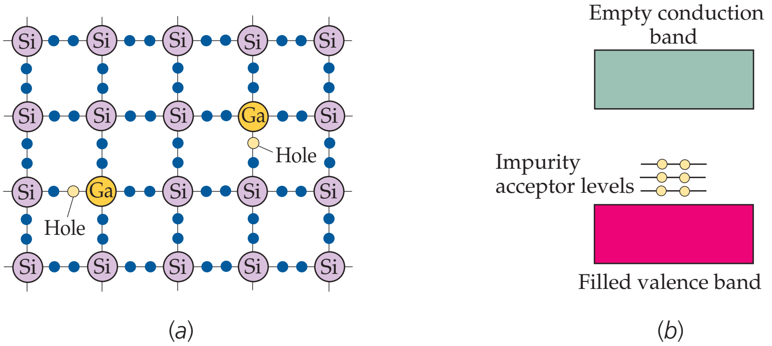

FIGURE 38-17 (*a*) A two-dimensional schematic illustration of silicon doped with gallium. Because gallium has only three valence electrons, there is a hole in one of its bonds. As electrons move into the hole the hole moves about, contributing to the conduction of electrical current. (*b*) Band structure of a *p*-type semiconductor, such as silicon doped with gallium. The impurity atoms provide empty energy levels just above the filled valence band that accept electrons from the valence band.

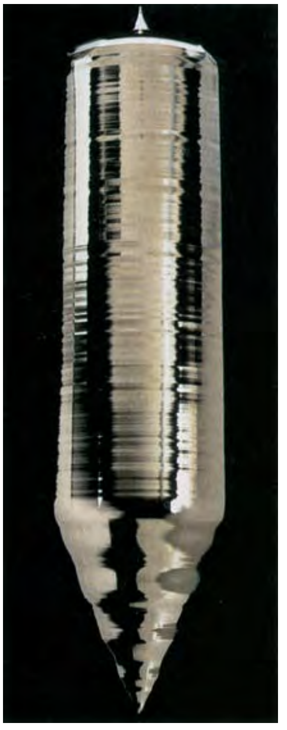

Synthetic crystal silicon is produced beginning with a raw material containing silicon (for instance, common beach sand), separating out the silicon, and melting it. From a seed crystal, the molten silicon grows into a cylindrical crystal, such as the one shown here. The crystals (typically about 1.3 m long) are formed under highly controlled conditions to ensure that they are flawless and the crystals are then sliced into thousands of thin wafers onto which the layers of an integrated circuit are etched. *(Museum of Modern Art.)*

Example 38-7 Number Density of Free Electrons in Arsenic-Doped Silicon — *Try It Yourself*

The number of free electrons in pure silicon is approximately 10^{10} electrons/cm^3 at ordinary temperatures. If one silicon atom out of every 10^6 atoms is replaced by an arsenic atom, how many free electrons per cubic centimeter are there? (The density of silicon is 2.33 g/cm^3 and its molar mass is 28.1 g/mol.)

PICTURE The number of silicon atoms per cubic centimeter, n_{Si}, can be found from $n_{\mathrm{Si}} = \rho N_{\mathrm{A}}/M$. Then, because each arsenic atom contributes one free electron, the number of electrons contributed by the arsenic atoms is $10^{-6}\, n_{\mathrm{Si}}$.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. Calculate the number of silicon atoms per cubic centimeter.	$n_{Si} = \frac{\rho N_A}{M} = \frac{(2.33\text{ g/cm}^3)(6.02 \times 10^{23}\text{ atoms/mol})}{28.1\text{ g/mol}} = 4.99 \times 10^{22}\text{ atoms/cm}^3$
2. Multiply by 10^{-6} to obtain the number of arsenic atoms per cubic centimeter, which equals the added number of free electrons per cubic centimeter.	$n_{As} = 10^{-6} n_{Si} = 4.99 \times 10^{16}\text{ atoms/cm}^3$
3. The number of free electrons per cubic centimeter is equal to the number of arsenic atoms per cubic centimeter plus 1×10^{-10} (the number of silicon atoms per cubic centimeter).	$n_e = n_{As} + 1 \times 10^{-10} n_{Si} = 4.99 \times 10^{16}\text{ cm}^{-3} + 1 \times 10^{10}\text{ cm}^{-3} \approx \boxed{5 \times 10^{16}\text{ electrons/cm}^3}$

CHECK As expected, the step-3 result is less than the number density of silicon atoms and more than the number density of conduction electrons in pure silicon.

TAKING IT FURTHER Because silicon has so few free electrons per atom, the number density of conduction electrons is increased by a factor of approximately 5 million per cubic centimeter by doping silicon with just one arsenic atom per million silicon atoms.

PRACTICE PROBLEM 38-3 How many free electrons are there per silicon atom in pure silicon?

* 38-7 SEMICONDUCTOR JUNCTIONS AND DEVICES

Semiconductor devices such as diodes and transistors make use of n-type semiconductors and p-type semiconductors joined together, as shown in Figure 38-18. In practice, the two types of semiconductors are often incorporated into a single silicon crystal doped with donor impurities on one side and acceptor impurities on the other side. The region in which the semiconductor changes from a p-type semiconductor to an n-type semiconductor is called a ***pn* junction.**

When an n-type semiconductor and a p-type semiconductor are placed in contact, the initially unequal concentrations of electrons and holes result in the diffusion of electrons across the junction from the n side to the p side and holes from the p side to the n side until equilibrium is established. The result of this diffusion is a net transport of positive charge from the p side to the n side. Unlike the case when two different metals are in contact, the electrons cannot travel very far from the junction region because the semiconductor is not a particularly good conductor. The diffusion of electrons and holes therefore creates a double layer of charge at the junction similar to that on a parallel-plate capacitor. There is, thus, a potential difference V across the junction, which tends to inhibit further diffusion. In equilibrium, the n side which has a net positive charge will be at a higher potential than the p side which has a net negative charge. In the junction region, between the charge layers, there will be very few charge carriers of either type, so the junction region has a high resistance. Figure 38-19 shows the energy-level diagram for a pn junction. The junction region is also called the **depletion region** because it has been depleted of charge carriers.

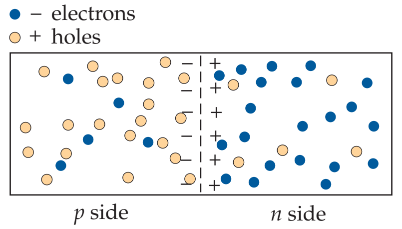

FIGURE 38-18 A pn junction. Because of the difference in their concentrations on either side of the pn junction, holes diffuse from the p side to the n side, and electrons diffuse from the n side to the p side. As a result, there is a double layer of charge at the junction, with the p side being negative and the n side being positive.

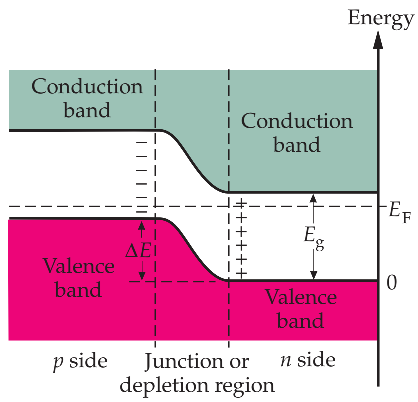

FIGURE 38-19 Electron energy levels for a pn junction.

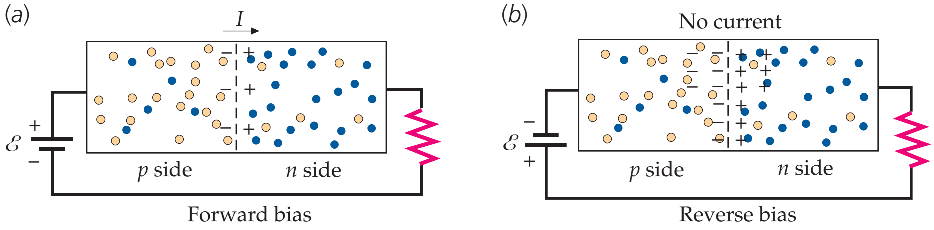

FIGURE 38-20 A *pn*-junction diode. (*a*) Forward-biased *pn* junction. The applied potential difference enhances the diffusion of holes from the *p* side to the *n* side and of electrons from the *n* side to the *p* side, resulting in a current *I*. (*b*) Reverse-biased *pn* junction. The applied potential difference inhibits the further diffusion of holes and electrons across the junction, so there is no current.

*DIODES

In Figure 38-20, an external potential difference has been applied across a *pn* junction by connecting a battery and a resistor to the semiconductor. When the positive terminal of the battery is connected to the *p* side of the junction, as shown in Figure 38-20*a*, the junction is said to be **forward biased.** Forward biasing lowers the potential across the junction. The diffusion of electrons and holes is thereby increased as they attempt to reestablish equilibrium, resulting in a current in the circuit.

If the positive terminal of the battery is connected to the *n* side of the junction, as shown in Figure 38-20*b*, the junction is said to be **reverse biased.** Reverse biasing tends to increase the potential difference across the junction, thereby further inhibiting diffusion. Figure 38-21 shows a plot of current versus voltage for a typical semiconductor junction. Essentially, the junction conducts only in one direction for applied voltages greater than the breakdown voltage. A single-junction semiconductor device is called a **diode.*** Diodes have many uses. One use is to convert alternating current into direct current, a process called *rectification.*

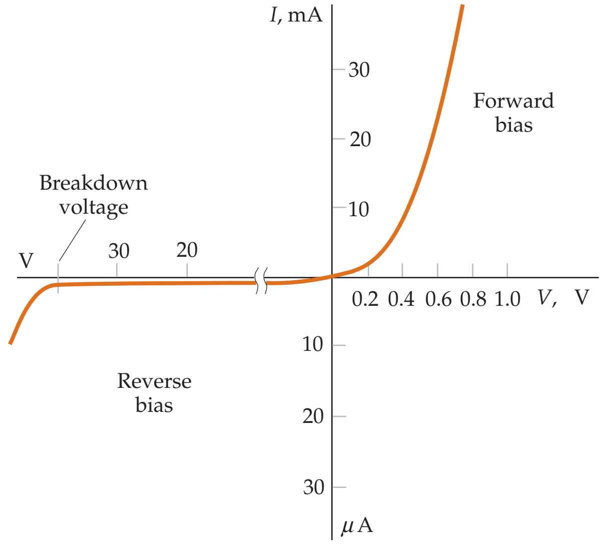

FIGURE 38-21 Plot of current versus applied voltage across a *pn* junction. Note the different scales on both axes for the forward and reverse bias conditions.

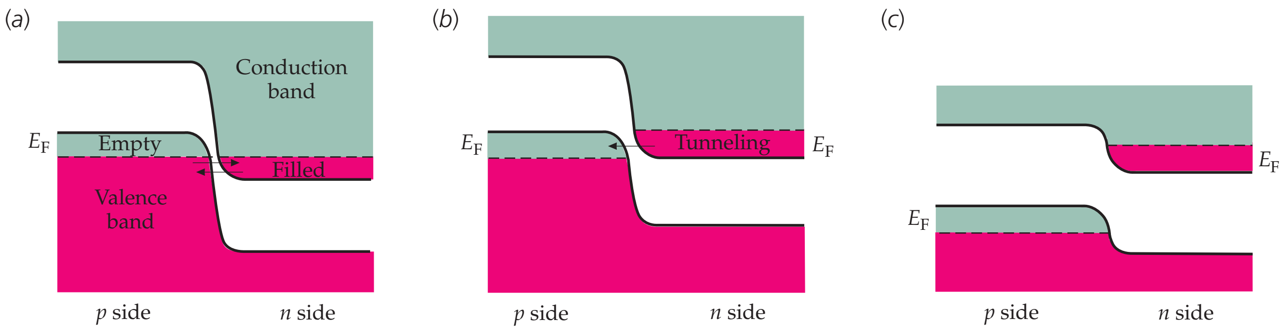
Note that the current in Figure 38-21 suddenly increases in magnitude at extreme values of reverse bias. In such large electric fields, electrons are stripped from their atomic bonds and accelerated across the junction. These electrons, in turn, cause others to break loose. This effect is called **avalanche breakdown.** Although such a breakdown can be disastrous in a circuit where it is not intended, the fact that it occurs at a sharply defined voltage makes it of use in a special voltage reference standard known as a **Zener diode.** Zener diodes are also used to protect devices from excessively high voltages.

An interesting effect, one that we discuss only qualitatively, occurs if both the *n* side and the *p* side of a *pn*-junction diode are so heavily doped that the donors on the *n* side provide so many electrons that the lower part of the conduction band is practically filled, and the acceptors on the *p* side accept so many electrons that the upper part of the valence band is nearly empty. Figure 38-22*a* shows the energy-level

FIGURE 38-22 Electron energy levels for a heavily doped *pn*-junction tunnel diode. (*a*) With no bias voltage, some electrons tunnel in each direction. (*b*) With a small bias voltage, the tunneling current is enhanced in one direction, making a sizable contribution to the net current. (*c*) With further increases in the bias voltage, the tunneling current decreases dramatically.



* The name *diode* originates from a vacuum tube device consisting of just two electrodes that also conducts electric current in one direction only.

diagram for this situation. Because the depletion region is now so narrow, electrons can easily penetrate the potential barrier across the junction and tunnel to the other side. The flow of electrons through the barrier is called a **tunneling current,** and such a heavily doped diode is called a **tunnel diode.**

At equilibrium where there is no bias, there is an equal tunneling current in each direction. When a small bias voltage is applied across the junction, the energy-level diagram is as shown in Figure 38-22*b*, and the tunneling of electrons from the n side to the p side is increased, whereas the tunneling of electrons in the opposite direction is decreased. This tunneling current, in addition to the usual current due to diffusion, results in a considerable net current. When the bias voltage is increased slightly, the energy-level diagram is as shown in Figure 38-22*c*, and the tunneling current is decreased. Although the diffusion current is increased, the net current is decreased. At large bias voltages, the tunneling current is completely negligible, and the total current increases with increasing bias voltage due to diffusion, as in an ordinary pn-junction diode. Figure 38-23 shows the current versus voltage curve for a tunnel diode. Such diodes are used in electric circuits because of their very fast response time. When operated near the peak in the current versus voltage curve, a small change in bias voltage results in a large change in the current.

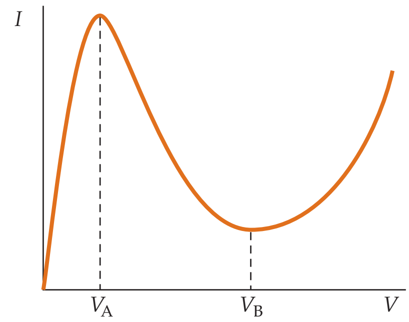


FIGURE 38-23 Current versus applied (bias) voltage V for a tunnel diode. For $V < V_A$, an increase in the bias voltage V enhances tunneling. For $V_A < V < V_B$, an increase in the bias voltage inhibits tunneling. For $V > V_B$, the tunneling is negligible, and the diode behaves like an ordinary pn-junction diode.

Another use for the pn-junction semiconductor is the **solar cell,** which is illustrated schematically in Figure 38-24. When a photon of energy greater than the gap energy (1.1 eV in silicon) strikes the p-type region, it can excite an electron from the valence band into the conduction band, leaving a hole in the valence band. This region is already rich in holes. Some of the electrons created by the photons will recombine with holes, but some will migrate to the junction. From there, they are accelerated into the n-type region by the electric field between the double layer of charge. This creates an excess negative charge in the n-type region and an excess positive charge in the p-type region. The result is a potential difference between the two regions, which in practice is approximately 0.6 V. If a load resistance is connected across the two regions, a charge flows through the resistance. Some of the incident light energy is thus converted into electrical energy. The current in the resistor is proportional to the rate of arrival of incident photons, which is in turn proportional to the intensity of the incident light.

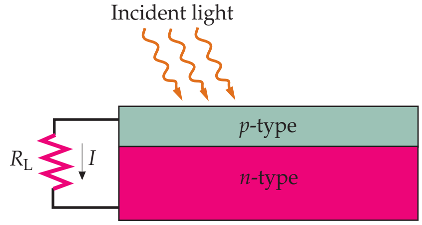

FIGURE 38-24 A pn-junction semiconductor as a solar cell. When light strikes the p-type region, electron-hole pairs are created, resulting in a current through the load resistance R_L.

There are many other applications of semiconductors with pn junctions. Particle detectors, called **surface-barrier detectors,** consist of a pn-junction semiconductor that has a large reverse bias so that there is ordinarily no current. When a high-energy particle, such as an electron, passes through the semiconductor, it creates many electron–hole pairs as it loses energy. The resulting current pulse signals the passage of the particle. **Light-emitting diodes** (LEDs) are pn-junction semiconductors that have large forward biases that produce large excess concentrations of electrons on the p sides and holes on the n sides of the junctions. Under these conditions, an LED emits light as the electrons and holes recombine. This is essentially the reverse of the process that occurs in a solar cell, in which electron–hole pairs are created by the absorption of light. LEDs are commonly used as warning indicators and as sources of infrared light beams.

*TRANSISTORS

The transistor, a semiconducting device that is used to produce a desired output signal in response to an input signal, was invented in 1948 by William Shockley, John Bardeen, and Walter Brattain and has revolutionized the electronics industry and our everyday world. A *simple bipolar junction transistor** consists of three distinct semiconductor regions called the **emitter,** the **base,** and the **collector.** The base is a very thin region of one type of semiconductor sandwiched between two regions of the opposite type. The emitter semiconductor is much more heavily

* Besides the bipolar junction transistor, there are other categories of transistors, notably, the field–effect transistor.

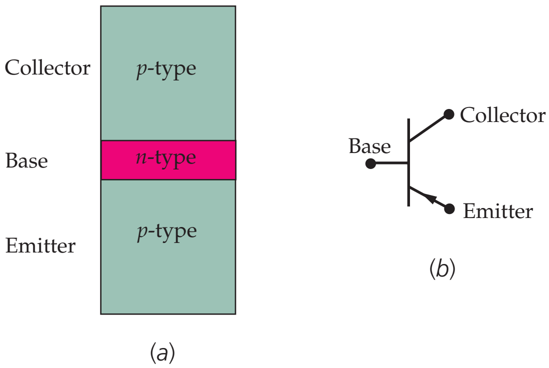

FIGURE 38-25 A *pnp* transistor. (*a*) The heavily doped emitter emits holes that pass through the thin base to the collector. (*b*) Symbol for a *pnp* transistor in a circuit. The arrow points in the direction of the conventional current, which is the same as that of the emitted holes.

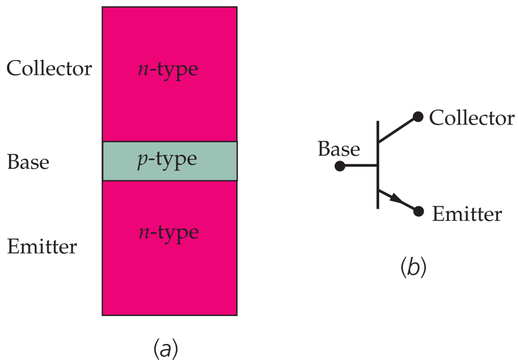

FIGURE 38-26 An *npn* transistor. (*a*) The heavily doped emitter emits electrons that pass through the thin base to the collector. (*b*) Symbol for an *npn* transistor. The arrow points in the direction of the conventional current, which is opposite the direction of the emitted electrons.

doped than either the base or the collector. In an *npn* transistor, the emitter and collector are *n*-type semiconductors and the base is a *p*-type semiconductor; in a *pnp* transistor, the base is an *n*-type semiconductor and the emitter and collector are *p*-type semiconductors.

Figure 38-25 and Figure 38-26 show, respectively, a *npn* transistor and an *npn* transistor, along with the symbols used to represent each transistor in circuit diagrams. We see that either transistor consists of two *pn* junctions. We will discuss the operation of a *npn* transistor. The operation of an *npn* transistor is similar.

In the normal operation of a *pnp* transistor, the emitter-base junction is forward biased, and the base-collector junction is reverse biased, as shown in Figure 38-27. The heavily doped *p*-type emitter emits holes that flow toward the emitter-base junction. This flow constitutes the emitter current I_e. Because the base is very thin, most of the holes flow across the base into the collector. This flow in the collector constitutes a current I_c. However, some of the holes recombine in the base producing a positive charge that inhibits the further flow of charge. To prevent this, some of the holes that do not reach the collector are drawn off the base as a base current I_b in a wire connected to the base. In Figure 38-27, therefore, I_c is almost but not quite equal to I_e, and I_b is much smaller than either I_c or I_e. It is customary to express I_c as

$$I_c = \beta I_b \qquad \text{38-31}$$

where β is called the current gain of the transistor. Transistors can be designed to have values of β as low as ten or as high as several hundred.

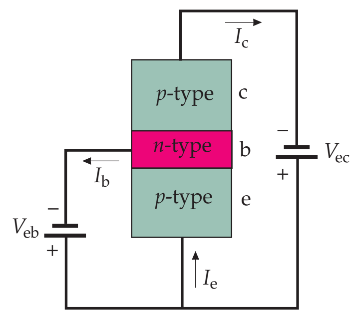

FIGURE 38-27 A *pnp* transistor biased for normal operation. Holes from the emitter can easily diffuse across the base, which is only tens of nanometers thick. Most of the holes flow to the collector, producing the current I_c.

Figure 38-28 shows a simple *pnp* transistor used as an amplifier. A small, time-varying input voltage v_s is connected in series with a constant bias voltage V_{eb}. The base current is then the sum of a steady current I_b produced by the bias voltage V_{eb} and a time-varying current i_b due to the signal voltage v_s. Because v_s may at any instant be either positive or negative, the bias voltage V_{eb} must be large enough to ensure that there is always a forward bias on the emitter-base junction. The collector current will consist of two parts: a constant direct current $I_c = \beta I_b$ and a time-varyng current $i_c = \beta i_b$. We thus have a current amplifier in which the time-varying output current i_c is β multiplied by the input current i_b. In such an amplifier, the steady currents I_c and I_b, although essential to the operation of the transistor, are usually not of interest. The input signal voltage v_s is related to the base current by Ohm's law:

$$i_b = \frac{v_s}{R_b + r_b} \qquad \text{38-32}$$

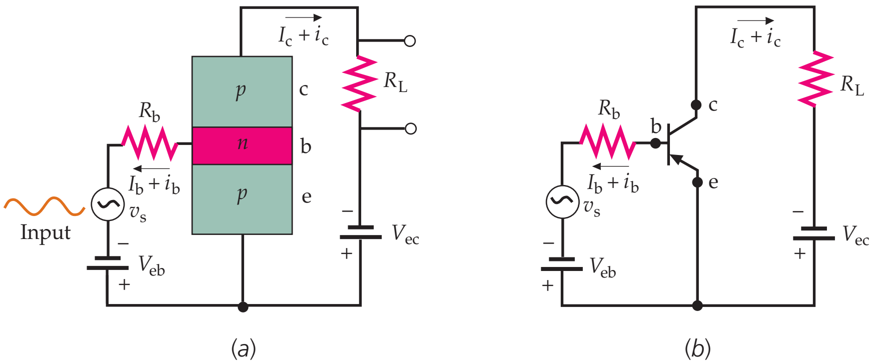

FIGURE 38-28 (*a*) A *pnp* transistor used as an amplifier. A small change i_b in the base current results in a large change i_c in the collector current. Thus, a small signal in the base circuit results in a large signal across the load resistor R_L in the collector circuit. (*b*) The same circuit as in Figure 38-28*a* with the conventional symbol for the transistor.

where r_b is the internal resistance of that part of the transistor between the base and emitter. Similarly, the collector current i_c produces a time-varying voltage v_L across the output or load resistance R_L given by

$$v_L = i_c R_L \qquad 38\text{-}33$$

Using Equation 38-31 and Equation 38-32, we have

$$i_c = \beta i_b = \beta \frac{v_s}{R_b + r_b} \qquad 38\text{-}34$$

The output voltage is thus related to the input voltage by

$$v_L = \beta \frac{v_s}{R_b + r_b} R_L = \beta \frac{R_L}{R_b + r_b} v_s \qquad 38\text{-}35$$

The ratio of the output voltage to the input voltage is the **voltage gain** of the amplifier:

$$\text{Voltage gain} = \frac{v_L}{v_s} = \beta \frac{R_L}{R_b + r_b} \qquad 38\text{-}36$$

A typical amplifier (for example, in a tape player) has several transistors, similar to the one shown in Figure 38-28, connected in series so that the output of one transistor serves as the input for the next. Thus, the very small voltage fluctuations produced by the motion of the magnetic tape past the pickup heads controls the large amounts of power required to drive the loudspeakers. The power delivered to the speakers is supplied by the dc sources connected to each transistor.

The technology of semiconductors extends well beyond individual transistors and diodes. Many of the electronic devices we use every day, such as laptop computers and the processors that govern the operation of vehicles and appliances, rely on large-scale integration of many transistors and other circuit components on a single chip. Large-scale integration combined with advanced concepts in semiconductor theory has created remarkable new instruments for scientific research.

38-8 SUPERCONDUCTIVITY

There are some substances for which the resistivity suddenly drops to zero below a certain temperature T_c, which is called the **critical temperature.** This amazing phenomenon, called **superconductivity,** was discovered in 1911 by the Dutch physicist H. Kamerlingh Onnes, who developed a technique for liquefying helium (boiling point equal to 4.2 K) and used his technique to explore the properties of substances at temperatures in that range. Figure 38-29 shows Onnes's plot of the resistance of mercury versus temperature. The critical temperature for mercury is approximately the same as the boiling point of helium, which is 4.2 K. Critical temperatures for other superconducting elements range from less than 0.1 K for hafnium and iridium to 9.2 K for niobium. The temperature range for superconductors is much higher for a number of metallic compounds. For example, the superconducting alloy Nb_3Ge, discovered in 1973, has a critical temperature of 25 K, which was the highest known until 1986, when the discoveries of J. Georg Bednorz and K. Alexander Müller launched the era of high-temperature superconductors, now defined as materials that exhibit superconductivity at temperatures above 77 K (the temperature at which nitrogen boils). The highest temperature at which superconductivity has been demonstrated, using thallium-doped $HgBa_2Ca_2Cu_3O_8$ + delta, is 138 K at atmospheric pressure. At extremely high pressures, some materials exhibit superconductivity at temperatures as high as 164 K.

The resistivity of a superconductor is zero. There can be a current in a superconductor even when there is no emf in the superconducting circuit. Indeed, in superconducting rings in which there was no electric field, steady currents have been observed to persist for years without apparent loss. Despite the cost and inconvenience of refrigeration using expensive liquid helium, many superconducting magnets have been built using superconducting materials, because such magnets require no power expenditure to maintain the large current needed to produce a large magnetic field.

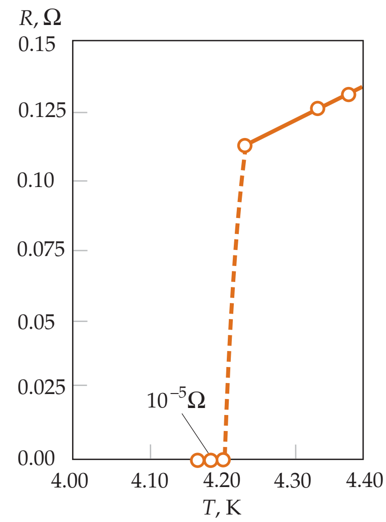

FIGURE 38-29 Plot by H. Kamerlingh Onnes of the resistance of mercury versus temperature, showing the sudden decrease at the critical temperature of $T = 4.2$ K.

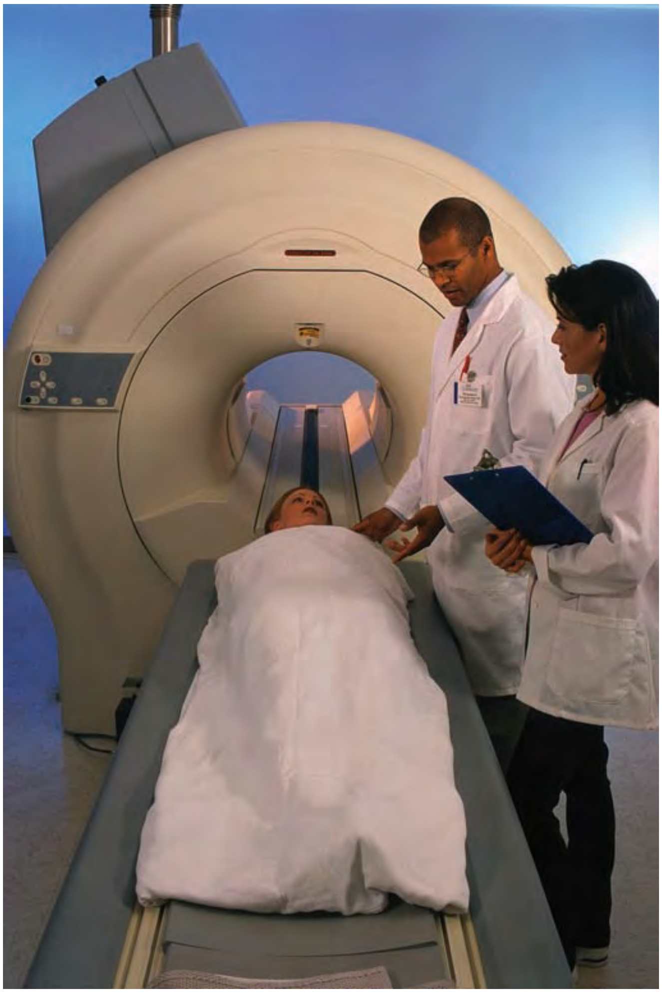

The wires for the magnetic field of a magnetic resonance imaging (MRI) machine carry large currents. To keep the wires from overheating, they are maintained at superconducting temperatures. To accomplish this, they are immersed in liquid helium. *(Corbis.)*

The discovery of high-temperature superconductors has revolutionized the study of superconductivity because relatively inexpensive liquid nitrogen, which boils at 77 K, can be used for a coolant. However, many problems, such as brittleness and the toxicity of the materials, make these new superconductors difficult to use. The search continues for new materials that will be superconductors at even higher temperatures.

THE BCS THEORY

It had been recognized for some time that low temperature superconductivity is due to a collective action of the conducting electrons. In 1957, John Bardeen, Leon Cooper, and Robert Schrieffer published a successful theory of low temperature superconductivity now known by the initials of the inventors as the **BCS theory.** According to this theory, the electrons in a superconductor are coupled in pairs at low temperatures. The coupling comes about because of the interaction between electrons and the crystal lattice. One electron interacts with the lattice and perturbs it. The perturbed lattice interacts with another electron in such a way that there is an attraction between the two electrons that at low temperatures can exceed the Coulomb repulsion between them. The electrons form a bound state called a **Cooper pair.** The electrons in a Cooper pair have equal and opposite spins, so they form a system with zero spin. Each Cooper pair acts as a *single particle* with zero spin, in other words, as a boson. Bosons do not obey the exclusion principle. Any number of Cooper pairs may be in the same quantum state with the same energy. In the ground state of a superconductor (at $T = 0$), all the conduction electrons are in Cooper pairs and all the Cooper pairs are in the same energy state. In the superconducting state, the Cooper pairs are correlated so that they act collectively. An electric current can be produced in a superconductor because all of the electrons in this collective state move together. But energy cannot be dissipated by individual collisions of electron and lattice ions unless the temperature is high enough to break the binding of the Cooper pairs. The required energy is called the *superconducting energy gap* E_g. In the BCS theory, this energy at zero temperature is related to the critical temperature by

$$E_g = \tfrac{7}{2}kT_c \qquad 38\text{-}37$$

The energy gap can be determined by measuring the current across a junction between a normal metal and a superconductor as a function of voltage. Consider two metals separated by a layer of insulating material, such as aluminum oxide, that is only a few nanometers thick. The insulating material between the metals forms a barrier that prevents most electrons from traversing the junction. However, waves can tunnel through a barrier if the barrier is not too thick, even if the energy of the wave is less than that of the barrier.

When the materials on either side of the gap are normal nonsuperconducting metals, the current resulting from the tunneling of electrons through the insulating layer obeys Ohm's law for low applied voltages (Figure 38-30*a*). When one of the metals is a normal metal and the other is a superconductor, there is no current (at absolute zero) unless the applied voltage V is greater than a critical voltage $V_c = E_g/(2e)$, where E_g is the superconductor energy gap. Figure 38-30*b* shows the plot of current versus voltage for this situation. The current escalates rapidly when the energy $2eV$ absorbed by a Cooper pair traversing the barrier approaches $E_g = 2eV_c$, the minimum energy needed to break up the pair. (The small current visible in Figure 38-30*b* before the critical voltage is reached is present because at any temperature above absolute zero some of the electrons in the superconductor are thermally excited above the energy gap and are therefore not paired.) At voltages slightly above V_c, the current versus voltage curve becomes that for a normal metal. The superconducting energy gap can thus be measured by measuring the average voltage for the transition region.

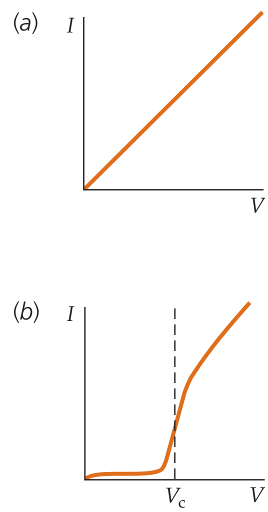

FIGURE 38-30 Tunneling current versus voltage for a junction of two metals separated by a thin oxide layer. (*a*) When both metals are normal metals, the current is proportional to the voltage, as predicted by Ohm's law. (*b*) When one metal is a normal metal and another metal is a superconductor, the current is approximately zero until the applied voltage V approaches the critical voltage $V_c = E_g/(2e)$.

Example 38-8 Superconducting Energy Gap for Mercury

Calculate the superconducting energy gap for mercury ($T_c = 4.2$ K) predicted by the BCS theory.

PICTURE The energy gap is related to the critical temperature by $E_g = 3.5\,kT_c$ (Equation 38-37).

SOLVE

1. The BCS prediction for the energy gap is $\quad E_g = 3.5kT_c$

2. Substitute $T_c = 4.2$ K:

$$E_g = 3.5kT_c$$

$$= 3.5(1.38 \times 10^{-23}\,\text{J/K})(4.2\,\text{K})\left(\frac{1\,\text{ev}}{1.6 \times 10^{-19}\,\text{J}}\right)$$

$$= \boxed{1.3 \times 10^{-3}\,\text{eV}}$$

Note that the energy gap for a typical superconductor is much smaller than the energy gap for a typical semiconductor, which is of the order of 1 eV. As the temperature is increased from $T = 0$, some of the Cooper pairs are broken. Then there are fewer pairs available for each pair to interact with, and the energy gap is reduced until at $T = T_c$ the energy gap is zero (Figure 38-31).

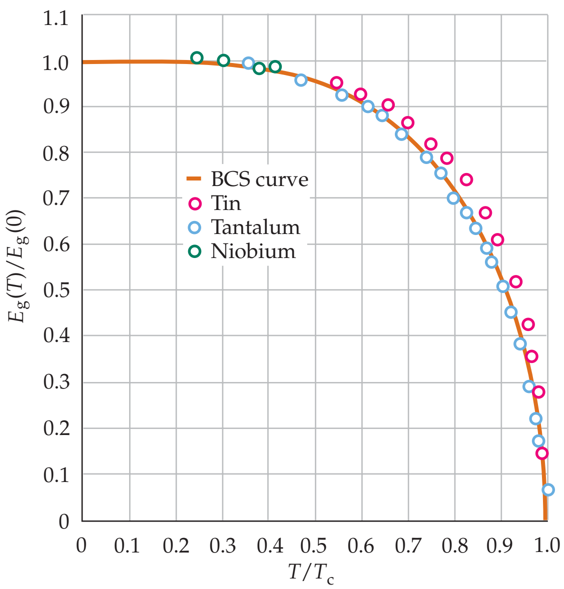

FIGURE 38-31 Ratio of the energy gap at temperature T to that at temperature $T = 0$ as a function of the relative temperature T/T_c. The solid curve is that predicted by the BCS theory.

THE JOSEPHSON EFFECT

When two superconductors are separated by a thin nonsuperconducting barrier (for example, a layer of aluminum oxide a few nanometers thick), the junction is called a **Josephson junction,** based on the prediction in 1962 by Brian Josephson that Cooper pairs could tunnel across such a junction from one superconductor to the other with no resistance. The tunneling of Cooper pairs constitutes a current, which does not require a voltage to be applied across the junction. The current depends on the difference in phase of the wave functions that describe the Cooper pairs. Let ϕ_1 be the phase constant for the wave function of a Cooper pair in one superconductor. All the Cooper pairs in a superconductor act coherently and have the same phase constant. If ϕ_2 is the phase constant for the Cooper pairs in the second superconductor, the current across the junction is given by

$$I = I_{\max} \sin(\phi_2 - \phi_1) \qquad 38\text{-}38$$

where $I_{\max}$ is the maximum current, which depends on the thickness of the barrier. This result has been observed experimentally and is known as the **dc Josephson effect.**

Josephson also predicted that if a dc voltage V were applied across a Josephson junction, there would be a current that alternates with frequency f given by

$$f = \frac{2e}{h}V \qquad 38\text{-}39$$

This result, known as the **ac Josephson effect,** has been observed experimentally, and careful measurement of the frequency allows a precise determination of the ratio e/h. Because frequency can be measured very accurately, the ac Josephson effect is also used to establish precise voltage standards. The inverse effect, in which the application of an alternating voltage across a Josephson junction results in a dc current, has also been observed.

Example 38-9 Frequency of Josephson Current

Using $e = 1.602 \times 10^{-19}$ C and $h = 6.626 \times 10^{-34}$ J·s, calculate the frequency of the Josephson current if the applied voltage is 1.000 μV.

PICTURE The frequency f is related to the applied voltage V by $hf = 2eV$ (Equation 38-39).

SOLVE

Substitute the given values into Equation 38-39 to calculate f:

$$f = \frac{2e}{h}V = \frac{2(1.602 \times 10^{-19}\text{ C})}{6.626 \times 10^{-34}\text{ J}\cdot\text{s}}(1.000 \times 10^{-6}\text{ V})$$

$$= 4.835 \times 10^{8}\text{ Hz} = \boxed{483.5\text{ MHz}}$$

38-9 THE FERMI–DIRAC DISTRIBUTION

The classical Maxwell–Boltzmann distribution (Equation 17-38) gives the number dN of molecules that have energy E in the range between E and $E + dE$. The number dN is equal to the product of $g(E)\,dE$ where $g(E)$ is the **density of states** (number of energy states in the range dE) and the Boltzmann factor $e^{-E/(kT)}$, which is the probability of a state being occupied. The distribution function for free electrons in a metal is called the **Fermi–Dirac distribution.** The Fermi–Dirac distribution can be written in the same form as the Maxwell–Boltzmann distribution, where the density of states calculated from quantum theory and the Boltzmann factor is replaced by the Fermi factor. Let $n(E)\,dE$ be the number of electrons that have energies between E and $E + dE$. This number is written

$$n(E)dE = f(E)g(E)dE \qquad 38\text{-}40$$

ENERGY DISTRIBUTION FUNCTION

where $g(E)\,dE$ is the number of states that have energies between E and $E + dE$ and $f(E)$ is the probability of a state being occupied, which is the Fermi factor. The density of states in three dimensions is somewhat challenging to calculate, so we just give the result. For electrons in a metal of volume V, the density of states is

$$g(E) = \frac{8\sqrt{2}\pi m_e^{3/2}V}{h^3}E^{1/2} \qquad 38\text{-}41$$

DENSITY OF STATES

As in the classical Maxwell–Boltzmann distribution, the density of states is proportional to $E^{1/2}$.

At $T = 0$, the Fermi factor is given by Equation 38-24:

$$f(E) = \begin{cases} 1 & E < E_F \\ 0 & E > E_F \end{cases}$$

The integral of $n(E)\,dE$ over all energies gives the total number of electrons N. We can derive the equation

$$E_F = \frac{h^2}{8m_e}\left(\frac{3N}{\pi V}\right)^{2/3}$$

(Equation 38-22*a*) for the Fermi energy at $T = 0$ by integrating $n(E)\,dE$ from $E = 0$ to $E = \infty$. We obtain

$$N = \int_0^\infty n(E)dE = \int_0^{E_F} n(E)dE + \int_{E_F}^\infty n(E)dE$$

$$= \int_0^{E_F} \frac{8\sqrt{2}\pi m_e^{3/2}V}{h^3} E^{1/2}\,dE + 0 = \frac{16\sqrt{2}\pi m_e^{3/2}V}{3h^3} E_F^{3/2}$$

Note that at $T = 0$, $n(E)$ is zero for $E > E_F$. Solving for E_F gives the Fermi energy at $T = 0$:

$$E_F = \frac{h^2}{8m_e}\left(\frac{3N}{\pi V}\right)^{2/3} \qquad \text{38-42}$$

which is Equation 38-22*a*. In terms of the Fermi energy, the density of states (Equation 38-41) is

$$g(E) = \frac{8\sqrt{2}\pi m_e^{3/2}V}{h^3} E^{1/2} = \frac{3}{2} N E_F^{-3/2} E^{1/2} \qquad \text{38-43}$$

DENSITY OF STATES IN TERMS OF E_F

which is obtained by solving Equation 38-42 for m_e, and then substituting for m_e in Equation 38-41. The average energy at $T = 0$ is calculated from

$$E_{av} = \frac{\int_0^{E_F} Eg(E)dE}{\int_0^{E_F} g(E)dE} = \frac{1}{N}\int_0^{E_F} Eg(E)dE \qquad \text{38-44}$$

where $N = \int_0^{E_F} g(E)dE$ is the total number of electrons. Substituting for $g(E)$ from Equation 38-43 and then evaluating the integral in Equation 38-44, we obtain Equation 38-23:

$$E_{av} = \tfrac{3}{5}E_F \qquad \text{38-45}$$

AVERAGE ENERGY AT $T = 0$

At $T > 0$, the Fermi factor is more complicated. It can be shown to be

$$f(E) = \frac{1}{e^{(E-E_F)/(kT)} + 1} \qquad \text{38-46}$$

FERMI FACTOR

We can see from this equation that for E greater than E_F, $e^{(E-E_F)/(kT)}$ becomes very large as T approaches zero, so at $T = 0$, the Fermi factor is zero for $E > E_F$. On the other hand, for E less than E_F, $e^{(E-E_F)/(kT)}$ approaches 0 as T approaches zero, so at $T = 0$, $f(E) = 1$ for $E < E_F$. Thus, the Fermi factor given by Equation 38-46 holds for all temperatures. Note also that for any nonzero value of T, $f(E) = \frac{1}{2}$ at $E = E_F$.

The complete Fermi-Dirac distribution function is thus

$$n(E)dE = g(E)f(E)dE = \frac{8\sqrt{2}\pi m_e^{3/2}V}{h^3}E^{1/2}\frac{1}{e^{(E-E_F)/(kT)}+1}dE \qquad 38\text{-}47$$

FERMI–DIRAC DISTRIBUTION

We can see that for those few electrons that have energies much greater than the Fermi energy, the Fermi factor approaches $1/e^{(E-E_F)/(kT)} = e^{(E_F-E)/(kT)} = e^{E_F/(kT)}e^{-E/(kT)}$, which is proportional to $e^{-E/(kT)}$. Thus, the high-energy tail of the Fermi–Dirac energy distribution decreases with increasing E as $e^{-E/(kT)}$, just like the classical Maxwell–Boltzmann energy distribution. The reason for this is that in this high-energy region there are many unoccupied energy states and few electrons, so the exclusion principle is not important. Thus, the Fermi–Dirac distribution approaches the classical Maxwell–Boltzmann distribution in the high-energy limit. This result has practical importance because it applies to the conduction electrons in semiconductors.

Example 38-10 Fermi Factor for Copper at 300 K

At what energy is the Fermi factor equal to 0.100 for copper at $T = 300$ K?

PICTURE We set $f(E) = 0.100$ in Equation 38-46, using $T = 300$ K and $E_F = 7.03$ eV from Table 38-1, and solve for E.

SOLVE

1. Solve Equation 38-46 for $e^{(E-E_F)/(kT)}$:

$$f(E) = \frac{1}{e^{(E-E_F)/(kT)}+1}$$

so

$$e^{(E-E_F)/(kT)} = \frac{1}{f(E)} - 1$$

2. Take the logarithm of both sides:

$$\frac{E-E_F}{\mathrm{kT}} = \ln\left[\frac{1}{f(E)} - 1\right]$$

3. Solve for E. For E_F, use the value for E_F at $T = 0$ K listed in Table 38-1:

$$E = E_F + \left[\frac{1}{f(E)} - 1\right]kT$$

$$= 7.03\text{ eV} + \ln\left[\frac{1}{0.100} - 1\right](8.62\times10^{-5}\text{ eV/K})(300\text{ K})$$

$$= \boxed{7.09\text{ eV}}$$

CHECK As expected, the energy is slightly above the Fermi energy when the Fermi factor is equal to 0.100.

Example 38-11 Probability of a Higher Energy State Being Occupied

Find the probability that an energy state in copper 0.100 eV above the Fermi energy is occupied at $T = 300$ K.

PICTURE The probability is the Fermi factor given in Equation 38-46, with $E_F = 7.03$ eV and $E = 7.13$ eV.

SOLVE

1. The probability of an energy state being occupied equals the Fermi factor:

$$P = f(E) = \frac{1}{e^{(E-E_F)/(kT)} + 1}$$

2. Calculate the exponent in the Fermi factor (exponents are always dimensionless):

$$\frac{E - E_F}{kT} = \frac{7.13\text{ eV} - 7.03\text{ eV}}{(8.62 \times 10^{-5}\text{ eV/K})(300\text{ K})} = 3.87$$

3. Use this result to calculate the Fermi factor:

$$f(E) = \frac{1}{e^{(E-E_F)/(kT)} + 1} = \frac{1}{e^{3.87} + 1}$$

$$= \frac{1}{48 + 1} = \boxed{0.020}$$

CHECK The probability that an energy state above the Fermi energy is occupied is less than one-half. As expected, the step 4 result less than one-half.

TAKING IT FURTHER The probability of an electron having an energy 0.100 eV above the Fermi energy at 300 K is only about 2 percent.

Example 38-12 Probability of a Lower Energy State Being Occupied *Try It Yourself*

Find the probability that an energy state in copper 0.10 eV *below* the Fermi energy is occupied at $T = 300$ K.

PICTURE The probability is the Fermi factor given in Equation 38-46, with $E_F = 7.03$ eV and $E = 6.93$ eV.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps / **Answers**

1. Write the Fermi factor:

$$f(E) = \frac{1}{e^{(E-E_F)/(kT)} + 1}$$

2. Calculate the exponent in the Fermi factor:

$$\frac{E - E_F}{kT} = \frac{6.93\text{ eV} - 7.03\text{ eV}}{(8.62 \times 10^{-5}\text{ eV/K})(300\text{ K})} = -3.87$$

3. Use your result from step 2 to calculate the Fermi factor:

$$f(E) = \frac{1}{e^{(E-E_F)/(kT)} + 1} = \frac{1}{e^{3.87} + 1}$$

$$= \frac{1}{0.021 + 1} = \boxed{0.98}$$

CHECK As expected, the step-3 result is greater than one-half.

TAKING IT FURTHER The probability of an electron having an energy of 0.10 eV *below* the Fermi energy at 300 K is approximately 98 percent.

PRACTICE PROBLEM 38-4 What is the probability of an energy state 0.10 eV below the Fermi energy being unoccupied at 300 K?

Summary

TOPIC	RELEVANT EQUATIONS AND REMARKS	
1. The Structure of Solids	Solids are often found in crystalline form in which a small structure, which is called the unit cell, is repeated over and over. A crystal may have a face-centered-cubic, body-centered-cubic, hexagonal close-packed, or other structure depending on the type of bonding between the atoms, ions, or molecules in the crystal and on the relative sizes of the atoms.	
Potential energy	$U = -\alpha\frac{ke^2}{r} + \frac{A}{r^n}$	38-3
	where r is the center-to-center separation distance between neighboring ions, α is the Madelung constant, which depends on the geometry of the crystal and is of the order of 1.8, and n is approximately 9.	
2. A Microscopic Picture of Conduction		
Resistivity	$\rho = \frac{m_e v_{av}}{n_e e^2 \lambda}$	38-14
	where v_{av} is the average speed of the electrons and λ is their mean free path between collisions with the lattice ions.	
Mean free path	$\lambda = \frac{vt}{n_{ion}\pi r^2 vt} = \frac{1}{n_{ion}\pi r^2} = \frac{1}{n_{ion}A}$	38-16
	where n_{ion} is the number of lattice ions per unit volume, r is their effective radius, and A is their effective cross-sectional area.	
3. Classical Interpretation of v_{av} and λ	v_{av} is determined from the Maxwell–Boltzmann distribution, and r is the actual radius of a lattice ion. (This interpretation is not consistent with measured results.)	
4. Quantum Interpretation of v_{av} and λ	v_{av} is determined from the Fermi–Dirac distribution and is approximately constant independent of temperature. The mean free path is determined from the scattering of electron waves, which occurs only because of deviations from a perfectly ordered array. The radius r is the amplitude of vibration of the lattice ion, which is proportional to $\sqrt{T}$, so A is proportional to T.	
5. Free Electrons		
Fermi energy E_F at $T = 0$	E_F is the energy of the last filled (or half-filled) energy state.	
E_F at $T > 0$	E_F is the energy at which the probability of being occupied is $\frac{1}{2}$.	
Approximate magnitude of E_F	E_F is between 5 eV and 10 eV for most metals.	
Dependence of E_F on the number density (N/V) of free electrons	$E_F = \frac{h^2}{8m_e}\left(\frac{3N}{\pi V}\right)^{2/3}$	38-22*a*
Average energy at $T = 0$	$E_{av} = \frac{3}{5}E_F$	38-23
Fermi factor at $T = 0$	The Fermi factor $f(E)$ is the probability of a state being occupied. $f(E) = \begin{cases} 1 & E < E_F \\ 0 & E > E_F \end{cases}$	38-24
Fermi temperature	$T_F = \frac{E_F}{k}$	38-25
Fermi speed	$u_F = \sqrt{\frac{2E_F}{m_e}}$	38-26

TOPIC	RELEVANT EQUATIONS AND REMARKS
Contact potential	When two different metals are placed in contact, electrons flow from the metal with the higher Fermi energy to the metal with the lower Fermi energy until the Fermi energies of the two metals are equal. In equilibrium, there is a potential difference between the metals that is equal to the difference in the work function of the two metals divided by the electronic charge e: $$V_{\text{contact}} = \frac{\phi_1 - \phi_2}{e} \qquad 38\text{-}27$$
Specific heat due to conduction electrons	$$c'_{\text{V}} = \tfrac{1}{2}\pi^2 R\frac{T}{T_{\text{F}}} \qquad 38\text{-}29$$
6. Band Theory of Solids	When many atoms are brought together to form a solid, the individual energy levels are split into bands of allowed energies. The splitting depends on the type of bonding and the lattice separation. The highest energy band that contains electrons is called the valence band. (The lowest energy band that is not filled with electrons is called the conduction band.) In a conductor, the valence band is only partially filled, so there are many available empty energy states for excited electrons. In an insulator, the valence band is completely filled and there is a large energy gap between it and the next allowed band, the conduction band. In a semiconductor, the energy gap between the filled valence band and the empty conduction band is small; so, at ordinary temperatures, an appreciable number of electrons are thermally excited into the conduction band.
7. Semiconductors	The conductivity of a semiconductor can be greatly increased by doping. In an n-type semiconductor, the doping adds electrons at energies just below that of the conduction band. In a p-type semiconductor, holes are added at energies just above that of the valence band.
8. *Semiconductor Junctions and Devices	
**pn* Junctions	Semiconductor devices such as diodes and transistors make use of n-type semiconductors and p-type semiconductors. The two types of semiconductors are typically a single silicon crystal doped with donor impurities on one side and acceptor impurities on the other side. The region in which the semiconductor changes from a p-type semiconductor to an n-type semiconductor is called a junction. Junctions are used in diodes, solar cells, surface barrier detectors, LEDs, and transistors.
*Diodes	A diode is a single-junction device that carries current in one direction only.
*Zener diodes	A Zener diode is a diode with a very high reverse bias. It breaks down suddenly at a distinct voltage and can therefore be used as a voltage reference standard.
*Tunnel diodes	A tunnel diode is a diode that is heavily doped so that electrons tunnel through the depletion barrier. At normal operation, a small change in bias voltage results in a large change in current.
*Transistors	A transistor consists of a very thin semiconductor of one type sandwiched between two semiconductors of the opposite type. Transistors are used in amplifiers because a small variation in the base current results in a large variation in the collector current.
9. Superconductivity	In a superconductor, the resistance drops suddenly to zero below a critical temperature T_c. Superconductors with critical temperatures as high as 138 K have been discovered.
The BCS theory	Superconductivity is described by a theory of quantum mechanics called the BCS theory in which the free electrons form Cooper pairs. The energy needed to break up a Cooper pair is called the superconducting energy gap E_g. When all the electrons are paired, individual electrons cannot be scattered by a lattice ion, so the resistance is zero.
Tunneling	When a normal conductor is separated from a superconductor by a thin layer of oxide, electrons can tunnel through the energy barrier if the applied voltage across the layer is $E_g/(2e)$, where E_g is the energy needed to break up a Cooper pair. The energy gap E_g can be determined by a measurement of the tunneling current versus the applied voltage.

TOPIC	RELEVANT EQUATIONS AND REMARKS
Josephson junction	A system of two superconductors separated by a thin layer of nonconducting material is called a Josephson junction.
dc Josephson effect	A dc current is observed to tunnel through a Josephson junction even in the absence of voltage across the junction.
ac Josephson effect	When a dc voltage V is applied across a Josephson junction, an ac current is observed with a frequency $$f = \frac{2e}{h}V \qquad 38\text{-}39$$ Measurement of the frequency of this current allows a precise determination of the ratio e/h.
10. The Fermi–Dirac Distribution	The number of electrons with energies between E and $E + dE$ is given by $$n(E)\,dE = f(E)\,g(E)\,dE \qquad 38\text{-}40$$ where $g(E)$ is the density of states and $f(E)$ is the Fermi factor.
Density of states	$$g(E) = \frac{8\sqrt{2}\pi m_e^{3/2}V}{h^3}E^{1/2} \qquad 38\text{-}41$$
Fermi factor at $T > 0$	$$f(E) = \frac{1}{e^{(E-E_F)/(kT)} + 1} \qquad 38\text{-}46$$

Answers to Practice Problems

38-1	$E_F = 9.40$ eV
38-2	5.53 eV
38-3	2×10^{-13} electrons/atom
38-4	One minus the probability of the energy state being occupied. That is, $1 - 0.98 = 0.02$ or 2 percent.

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • In the classical model of conduction, the electron loses energy on average during a collision because it loses the drift velocity it had acquired since the last collision. Where does this energy appear?

2 • A metal is a good conductor because the valence energy band for electrons is (*a*) empty, (*b*) partly filled, (*c*) filled, but there is only a small gap to a higher empty band, (*d*) completely filled, (*e*) none of the above.

3 • Thomas refuses to believe that a potential difference can be created simply by bringing two different metals into contact with each other. John talks him into making a small wager and is about to win the bet. (*a*) Which two metals from Table 38-2 would demonstrate his point most effectively? (*b*) What is the value of that contact potential?

4 • (*a*) In Problem 3, which choices of different metals would make the least impressive demonstration? (*b*) What is the value of that contact potential?

5 • When a sample of pure copper is cooled from 300 K to 4 K, its resistivity decreases more than the resistivity of a sample of brass when it is cooled through the same temperature difference. Why? SSM

6 • Insulators are poor conductors of electricity because (*a*) there is a small energy gap between the filled valence band and the next higher band where electrons can exist, (*b*) there is a large energy gap between the completely filled valence band and the next higher band where electrons can exist, (*c*) the valence band has a few vacancies for electrons, (*d*) the valence band is only partly filled, (*e*) none of the above.

7 • How does the sign of the change in the resistivity of a sample of copper compare with the sign of the change in the resistivity of a sample of silicon when the temperatures of both samples increase? SSM

8 • True or false:

(*a*) Solids that are good electrical conductors are usually good heat conductors.

(*b*) At $T = 0$, an intrinsic semiconductor is an insulator.

(*c*) The Fermi energy is the average energy of an electron in a solid.
(*d*) At $T = 0$, the value of the Fermi factor can be either 1 or 0.
(*e*) Semiconductors conduct current in one direction only.
(*f*) The classical free-electron theory adequately explains the heat capacity of metals.
(*g*) The contact potential between two metals is proportional to the difference in the work functions of the two metals.

9 • Which of the following elements are most likely to act as acceptor impurities in germanium? (*a*) bromine, (*b*) gallium, (*c*) silicon, (*d*) phosphorus, (*e*) magnesium

10 • Which of the following elements are most likely to serve as donor impurities in germanium? (*a*) bromine, (*b*) gallium, (*c*) silicon, (*d*) phosphorus, (*e*) magnesium

11 • An electron hole is created when a photon is absorbed by a semiconductor. How does this hole enable the semiconductor to conduct electricity?

12 • Examine the positions of phosphorus, boron, thallium, and antimony in Table 36-1. (*a*) Which of these elements can be used to dope silicon to create an *n*-type semiconductor? (*b*) Which of these elements can be used to dope silicon to create a *p*-type semiconductor?

13 • When photons of visible light strike the *p*-type semiconductor in a *pn* junction solar cell, (*a*) only free electrons are created, (*b*) only positive holes are created, (*c*) both electrons and holes are created, (*d*) protons are created, (*e*) none of the above.

ESTIMATION AND APPROXIMATION

14 • The ratio of the resistivity of the most resistive (least conductive) material to that of the least resistive material (excluding superconductors) is approximately 10^{24}. You can develop a feeling for how remarkable this range is by considering what the ratio is of the largest values to smallest values of other material properties. Choose any three properties of materials, and using tables in this book or some other resource, calculate the ratio of the largest instance of the property to the smallest instance of that property (other than zero) and rank these in decreasing order. Can you find any other property that shows a range as large as that of electrical resistivity?

15 • A device is said to be "ohmic" if a graph of current versus applied voltage is a straight line through the origin. The resistance R of the device is the reciprocal of the slope of this line. A *pn* junction is an example of a nonohmic device, as may be seen from Figure 38-21. For nonohmic devices, it is sometimes convenient to define the *differential resistance* as the reciprocal of the slope of the I versus V curve. Using the curve in Figure 38-21, estimate the differential resistance of the *pn* junction at applied voltages of -20 V, $+0.2$ V, $+0.4$ V, $+0.6$ V, and $+0.8$ V.

THE STRUCTURE OF SOLIDS

16 • Calculate the center-to-center separation distance r_0 between the K^+ and the Cl^- ions in KCl. Do this by assuming that each ion occupies a cubic volume of side r_0. The molar mass of KCl is 74.55 g/mol and its density is 1.984 g/cm^3.

17 • The center-to-center separation distance between the Li^+ and Cl^- ions in LiCl is 0.257 nm. Use that value and the molar mass of LiCl (42.4 g/mol) to compute the density of LiCl.

18 • Find the value of n in Equation 38-6 that gives the measured dissociation energy of 741 kJ/mol for LiCl, which has the same structure as NaCl and for which $r_0 = 0.257$ nm.

19 •• (*a*) Use Equation 38-6 and calculate $U(r_0)$ for calcium oxide, CaO, where $r_0 = 0.208$ nm. Assume $n = 8$. (*b*) If n increases from 8 to 10, what is the fractional change in $U(r_0)$?

A MICROSCOPIC PICTURE OF CONDUCTION

20 • A measure of the density of the free electrons in a metal is the distance r_s, which is defined as the radius of the sphere whose volume equals the volume per conduction electron. (*a*) Show that $r_s = [3/(4\pi n)]^{1/3}$, where n is the free-electron number density. (*b*) Calculate r_s for copper in nanometers.

21 • (*a*) Given a mean free path $\lambda = 0.400$ nm and a mean speed $v_{av} = 1.17 \times 10^5$ m/s for the charge flow in copper at a temperature of 300 K, calculate the classical value for the resistivity ρ of copper. (*b*) The classical model suggests that the mean free path is temperature independent and that v_{av} depends on temperature. According to this model, what would ρ be at 100 K?

FREE ELECTRONS IN A SOLID

22 •• Silicon has a molar mass of 28.09 g/mol and a density of 2.41×10^3 kg/m^3. Each atom of silicon has four valence electrons and the Fermi energy of the material is 4.88 eV. (*a*) Given that the electron mean free path at room temperature is $\lambda = 27.0$ nm, estimate the resistivity. (*b*) The accepted value for the resistivity of silicon is $640\ \Omega \cdot$m (at room temperature). How does this accepted value compare to the value calculated in Part (*a*) ?

23 • Calculate the number density of free electrons in (*a*) Ag ($\rho = 10.5$ g/cm^3) and (*b*) Au ($\rho = 19.3$ g/cm^3), assuming one free electron per atom, and compare your results with the values listed in Table 38-1.

24 • The density of aluminum is 2.7 g/cm^3. How many free electrons are present per aluminum atom?

25 • The density of tin is 7.3 g/cm^3. How many free electrons are present per tin atom?

26 • Calculate the Fermi temperature for (*a*) Mg, (*b*) Mn, and (*c*) Zn.

27 • What is the speed of a conduction electron whose energy is equal to the Fermi energy E_F for (*a*) Na, (*b*) Au, and (*c*) Sn?

28 • Calculate the Fermi energy for (*a*) Al, (*b*) K, and (*c*) Sn using the number densities given in Table 38-1.

29 • Find the average energy of the conduction electrons at $T = 0$ in (*a*) copper and (*b*) lithium.

30 • Calculate (*a*) the Fermi temperature and (*b*) the Fermi energy at $T = 0$ for iron.

31 •• (*a*) Assuming that each gold atom in a sample of gold metal contributes one free electron, calculate the free-electron density in gold knowing that its atomic mass is 196.97 g/mol and its density is 19.3×10^3 kg/m^3. (*b*) If the Fermi speed for gold is 1.39×10^6 m/s, what is the Fermi energy in electron volts? (*c*) By what factor is the Fermi energy higher than the kT energy at room temperature? (*d*) Explain the difference between the Fermi energy and the kT energy. SSM

32 •• The bulk modulus B of a material can be defined by $B = -V\partial P/\partial V$ (*a*) Use the monatomic ideal-gas relation $PV = \frac{2}{3}NE_{av}$, where E_{av} is the average kinetic energy, Equation 38-22 and Equation 38-23 to show that $P = \frac{2}{5}NE_F/V = CV^{-5/3}$, where C is a constant independent of V. (*b*) Show that the bulk modulus of the free electrons in a solid metal is therefore $B = \frac{5}{3}P = \frac{2}{3}NE_F/V$. (*c*) Compute the bulk modulus in newtons per square meter for the free electrons in a sample of copper and compare your result with the measured value of 140×10^9 N/m^2.

33 •• The pressure of a monatomic ideal gas is related to the average kinetic energy of the gas particles by $PV = \frac{2}{3}NE_{av}$, where n is the number of particles and E_{av} is the average kinetic energy. Use this information to calculate the pressure of the free electrons in a sample of copper in newtons per square meter, and compare your result with atmospheric pressure, which is about 10^5 N/m^2. (*Note:* The units are most easily handled by using the conversion factors 1 N/m^2 = 1 J/m^3 and 1 eV = 1.602×10^{-19} J.) SSM

34 • Calculate the contact potential between (*a*) Ag and Cu, (*b*) Ag and Ni, and (*c*) Ca and Cu.

HEAT CAPACITY DUE TO ELECTRONS IN A METAL

35 •• Gold has a Fermi energy of 5.53 eV. Determine the molar specific heat at constant volume for gold at room temperature. SSM

QUANTUM THEORY OF ELECTRICAL CONDUCTION

36 • The resistivities and Fermi speeds of Na, Au, and Sn at T = 273 K are 4.2 $\mu\Omega \cdot$cm, 2.04 $\mu\Omega \cdot$cm, and 10.6 $\mu\Omega \cdot$cm, and 1.07×10^6 m/s, 1.39×10^6 m/s, and 1.89×10^6 m/s, respectively. Use those values to find the mean free paths for the conduction electrons in these elements.

37 •• The resistivity of pure copper increases by approximately 1.0×10^{-8} $\Omega \cdot$m with the addition of 1.0 percent (by number of atoms) of an impurity distributed throughout the metal. The mean free path λ depends on both the impurity and the oscillations of the lattice ions according to the equation $1/\lambda = 1/\lambda_t + 1/\lambda_i$, where λ_t is the mean free path associated with the thermal vibrations of the ions and λ_i is the mean free path associated with the impurities. (*a*) Estimate λ_i using Equation 38-14 and the data given in Table 38-1. (*b*) If r is the effective radius of an impurity lattice ion seen by an electron, the scattering cross section is πr^2. Estimate this area, using the fact that r is related to λ_i by Equation 38-16. SSM

BAND THEORY OF SOLIDS

38 • Electromagnetic radiation is incident on the surface of a semiconductor. The maximum wavelength of this light that is required if electrons are to cross the energy gap between the valence band and the conduction band is 380.0 nm. What is the energy gap, in electron volts, for the semiconductor?

39 • An electron occupies the highest energy level of the valence band in a silicon sample. What is the maximum photon wavelength that will excite the electron across the energy gap if the gap is 1.14 eV? SSM

40 • An electron occupies the highest energy level of the valence band in a germanium sample. What is the maximum photon wavelength that will excite the electron into the conduction band? In germanium, the energy gap between the valence and conduction bands is 0.74 eV.

41 • An electron occupies the highest energy level of the valence band in a diamond sample. What is the maximum photon wavelength that will excite the electron into the conduction band? In diamond, the energy gap between the valence and conduction bands is 7.0 eV.

42 •• A photon of wavelength 3.35 μm has just enough energy to raise an electron from the valence band to the conduction band in a lead sulfide sample. (*a*) Find the energy gap between the bands in lead sulfide. (*b*) Find the temperature T for which kT equals that energy gap.

SEMICONDUCTORS

43 • The donor energy levels in an n-type semiconductor are 0.0100 eV below the conduction band. Find the temperature for which kT = 0.0100 eV.

44 •• When a thin slab of semiconducting material is illuminated with monochromatic electromagnetic radiation, most of the radiation is transmitted through the slab if the wavelength is greater than 1.85 mm. For wavelengths less than 1.85 mm, most of the incident radiation is absorbed. Determine the energy gap of the semiconductor.

45 •• The relative binding of the extra electron in the arsenic atom that replaces an atom in silicon or germanium can be understood from a calculation of the first Bohr radius of the electron in these materials. Four of arsenic's valence electrons form covalent bonds, so the fifth electron sees a center of attraction with a charge of $+e$. This model is a modified hydrogen atom. In the Bohr model of the hydrogen atom, the electron moves in free space at a radius a_0 given by $a_0 = 4\pi\epsilon_0\hbar^2/(m_e e^2)$ (Equation 36-12). When an electron moves in a crystal, we can approximate the effect of the other atoms by replacing ϵ_0 with $\kappa\epsilon_0$ and m_e with an effective mass for the electron. For silicon, κ is 12 and the effective mass is approximately $0.2m_e$. For germanium, κ is 16 and the effective mass is approximately $0.1m_e$. Estimate the Bohr radii for the valence electron as it orbits the impurity arsenic atom in silicon and in germanium.

46 •• The ground-state energy of the hydrogen atom is given by $E_1 = -m_e e^4/(8\epsilon_0^2 h^2)$ (Equations 36-15 and 36-16 where $4\pi\epsilon_0$ is substituted for k^{-1}). Modify this equation using information in Problem 45 by replacing ϵ_0 with $\kappa\epsilon_0$ and m_e with an effective mass for the electron to estimate the binding energy of the extra electron of an impurity arsenic atom in (*a*) silicon and (*b*) germanium.

47 •• A doped n-type silicon sample has 1.00×10^{16} electrons per cubic centimeter in the conduction band and has a resistivity of 5.00×10^{23} $\Omega \cdot$m at 300 K. Find the mean free path of the electrons. Use the effective mass of $0.2m_e$ for the mass of the electrons. (See Problem 45.) Compare this mean free path with that of conduction electrons in copper at 300 K.

48 ••• In the Hall effect, the Hall coefficient R_H is the proportionality constant between the transverse electric field and the product of the applied magnetic field and the current density. That is, $E_y = R_H B_z J_x$, where the current density, the transverse electric field, and the applied magnetic field are in the $+x$, $-y$, and $+z$ directions, respectively. (The Hall effect is presented in Chapter 26.) The measured Hall coefficient of a doped silicon sample is 0.0400 V $\cdot$ m/(A $\cdot$ T) at room temperature. If all the doping impurities have contributed to the total number of charge carriers of the sample, find (*a*) the type of impurity (donor or acceptor) used to dope the sample and (*b*) the concentration of the impurities.

*SEMICONDUCTOR JUNCTIONS AND DEVICES

49 •• Simple theory for the current versus the bias voltage across a pn junction yields the equation $I = I_0(e^{eV_b/kT} - 1)$. Sketch I versus V_b for both positive and negative values of V_b using that equation.

50 • The base current in an npn transistor circuit is 25.0 mA. If 88.0 percent of the electrons entering the base from the emitter reach the collector, what is the base current?

51 •• In Figure 38-28 for the npn-transistor amplifier, suppose R_b = 2.00 kΩ and R_L = 10.0 kΩ. Suppose further that a 10.0-μA ac base current i_b generates a 0.500-mA ac collector current i_c. What is the voltage gain of the amplifier? SSM

52 •• Germanium can be used to measure the energy of incident photons. Consider a 660-keV gamma ray emitted from ^{137}Cs. (*a*) Given that the band gap in germanium is 0.72 eV, how many electron-hole pairs can be generated as this gamma ray travels through germanium? (*b*) The number N of pairs in Part (*a*) will have statistical fluctuations given by $\pm\sqrt{N}$. What then is the energy resolution of the detector in that photon energy region?

53 •• Make a sketch showing the valence and conduction band edges and Fermi energy of a *pn*-junction diode when biased (*a*) in the forward direction and (*b*) in the reverse direction.

54 •• A good silicon diode has the current-voltage characteristic given by $I = I_0(e^{eV_b/kT} - 1)$. Let $kT = 0.025$ eV (room temperature) and the saturation current $I_0 = 1.0$ nA. (*a*) Show that for small reverse-bias voltages, the resistance is 25 MΩ. *Hint: Do a Taylor-series expansion of the exponential function about $V_b = 0$, or use the expansion for e^x found in Table M-4 of the Math Tutorial.* (*b*) Find the dc resistance for a reverse bias of 0.50 V. (*c*) Find the resistance V/I for a 0.50-V forward bias. What is the current in this case? (*d*) Calculate the differential resistance dV/dI for a 0.50-V forward bias.

55 •• A long slab of silicon of thickness $T = 1.0$ mm and width $w = 1.0$ cm is placed in a magnetic field $B = 0.40$ T. The slab is in the xy plane, where the length of the slab is parallel with the x axis and the magnetic field points in the $+z$ direction. When a current of 0.20 A exists in the sample in the $+x$ direction, a potential difference of 5.0 mV develops across the width of the sample and the electric field in the sample points in the $+y$ direction. Determine the semiconductor type (n or p) and the concentration of charge carriers. (The Hall effect is presented in Chapter 26.)

THE BCS THEORY

56 • (*a*) Use Equation 38-37 to calculate the superconducting energy gap for tin, and compare your result with the measured value of 6.00×10^{-4} eV. (*b*) Use the measured value to calculate the minimum value of the wavelength of a photon that has sufficient energy to break up Cooper pairs in lead ($T_c = 3.72$ K) at $T = 0$.

57 • (*a*) Use Equation 38-37 to calculate the superconducting energy gap for lead, and compare your result with the measured value of 2.73×10^{-3} eV. (*b*) Use the measured value to calculate the minimum value of the wavelength of a photon that has sufficient energy to break up Cooper pairs in tin ($T_c = 7.19$ K) at $T = 0$. SSM

THE FERMI–DIRAC DISTRIBUTION

58 •• The number of electrons in the conduction band of an insulator or intrinsic semiconductor is governed chiefly by the Fermi factor. Because the valence band in these materials is nearly filled and the conduction band is nearly empty, the Fermi energy E_F is generally midway between the top of the valence band and the bottom of the conduction band; that is, it is at $E_g/2$, where E_g is the band gap between the two bands and the energy is measured from the top of the valence band. (*a*) In silicon, $E_g \approx 1.0$ eV. Show that in this case the Fermi factor for electrons at the bottom of the conduction band is given by $\exp(-E_g/2kT)$ and evaluate this factor. Discuss the significance of the result if there are 10^{22} valence electrons per cubic centimeter and the probability of finding an electron in the conduction band is given by the Fermi factor. (*b*) Repeat the calculation in Part (*a*) for an insulator with a band gap of 6.0 eV.

59 •• Approximately how many energy states that have energies between 2.00 eV and 2.20 eV are available to electrons in a cube of silver measuring 1.00 mm on a side?

60 •• Show that at $E = E_F$, the expression for the Fermi factor (Equation 38-24) is equal to 0.5.

61 •• (*a*) Using the equation $E_F = [h^2/(8m_e)][3N/(\pi V)]^{2/3}$ (Equation 38-22*a*), calculate the Fermi energy for silver. (*b*) Determine the average kinetic energy of a free electron and (*c*) find the Fermi speed for silver. SSM

62 •• What is the difference between the energies at which the Fermi factor is 0.9 and 0.1 at 300 K in (*a*) copper, (*b*) potassium, and (*c*) aluminum.

63 •• What is the probability that a conduction electron in silver will have a kinetic energy of 4.90 eV at $T = 300$ K? SSM

64 •• Show that $g(E) = \frac{3}{2}NE_F^{-3/2}E^{1/2}$ (Equation 38-43) follows from Equation 38-41 for $g(E)$, and from Equation 38-22*a* for E_F.

65 •• Carry out the integration $E_{av} = (1/N)\int_0^{E_F} Eg(E)dE$ to show that the average energy at $T = 0$ is $\frac{3}{5}E_F$.

66 •• The density of the electron states in a metal can be written $g(E) = AE^{1/2}$, where A is a constant and E is measured from the bottom of the conduction band. (*a*) Show that the total number of states is $\frac{2}{3}AE_F^{3/2}$. (*b*) Approximately what fraction of the conduction electrons are within kT of the Fermi energy? (*c*) Evaluate that fraction for copper at $T = 300$ K.

67 •• What is the probability that a conduction electron in silver will have a kinetic energy of 5.49 eV at $T = 300$ K?

68 •• Using the expression $g(E) = (8\sqrt{2}\pi m_e^{3/2}V/h^3)E^{1/2}$ (Equation 38-41) for the density of states, estimate the fraction of the conduction electrons in copper that can absorb energy from collisions with the vibrating lattice ions at (*a*) 77 K and (*b*) 300 K.

69 •• In an intrinsic semiconductor, the Fermi energy is about midway between the top of the valence band and the bottom of the conduction band. In germanium, the forbidden energy band has a width of 0.70 eV. Show that at room temperature the distribution function of electrons in the conduction band is given by the Maxwell–Boltzmann distribution function.

70 ••• The root-mean-square (rms) value of a variable is obtained by calculating the average value of the square of that variable and then taking the square root of the result. Use that procedure to determine the rms energy of a Fermi distribution. Express your result in terms of E_F and compare it to the average energy. Why do E_{av} and E_{rms} differ?

GENERAL PROBLEMS

71 • The density of potassium is 0.851 g/cm³. How many free electrons are there per potassium atom in a crystal of potassium?

72 • Calculate the number density of free electrons for (*a*) magnesium, which has a density of 1.74 g/cm³, and (*b*) zinc, which has a density of 7.14 g/cm³. For the calculations assume there are two free electrons per atom, and compare your results with the values listed in Table 38-1.

73 •• Estimate the fraction of free electrons in copper that are in energy states above the Fermi energy at (*a*) 300 K (about room temperature) and (*b*) 1000 K.

74 •• A certain free-electron energy state of manganese has a 10.0 percent chance of being occupied when the temperature of the manganese is $T = 1300$ K. What is the energy of the state?

75 •• The semiconducting compound CdSe is widely used for light-emitting diodes (LEDs). The energy gap in CdSe is 1.80 eV. What is the frequency of the light emitted by a CdSe LED?

76 ••• A 2.00-cm² wafer of pure silicon is irradiated with electromagnetic radiation having a wavelength of 775 nm. The intensity of the radiation is 4.00 W/m² and every photon that strikes the sample is absorbed and creates an electron-hole pair. (*a*) How many electron-hole pairs are produced in one second? (*b*) If the number of electron-hole pairs in the sample is 6.25×10^{11} in the steady state, at what rate do the electron-hole pairs recombine? (*c*) If every recombination event results in the radiation of one photon, at what rate is energy radiated by the sample?

CHAPTER 39

THE ANDROMEDA GALAXY BY MEASURING THE FREQUENCY OF THE LIGHT COMING TO US FROM DISTANT OBJECTS, WE ARE ABLE TO DETERMINE HOW FAST THE OBJECTS ARE APPROACHING TOWARD US OR RECEDING FROM US. *(NASA.)*

? Have you wondered how the frequency of the light enables us to determine the speed of recession of a distant galaxy? (See Example 39-5.)

Relativity

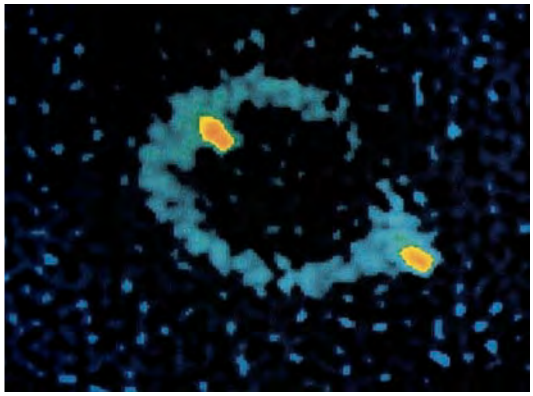
The theory of relativity consists of two rather different theories, the special theory and the general theory. The special theory, developed by Albert Einstein and others in 1905, describes measurements made in different inertial reference frames moving with constant velocity relative to one another. Its consequences, which can be derived with a minimum of mathematics, are applicable in a wide variety of situations encountered in physics and in engineering. On the other hand, the general theory, also developed by Einstein and others around 1916, describes accelerated reference frames and gravity. A thorough understanding of the general theory requires sophisticated mathematics, and the applications of the theory are mainly in the area of gravitation. The general theory is of great importance in cosmology, but it is rarely encountered in other areas of physics or in engineering. The general theory is applied, however, in the engineering of the Global Positioning System (GPS).*

* The satellites used in GPS contain atomic clocks.

In this chapter, we concentrate on the special theory (often referred to as special relativity*). General relativity theory (general relativity) will be discussed briefly near the end of the chapter. Special relativity is first presented in Chapter R (which precedes Chapter 11). You should consider reviewing the material in Chapter R before proceeding in this chapter.*

39-1 NEWTONIAN RELATIVITY

Newton's first law does not distinguish between a particle at rest and a particle moving with constant velocity. If there is no net external force acting, the particle will remain in its initial state, either at rest or moving with its initial velocity. A particle at rest relative to you is moving with constant velocity relative to an observer who is moving with constant velocity relative to you. How might we distinguish whether you and the particle are at rest and the second observer is moving with constant velocity, or the second observer is at rest and you and the particle are moving?



The ringlike structure of the radio source MG1131 + 0456 is thought to be due to *gravitational lensing,* first proposed by Albert Einstein in 1936, in which a source is imaged into a ring by a large, massive object in the foreground. *(NRAO/AUI.)*

Let us consider some simple experiments. Suppose we have a railway boxcar moving along a straight, flat track with a constant velocity v. (The velocity v is a signed quantity, and the sign indicates the direction of the motion of the boxcar along the track.) We note that a ball at rest in the boxcar remains at rest relative to the car. If we drop the ball, it falls straight down, relative to the boxcar, with an acceleration g due to gravity. Of course, when viewed from the reference frame of the track, the ball moves along a parabolic path because it has an initial velocity v to the right. No mechanics experiment that we can do—measuring the period of a pendulum, observing the collisions between two objects, or whatever—will tell us whether the boxcar is moving and the track is at rest or the track is moving and the boxcar is at rest. If we have a coordinate system attached to the track and another attached to the boxcar, Newton's laws hold in either system.

A set of coordinate systems at rest relative to each other is called a *reference frame*. A reference frame in which Newton's laws hold is called an *inertial reference frame*.* All reference frames moving at constant velocity relative to an inertial reference frame are also inertial reference frames. If we have two inertial reference frames moving with constant velocity relative to each other, there are no mechanics experiments that can tell us which is at rest and which is moving or if they are both moving. This result is known as the principle of **Newtonian relativity:**

> Absolute motion cannot be detected.
>
> PRINCIPLE OF NEWTONIAN RELATIVITY

This principle was well known by Galileo, Newton, and others in the seventeenth century. By the late nineteenth century, however, this view had changed. It was then generally thought that Newtonian relativity was not valid and that absolute motion could be detected in principle by a measurement of the speed of light.

ETHER AND THE SPEED OF LIGHT

We saw in Chapter 15 that the velocity of a wave depends on the properties of the medium in which the wave travels and not on the velocity of the source of the waves. For example, the velocity of sound relative to still air depends on the temperature of the air. Light and other electromagnetic waves (for example, radio

* Reference frames were first discussed in Section 3-1. Inertial reference frames were also discussed in Section 4-1.

waves and X rays) travel through a vacuum with a speed $c = 3.00 \times 10^8$ m/s that is predicted by James Clerk Maxwell's equations for electricity and magnetism. But what is this speed relative to? What is the equivalent of still air for a vacuum? A proposed medium for the propagation of light was called the *ether;* it was thought to pervade all space. The velocity of light relative to the ether was assumed to be c, as predicted by Maxwell's equations. The velocity of any object relative to the ether was considered to be the absolute velocity of the object.

Albert Michelson, first in 1881 and then again with Edward Morley in 1887, set out to measure the velocity of Earth relative to the ether by an ingenious experiment in which the velocity of light relative to Earth was compared for two light beams, one parallel to the direction of Earth's motion relative to the Sun and the other perpendicular to the direction of Earth's motion. Despite painstakingly careful measurements, they could detect no difference. The experiment has since been repeated under various conditions by a number of people, and no difference has ever been found. The absolute motion of Earth relative to the ether cannot be detected.

39-2 EINSTEIN'S POSTULATES

In 1905, at the age of 26, Albert Einstein published a paper on the electrodynamics of moving bodies.* In this paper, he postulated that absolute motion cannot be detected by any experiment. That is, there is no ether. Earth can be considered to be at rest and the velocity of light will be the same in any direction.† His theory of special relativity can be derived from two postulates. Simply stated, these postulates are as follows:

> Postulate 1: Absolute uniform motion cannot be detected.
>
> Postulate 2: The speed of light is independent of the motion of the source.
>
> EINSTEIN'S POSTULATES

Postulate 1 is merely an extension of the Newtonian principle of relativity to include all types of physical measurements (not just those measurements that are mechanical). Postulate 2 describes a common property of many waves. For example, the speed of sound waves does not depend on the motion of the sound source. The sound waves from a car horn travel through the air with the same speed, relative to the air, independent of whether the car is moving relative to the air or not. The speed of the waves depends only on the properties of the air, such as its temperature.

Although each postulate seems quite reasonable, many of the implications of the two postulates together are quite surprising and contradict what is often called common sense. For example, one important implication of these postulates is that every observer measures the same value for the speed of light independent of the relative motion of the source and the observer. Consider a light source S and two observers, R_1 at rest relative to S and R_2 moving toward S with speed v, as shown in Figure 39-1*a*. The speed of light measured by R_1 is $c = 3.00 \times 10^8$ m/s. What is the speed measured by R_2? The answer is *not* $c + v$. By postulate 1, Figure 39-1*a* is equivalent to Figure 39-1*b*, in which R_2 is at rest and the source S and R_1 are

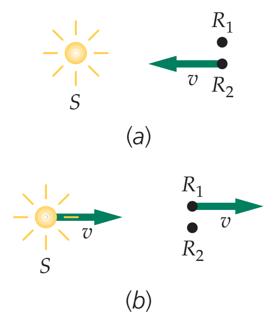


FIGURE 39-1 (*a*) A stationary light source S, a stationary observer R_1, and a second observer R_2 moving toward the source with speed v. (*b*) In the reference frame in which the observer R_2 is at rest, the light source S and observer R_1 move to the right with speed v. If absolute motion cannot be detected, the two views are equivalent. Because the speed of light does not depend on the motion of the source, observer R_2 measures the same value for that speed as observer R_1.

* *Annalen der Physik,* vol. 17, 1905, p. 841. For a translation from the original German, see W. Perrett and G. B. Jeffery (trans.), *The Principle of Relativity: A Collection of Original Memoirs on the Special and General Theory of Relativity* by H. A. Lorentz, A. Einstein, H. Minkowski, and W. Weyl, Dover, New York, 1923.

† Einstein did not set out to explain the results of the Michelson–Morley experiment. His theory arose from his considerations of the theory of electricity and magnetism and the unusual property of electromagnetic waves that they propagate in a vacuum. In his first paper, which contains the complete theory of special relativity, he made only a passing reference to the Michelson–Morley experiment, and in later years he could not recall whether he was aware of the details of the experiment before he published his theory.

moving with speed v. That is, because absolute motion cannot be detected, it is not possible to say which is really moving and which is at rest. By postulate 2, the speed of light from a moving source is independent of the motion of the source. Thus, looking at Figure 39-1*b*, we see that R_2 measures the speed of light to be c, just as R_1 does. This result is often considered as an alternative to Einstein's second postulate:

> Postulate 2 (alternate): Every observer measures the same value c for the speed of light.

This result contradicts our intuitive ideas about relative velocities. If a car moves at 50 km/h away from an observer and another car moves at 80 km/h in the same direction, the velocity of the second car relative to the first car is 30 km/h. This result is easily measured and conforms to our intuition. However, according to Einstein's postulates, if a light beam is moving in the direction of the cars, observers in both cars will measure the same speed for the light beam. Our intuitive ideas about the combination of velocities are approximations that hold only when the speeds are very small compared with the speed of light. Even in an airplane moving with the speed of sound, to measure the speed of light accurately enough to distinguish the difference between the results c and $c + v$, where v is the speed of the plane, would require a measurement with six-digit accuracy.

39-3 THE LORENTZ TRANSFORMATION

Einstein's postulates have important consequences for measuring time intervals and space intervals, as well as relative velocities. Throughout this chapter, we will be comparing measurements of the positions and times of events (such as lightning flashes) made by observers who are moving relative to each other. We will use a rectangular coordinate system xyz that has an origin O and is called the S reference frame; we will use another system $x'y'z'$ that has an origin O', is called the S' frame, and is moving with a constant velocity $\vec{v}$ relative to the S frame. Relative to the S' frame, the S frame is moving with a constant velocity $-\vec{v}$. For simplicity, we will consider the S' frame to be moving along the x axis in the $+x$ direction relative to S, where the $+x'$ direction is the same as the $+x$ direction. In each frame, we will assume that there are as many observers as are needed who have measuring devices, such as clocks and metersticks, that are identical when compared at rest (see Figure 39-2).

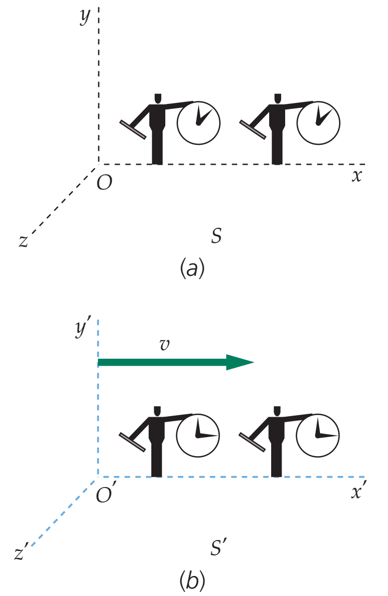

FIGURE 39-2 Coordinate reference frames S and S' moving with relative speed v. In each frame, there are observers who have metersticks and clocks that are identical when compared at rest.

We will use Einstein's postulates to find the general relation between the coordinates x, y, and z and the time t of an event as seen in reference frame S and the coordinates x', y', and z' and the time t' of the same event as seen in reference frame S', which is moving with uniform velocity relative to S. For convenience, we assume that the origins are coincident at time $t = t' = 0$. The classical relation, called the **Galilean transformation,** is

$$x = x' + vt', \quad y = y', \quad z = z', \quad t = t' \qquad \text{39-1}a$$

GALILEAN TRANSFORMATION

The inverse transformation is

$$x' = x - vt, \quad y' = y, \quad z' = z, \quad t' = t \qquad \text{39-1}b$$

These equations are consistent with experimental observations as long as v is much less than c. They lead to the familiar classical rules for velocities. If a particle has velocity $u_x = dx/dt$ in frame S, its velocity in frame S' is

$$u'_x = \frac{dx'}{dt'} = \frac{dx'}{dt} = \frac{d}{dt}(x - vt) = u_x - v \qquad \text{39-2}$$

If we differentiate this equation again, we find that the acceleration of the particle is the same in both frames:

$$a_x = \frac{du_x}{dt} = \frac{du'_x}{dt'} = a'_x$$

It should be clear that the Galilean transformation is not consistent with Einstein's postulates of special relativity. If light moves along the x axis with speed $u'_x = c$ in S', these equations imply that the speed in S' is $u_x = c + v$ rather than $u_x = c$, which is consistent with Einstein's postulates and with experiment. The classical transformation equations must therefore be modified to make them consistent with Einstein's postulates. We will give a brief outline of one method of obtaining the relativistic transformation.

We assume that the relativistic transformation equation for x is the same as the classical equation (Equation 39-1*a*) except for a constant multiplier on the right side. That is, we assume the equation is of the form

$$x = \gamma(x' + vt') \qquad \text{39-3}$$

where γ is a constant that can depend on v and c but not on the coordinates. The inverse transformation must look the same except for the plus sign:

$$x' = \gamma(x - vt) \qquad \text{39-4}$$

Let us consider a light pulse that starts at the origin of S at $t = 0$. Because we have assumed that the two origins are coincident at $t = t' = 0$, the pulse also starts at the origin of S' at $t' = 0$. Einstein's postulates require that the equation for the x component of the wave front of the light pulse is $x = ct$ in frame S and $x' = ct'$ in frame S'. Substituting ct for x and ct' for x' in Equation 39-3 and Equation 39-4, we obtain

$$ct = \gamma(c + v)t' \qquad \text{39-5}$$

and

$$ct' = \gamma(c - v)t \qquad \text{39-6}$$

We divide both sides of Equations 39-5 and 39-6 by t, and then eliminate the ratio t'/t from the two equations and determine γ. Thus,

$$\gamma = \frac{1}{\sqrt{1 - (v^2/c^2)}} \qquad \text{39-7}$$

(Note that γ is always greater than 1, and when v is much less than c, $\gamma \approx 1$.) The relativistic transformation for x and x' is therefore given by Equation 39-3 and Equation 39-4, where γ is given by Equation 39-7. We can obtain equations for t and t' by combining Equation 39-3 with the inverse transformation given by Equation 39-4. Substituting $x = \gamma(x' + vt')$ for x in Equation 39-4, we obtain

$$x' = \gamma[\gamma(x' + vt') - vt] \qquad \text{39-8}$$

which can be solved for t in terms of x' and t'. The complete relativistic transformation is

$$x = \gamma(x' + vt'), \quad y = y', \quad z = z' \qquad \text{39-9}$$

$$t = \gamma\left(t' + \frac{vx'}{c^2}\right) \qquad \text{39-10}$$

LORENTZ TRANSFORMATION

The inverse transformation is

$$x' = \gamma(x - vt), \quad y' = y, \quad z' = z \qquad \text{39-11}$$

$$t' = \gamma\left(t - \frac{vx}{c^2}\right) \qquad \text{39-12}$$

The transformation described by Equations 39-9 through 39-12 is called the **Lorentz transformation.** It relates the space and time coordinates x, y, z, and t of an event in frame S to the coordinates x', y', z', and t' of the same event as seen in frame S', which is moving along the x axis with speed v relative to frame S.

We will now look at some applications of the Lorentz transformation.

TIME DILATION

Consider two events, one that occurs on the x' axis at point x'_0 at time t'_1 in frame S' and another that occurs on the x' axis at point x'_0 at time t'_2 in frame S'. (Both events occur at point x'_0 in S'.) We can find the times t_1 and t_2 for the events in S from Equation 39-10. We have

$$t_1 = \gamma\left(t'_1 + \frac{vx'_0}{c^2}\right)$$

and

$$t_2 = \gamma\left(t'_2 + \frac{vx'_0}{c^2}\right)$$

so

$$t_2 - t_1 = \gamma(t'_2 - t'_1)$$

The time between two events that happen at the *same place* in a reference frame is called **proper time Δt_p** between the events. In this case, the time interval $t'_2 - t'_1$ measured in frame S' is proper time. The time interval Δt measured in any other reference frame is always longer than the proper time. This expansion is called **time dilation:**

$$\Delta t = \gamma\,\Delta t_p \qquad \text{39-13}$$

TIME DILATION

Example 39-1 Spatial Separation and Temporal Separation of Two Events

Two events occur at the same point x'_0 at times t'_1 and t'_2 in frame S', which is traveling in the $+x$ direction at speed v relative to frame S. (*a*) What is the spatial separation of the events in frame S? (*b*) What is the temporal separation of the events in frame S?

PICTURE The spatial separation in S is $x_2 - x_1$, where x_2 and x_1 are the coordinates of the events in S, which are found using Equation 39-9.

SOLVE

(*a*) 1. The position x_1 in S is given by Equation 39-9 with $x'_1 = x'_0$: $\quad x_1 = \gamma(x'_0 + vt'_1)$

2. Similarly, the position x_2 in S is given by: $\quad x_2 = \gamma(x'_0 + vt'_2)$

3. Subtract to find the spatial separation: $\quad \Delta x = x_2 - x_1 = \gamma v(t'_2 - t'_1) = \boxed{\dfrac{v(t'_2 - t'_1)}{\sqrt{1 - (v^2/c^2)}}}$

(*b*) Using the time dilation formula, relate the two time intervals. The two events occur at the same place in S', so the proper time between the two events is $\Delta t_p = t'_2 - t'_1$: $\quad \Delta t = t_2 - t_1 = \gamma(t'_2 - t'_1) = \boxed{\dfrac{(t'_2 - t'_1)}{\sqrt{1 - (v^2/c^2)}}}$

CHECK Taking the limits of the Part-(*a*) and Part-(*b*) results as c approaches infinity gives $\Delta x = v(t_2' - t_1')$ and $\Delta t = t_2' - t_1'$, respectively. Combining these expressions gives $\Delta x = v\Delta t$. This is just the classical (nonrelativistic) equation that displacement equals velocity multiplied by time that is developed in Chapter 2 for one-dimensional motion. In addition, the equation $\Delta t = t_2' - t_1'$ is just the classical result that the length of the time between events is the same in both reference frames.

TAKING IT FURTHER Dividing the Part-(*a*) result by the Part-(*b*) result gives $\Delta x/\Delta t = v$. The spatial separation Δx of the two events in S is the distance a fixed point, such as x_0' in S', moves in S during the time interval between the events in S.

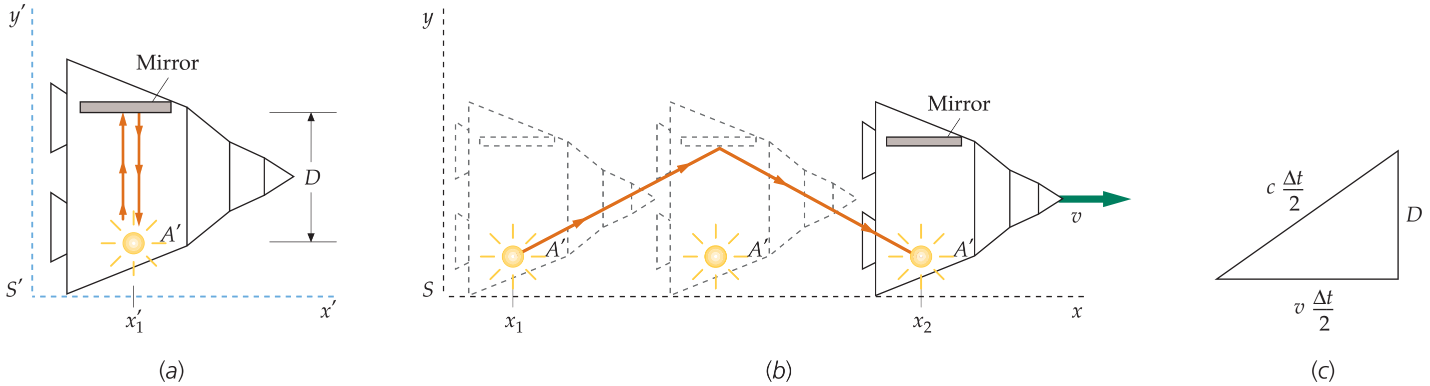

FIGURE 39-3 (*a*) Observer A' and the mirror are in a spaceship at rest in frame S'. The time it takes for the light pulse to reach the mirror and return is measured by A' to be $2D/c$. (*b*) In frame S, the spaceship is moving to the right with speed v. If the speed of light is the same in both frames, the time it takes for the light to reach the mirror and return is longer than $2D/c$ in S because the distance traveled is greater than $2D$. (*c*) A right triangle for computing the time Δt in frame S.

We can understand time dilation directly from Einstein's postulates without using the Lorentz transformation. Figure 39-3*a* shows an observer A' a distance D from a mirror. The observer and the mirror are in a spaceship that is at rest in frame S'. The observer explodes a flash gun and measures the time interval $\Delta t'$ between the original flash (Event 1) and his seeing the return flash from the mirror (Event 2). Because light travels with speed c, this time is

$$\Delta t' = \frac{2D}{c}$$

We now consider the same two events, the original flash of light and the receiving of the return flash, as observed in reference frame S, in which observer A' and the mirror are moving to the right with speed v, as shown in Figure 39-3*b*. Events 1 and 2 happen at positions x_1 and x_2, respectively, in frame S. During the time interval Δt (as measured in S) between the original flash and the return flash, observer A' and his spaceship have moved to the right a distance $v\,\Delta t$. In Figure 39-3, we can see that the path traveled by the light is longer in S than in S'. However, by Einstein's postulates, light travels with the same speed c in frame S as it does in frame S'. Because light travels farther in S at the same speed, it takes longer in S to reach the mirror and return. The time interval in S is thus longer than it is in S'. From the triangle in Figure 39-3*c*, we have

$$\left(\frac{c\,\Delta t}{2}\right)^2 = D^2 + \left(\frac{v\,\Delta t}{2}\right)^2$$

or

$$\Delta t = \frac{2D}{\sqrt{c^2 - v^2}} = \frac{2D}{c}\,\frac{1}{\sqrt{1 - (v^2/c^2)}}$$

Using $\Delta t' = 2D/c$, we obtain

$$\Delta t = \frac{\Delta t'}{\sqrt{1 - (v^2/c^2)}} = \gamma\,\Delta t'$$

Example 39-2 How Long Is a One-Hour Nap? *Try It Yourself*

Astronauts in a spaceship traveling at $v = 0.600c$ relative to Earth sign off from space control, saying that they are going to nap for 1.00 h and then call back. How long does their nap last as measured on Earth?

PICTURE Because the astronauts go to sleep (Event 1) and wake up (Event 2) at the same place in the reference frame of the ship, the time interval for their nap of 1.00 h, as measured by a clock on the ship, is the proper time between the two events. In the reference frame of Earth, they move a considerable distance during the time between the two events. The time interval measured in Earth's frame is measured using two clocks that are stationary relative to Earth. Clock 1 is located at the position of Event 1 and measures the time of occurrence of Event 1. Clock 2 is located at the position of Event 2 and measures the time of occurrence of Event 2. The difference between the two times is longer than the proper time between the two events by the factor γ.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. Relate the time interval measured on Earth Δt to the proper time Δt_{p} (Equation 39-13).	$\Delta t = \gamma\, \Delta t_{\text{p}}$
2. Calculate γ for $v = 0.6c$ (Equation 39-7).	$\gamma = 1.25$
3. Substitute the value for γ to calculate the time of the nap in Earth's frame.	$\Delta t = \gamma\, \Delta t_{\text{p}} = \boxed{1.25\text{ h}}$

CHECK The time interval is longer in the reference frame in which the two events occur at different locations as expected.

PRACTICE PROBLEM 39-1 If the spaceship is moving at $v = 0.800c$, how long would a 1.00 h nap last as measured on Earth?

LENGTH CONTRACTION

A phenomenon closely related to time dilation is **length contraction.** The length of an object measured in the reference frame in which the object is at rest is called its **proper length** L_{p}. In a reference frame in which the object is moving parallel to its length, the measured length is shorter than its proper length. Consider a rod at rest in frame S' with one end at x_2' and the other end at x_1'. The length of the rod in this frame is its proper length $L_{\text{p}} = x_2' - x_1'$. Some care must be taken to find the length of the rod in frame S. In that frame, the rod is moving to the right with speed v, the speed of frame S'. The length of the rod in frame S is defined as $L = x_2 - x_1$, where x_2 is the position of one end at some time t_2, and x_1 is the position of the other end *at the same time* $t_1 = t_2$ as measured in frame S. To calculate $x_2 - x_1$ at some time t we use Equation 39-11:

$$x_2' = \gamma(x_2 - vt_2)$$

and

$$x_1' = \gamma(x_1 - vt_1)$$

Because $t_2 = t_1$, by subtracting the second equation from the first we obtain

$$x_2' - x_1' = \gamma(x_2 - x_1)$$

Solving for $x_2 - x_1$ gives

$$x_2 - x_1 = \frac{1}{\gamma}(x_2' - x_1') = (x_2' - x_1')\sqrt{1 - \frac{v^2}{c^2}}$$

or

$$L = \frac{1}{\gamma}L_\mathrm{p} = L_\mathrm{p}\sqrt{1 - \frac{v^2}{c^2}} \qquad 39\text{-}14$$

LENGTH CONTRACTION

Because $1/\gamma$ is less than one, it follows that the length of the rod is smaller when it is measured in a frame in which it is moving parallel to its length. Before Einstein's paper was published, Hendrik A. Lorentz and George F. FitzGerald tried to explain the null result of the Michelson–Morley experiment by assuming that distances in the direction of motion contracted by the amount given in Equation 39-14. This length contraction is now known as the **Lorentz–FitzGerald contraction.**

Example 39-3 The Length of a Moving Meterstick

A stick that has a proper length of 1.00 m moves in a direction parallel to its length with speed v relative to you. The length of the stick as measured by you is 0.914 m. What is the speed v?

PICTURE We can find v directly from Equation 39-14.

SOLVE

1. Equation 39-14 relates the lengths L and L_p and the speed v: $L = L_\mathrm{p}\sqrt{1 - \frac{v^2}{c^2}}$

2. Solve for v: $v = c\sqrt{1 - \frac{L^2}{L_\mathrm{p}^2}} = c\sqrt{1 - \frac{(0.914\text{ m})^2}{(1.00\text{ m})^2}} = \boxed{0.406c}$

CHECK As expected, the speed is a significant fraction of c.

An interesting example of time dilation or length contraction is the generation of muons as secondary radiation from cosmic rays. Muons decay according to the statistical law of radioactivity:

$$N(t) = N_0 e^{-t/\tau} \qquad 39\text{-}15$$

where N_0 is the number of muons at time $t = 0$, $N(t)$ is the number remaining at time t, and τ is the mean lifetime, which is approximately 2.2 μs for muons at rest. Because muons are generated (from the decay of pions) high in the atmosphere, usually several thousand meters above sea level, few muons should reach sea level. A typical muon moving with speed $0.9978c$ would travel only about 660 m in 2.2 μs. However, the lifetime of the muon measured in Earth's reference frame is increased by the factor $1/\sqrt{1 - (v^2/c^2)}$, which is 15 for this particular speed. The mean lifetime measured in Earth's reference frame is therefore 33 μs, and a muon with speed $0.9978c$ travels approximately 10 000 m during this time. From the muon's point of view, it exists for only 2.2 μs, but the atmosphere is rushing past it with a speed of $0.9978c$. The distance of 10 000 m in Earth's frame is thus contracted to only 660 m in the muon's frame, as indicated in Figure 39-4.

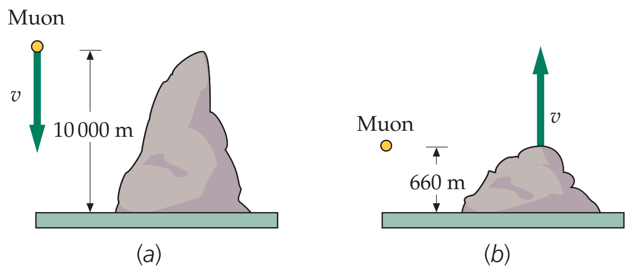

FIGURE 39-4 Although muons are created high above Earth and their mean lifetime is only about 2.2 μs when at rest, many appear at Earth's surface. (*a*) In Earth's reference frame, a typical muon moving at $0.9978c$ has a mean lifetime of 33 μs and travels 10 000 m during that time. (*b*) In the reference frame of the muon, the distance traveled by Earth is only 660 m in the muon's lifetime of 2.2 μs.

It is easy to distinguish experimentally between the classical and relativistic predictions of the observation of muons at sea level. Suppose that we observe 10^8 muons at an altitude of 10 000 m during some time interval with a muon detector. How many would we expect to observe at sea level during the same time interval? According to the nonrelativistic prediction, the time it takes for the muons to travel 10 000 m is $(10\,000\text{ m})/(0.998c) \approx 33\ \mu\text{s}$, which is 15 lifetimes. Substituting $N_0 = 1.0 \times 10^8$ and $t = 15\tau$ into Equation 39-15, we obtain

$$N = N_0 e^{-t/\tau} = 1.0 \times 10^8 e^{-15} = 31$$

We would thus expect all but about 31 of the original 100 million muons to decay before reaching sea level.

According to the relativistic prediction, Earth must travel only the contracted distance of 660 m in the rest frame of the muon. This trip takes only $2.2\ \mu\text{s} = 1\tau$. Therefore, the number of muons expected at sea level is

$$N = N_0 e^{-t/\tau} = 1.0 \times 10^8 e^{-1} = 37 \times 10^6$$

Thus, relativity predicts that we would observe 37 million muons during the same time interval. Experiments have confirmed the relativistic prediction of 37 million muons.

***See* Math Tutorial *for more information on the* The Exponential Function**

THE RELATIVISTIC DOPPLER EFFECT

For light or other electromagnetic waves in a vacuum, a distinction between the motion of the source and the motion of the receiver cannot be made. Therefore, the expressions we derived in Chapter 15 for the Doppler effect cannot be correct for light. The reason it is not correct is that in Chapter 15 we assumed the time intervals in the reference frames of the source and receiver to be the same.

Consider a source moving toward a receiver with speed v, relative to the receiver. If the source emits N electromagnetic-wave crests during a time Δt_R (measured in the frame of the receiver), the first crest will travel a distance $c\,\Delta t_R$ and the source will travel a distance $v\,\Delta t_R$ measured in the frame of the receiver. The wavelength in this reference frame will be

$$\lambda' = \frac{c\,\Delta t_R - v\,\Delta t_R}{N}$$

The frequency f' observed by the receiver will therefore be

$$f' = \frac{c}{\lambda'} = \frac{c}{(c - v)}\frac{N}{\Delta t_R} = \frac{1}{1 - (v/c)}\frac{N}{\Delta t_R}$$

If the frequency of the source in the reference frame of the source is f_0, it will emit $N = f_0\,\Delta t_S$ waves in the time Δt_S measured by the source. Then

$$f' = \frac{1}{1 - (v/c)}\frac{N}{\Delta t_R} = \frac{1}{1 - (v/c)}\frac{f_0\,\Delta t_S}{\Delta t_R} = \frac{f_0}{1 - (v/c)}\frac{\Delta t_S}{\Delta t_R}$$

Here Δt_S is the proper time interval (the first wave and the Nth wave are emitted at the same place in the reference frame of the source). Times Δt_S and Δt_R are related by Equation 39-13 for time dilation:

$$\Delta t_R = \gamma\,\Delta t_S = \frac{\Delta t_S}{\sqrt{1 - (v^2/c^2)}}$$

Thus, when the source and the receiver are moving toward one another we obtain

$$f' = \frac{f_0}{1 - (v/c)}\sqrt{1 - (v^2/c^2)} = \sqrt{\frac{1 + (v/c)}{1 - (v/c)}}\,f_0 \quad \text{approaching} \qquad \text{39-16}a$$

This differs from our classical equation only in the time-dilation factor. It is left as a problem (Problem 25) for you to show that the same results are obtained if the calculations are done in the reference frame of the receiver.

When the source and the receiver are moving away from one another, the same analysis shows that the observed frequency is given by

$$f' = \frac{f_0}{1 + (v/c)}\sqrt{1 - (v/c^2)} = \sqrt{\frac{1 - (v/c)}{1 + (v/c)}}f_0 \quad \text{receding} \qquad \text{39-16}b$$

An application of the relativistic Doppler effect is the **redshift** observed in the light from distant galaxies. Because the galaxies are moving away from us, the light they emit is shifted toward the longer wavelengths. (Because light that has the longest visible wavelengths appears red, this is referred to as a redshift.) The speed of the galaxies relative to us can be determined by measuring this shift.

Example 39-4 Red Light/Green Light

You are spending the day shadowing two police officers. You have just witnessed the officers pulling over a car that went through a red light. The driver claims that the red light looked green because the car was moving toward the stoplight, which shifted the wavelength of the observed light. You quickly do some calculations to see if the driver has a reasonable case.

PICTURE We can use the Doppler shift formula for approaching objects in Equation 39-16*a*. This will tell us the velocity, but we need to know the frequencies of the light. We can make good guesses for the wavelengths of red light and green light and use $c = f\lambda$ to determine the frequencies.

SOLVE

1. The observer is approaching the light source, so we use the Doppler formula (Equation 39-16*a*) for approaching sources:

$$f' = \sqrt{\frac{1 + (v/c)}{1 - (v/c)}}f_0$$

2. Substitute c/λ for f, then simplify:

$$\frac{c}{\lambda'} = \sqrt{\frac{1 + (v/c)}{1 - (v/c)}}\frac{c}{\lambda_0}$$

$$\left(\frac{\lambda_0}{\lambda'}\right)^2 = \frac{1 + (v/c)}{1 - (v/c)}$$

3. Cross multiply and solve for v/c:

$$(\lambda_0)^2\left(1 - \frac{v}{c}\right) = (\lambda')^2\left(1 + \frac{v}{c}\right)$$

$$(\lambda_0)^2 - (\lambda')^2 = \left[(\lambda_0)^2 + (\lambda')^2\right]\left(\frac{v}{c}\right)$$

$$\frac{v}{c} = \frac{(\lambda_0)^2 - (\lambda')^2}{(\lambda_0)^2 + (\lambda')^2} = \frac{1 - (\lambda'/\lambda_0)^2}{1 + (\lambda'/\lambda_0)^2}$$

4. The values for the wavelengths for the colors of the visible spectrum can be found in Table 30-1. The wavelengths for red are 625 nm or longer, and the wavelengths for green are 530 nm or shorter. Solve for the speed needed to shift the wavelength from 625 nm to 530 nm:

$$\frac{\lambda'}{\lambda_0} = \frac{530\text{ nm}}{625\text{ nm}} = 0.848$$

$$\frac{v}{c} = \frac{1 - 0.848^2}{1 + 0.848^2} = 0.163$$

$$v = 0.163c = 4.90 \times 10^7\text{ m/s} = 1.10 \times 10^8\text{ mi/h}$$

5. This speed is beyond any possible speed for a car:

$$\boxed{\text{The driver does not have a plausible case.}}$$

CHECK A car cannot travel at relativistic speeds, so the answer to this problem was obvious.

Example 39-5 Finding Speed from the Doppler Shift

Try It Yourself

The emission spectrum of hydrogen includes a line that has the wavelength $\lambda_0 = 656$ nm. In light reaching us from a distant galaxy, the wavelength of that spectral line is measured to be $\lambda' = 1458$ nm. Find the speed at which the distant galaxy is receding from Earth.

PICTURE Wavelength is related to frequency by $c = f\lambda$ and the received frequency is related to the unshifted frequency by the Doppler shift equation for a receding source (Equation 39-16*b*).

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	**Answers**
1. Use Equation 39-16*b* to relate the speed v to the received frequency f' and the unshifted frequency f_0.	$f' = \sqrt{\dfrac{1-(v/c)}{1+(v/c)}}\,f_0$
2. Substitute $f' = c/\lambda'$ and $f_0 = c/\lambda_0$ and solve for v/c.	$\dfrac{v}{c} = \dfrac{1-(\lambda_0/\lambda')^2}{1+(\lambda_0/\lambda')^2} = 0.664$
	$v = \boxed{0.664c}$

CHECK As expected, the result is a significant fraction of c. This result is expected because the wavelength of the received light is large in comparison to the wavelength of the same spectral line in the reference frame of the source.

39-4 CLOCK SYNCHRONIZATION AND SIMULTANEITY

We saw in Section 39-3 that proper time is the time interval between two events that occur at the same point in some reference frame. It can therefore be measured on a single clock. (Remember, in each frame there is, in principle, a stationary clock at each point in space, and the time of an event in a given frame is measured by the clock at that point.) However, in another reference frame moving relative to the first, the same two events occur at different places, so two stationary clocks are needed in this reference frame to record the times. The time of each event is measured on a different clock, and the interval is found by subtraction of the measured times. This procedure requires that the clocks be **synchronized.** We will show in this section that

> Two clocks that are synchronized in one reference frame are typically not synchronized in any other frame moving relative to the first frame.
>
> SYNCHRONIZED CLOCKS

Here is a corollary to this result:

> Two events that are simultaneous in one reference frame typically are not simultaneous in another frame that is moving relative to the first.*
>
> SIMULTANEOUS EVENTS

* This is true unless the x coordinates of the two events are equal, where the x axis is parallel to the relative velocity of the two frames.

Comprehension of these facts usually resolves all relativity paradoxes. Unfortunately, the intuitive (and incorrect) belief that simultaneity is an absolute relation is difficult to overcome.

Suppose we have two clocks at rest, one at point A and the other at point B, where points A and B are a distance L apart in frame S. How can we synchronize the two clocks? If an observer at A looks at the clock at B and sets her clock to read the same time, the clocks will not be synchronized because of the time L/c it takes light to travel from one clock to another. To synchronize the clocks, the observer at A must set her clock ahead by the time L/c. Then she will see that the clock at B reads a time that is L/c behind the time on her clock, but she will calculate that the clocks are synchronized when she allows for the time L/c for the light to reach her. Any other observers in S (except those equidistant from the two clocks) will see the clocks reading different times, but they will also calculate that the clocks are synchronized when they correct for the time it takes the light to reach them. An equivalent method for synchronizing two clocks would be for an observer at point C, a point midway between the clocks, to send a light signal and for the observers at A and B to set their clocks to some prearranged time when they receive the signal.

We now examine the question of **simultaneity.** Suppose observers at A and B agree to explode flashguns at t_0 (having previously synchronized their clocks). The observer at C will see the light from the two flashes at the same time, and because he is equidistant from A and B, he will conclude that the flashes were simultaneous. Other observers in frame S will see the light from A or B first, depending on their location, but after correcting for the time the light takes to reach them, they also will conclude that the flashes were simultaneous. We can thus define simultaneity as follows:

> Two events in a reference frame are simultaneous if light signals from the events reach an observer halfway between the events at the same time.
>
> DEFINITION—SIMULTANEITY

To show that two events that are simultaneous in frame S are not simultaneous in another frame S' moving relative to S, we will use an example introduced by Einstein. A train is moving with speed v past a station platform. We will consider the train to be at rest in S' and the platform to be at rest in S. We have observers A', B', and C' at the front, back, and middle of the train (Figure 39-5). We now suppose that the train and platform are struck by lightning at the front and back of the train and that the lightning bolts are simultaneous in the frame of the platform S. That is, an observer C on the platform halfway between the positions A and B, where the lightning strikes, sees the light from the two strikes at the same time.

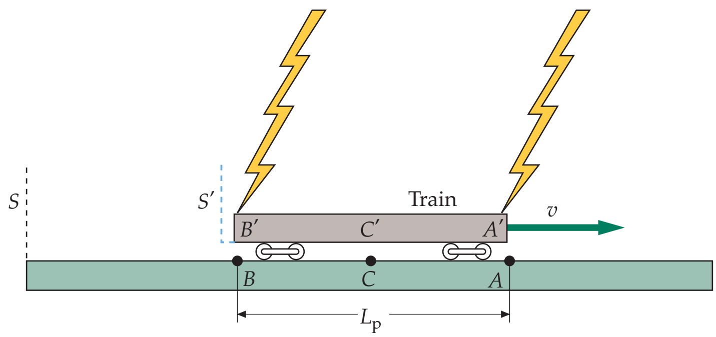

FIGURE 39-5 In frame S attached to the platform, simultaneous lightning bolts strike the ends of a train traveling with speed v. The light from the simultaneous events reaches observer C, standing on the platform midway between the events, at the same time. The distance between the bolts is $L_{\text{p platform}}$.

It is convenient to suppose that the lightning scorches both the train and platform so that the events can be easily located. Because C' is in the middle of the train, halfway between the places on the train that are scorched, the events are simultaneous in S' only if C' sees the flashes at the same time. However, the flash from the front of the train is seen by C' before the flash from the back of the train. We can understand this by considering the motion of C' as seen in frame S (Figure 39-6). By the time the light from the front flash reaches C', C' has moved some distance toward the front flash and some distance away from the back flash. Thus, the light from the back flash has not yet reached C', as indicated in the figure. Observer C' must therefore conclude that the events are not simultaneous and that the front of the train was struck before the back. Furthermore, all observers in S' on the train will agree with C' when they have corrected for the time it takes the light to reach them.

Figure 39-7 shows the events of the lightning bolts as seen in the reference frame of the train (S'). In this frame the platform is moving, so the distance between the scorch marks on the platform is contracted. The platform is shorter than it is in S, and, because the train is at rest, the train is longer than its contracted length in S. When the lightning bolt strikes the front of the train at A', the front of the train is at point A, and the back of the train has not yet reached point B. Later, when the lightning bolt strikes the back of the train at B', the back has reached point B on the platform.

The time discrepancy of two clocks that are synchronized in frame S as seen in frame S' can be found from the Lorentz transformation equations. Suppose we have clocks at points x_1 and x_2 that are synchronized in S. What are the times t_1 and t_2 on the clocks as observed from frame S' at a time t'_0?

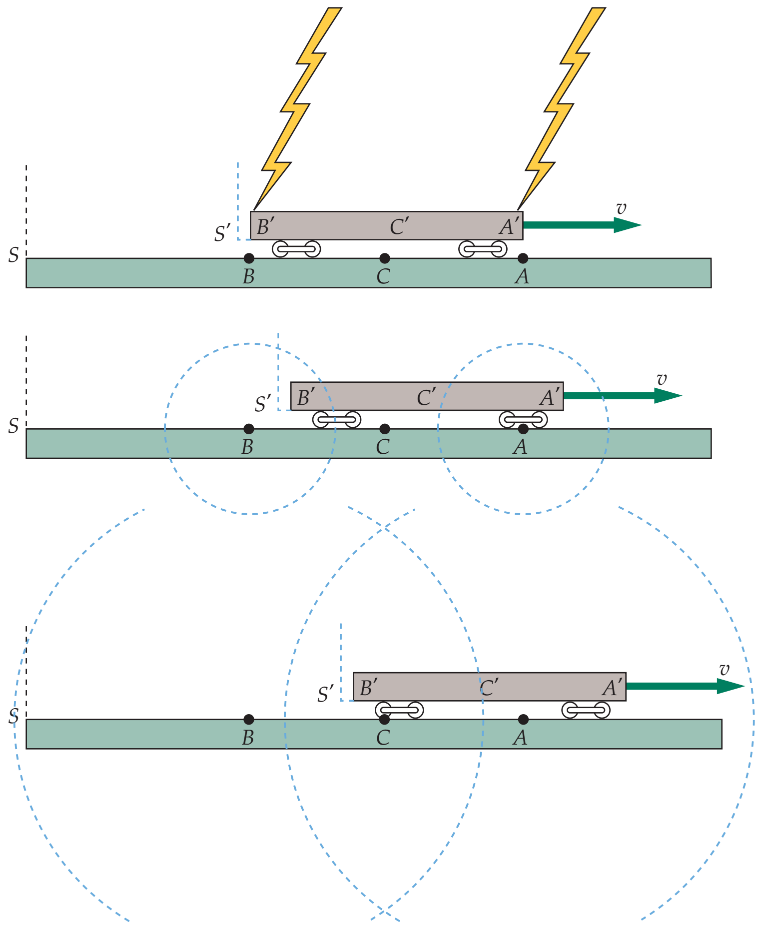

FIGURE 39-6 In frame S attached to the platform, the light from the lightning bolt at the front of the train reaches observer C', standing on the train at its midpoint, before the light from the bolt at the back of the train. Because C' is midway between the events (which occur at the front and rear of the train), the events are not simultaneous for him.

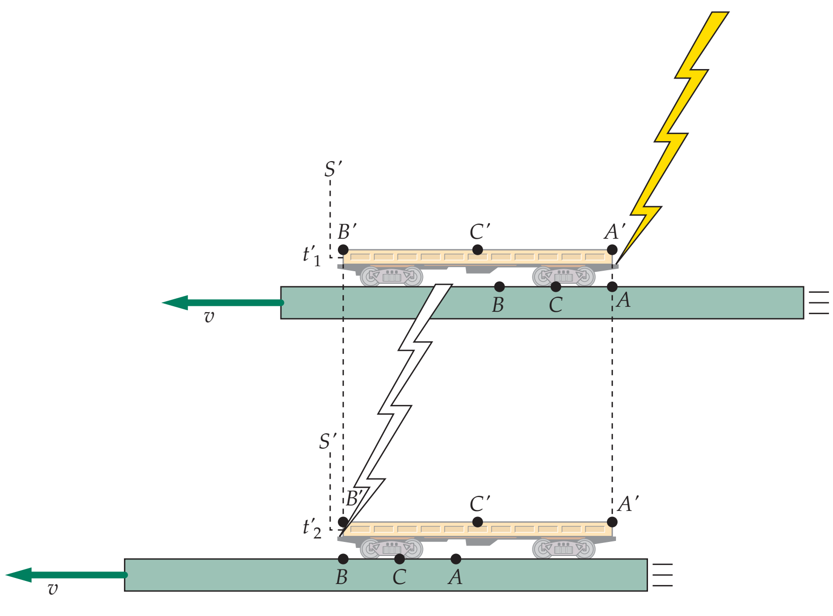

FIGURE 39-7 The lightning bolts of Figure 39-5 as seen in frame S' of the train. In this frame, the distance between A and B on the platform is less than $L_{\text{p platform}}$, and the proper length of the train $L_{\text{p train}}$ is longer than $L_{\text{p platform}}$. The first lightning bolt strikes the front of the train when A' and A are coincident. The second bolt strikes the rear of the train when B' and B are coincident.

From Equation 39-12, when $t'_1 = t'_2 = t'_0$, we have

$$t'_0 = \gamma\left(t_1 - \frac{vx_1}{c^2}\right)$$

and

$$t'_0 = \gamma\left(t_2 - \frac{vx_2}{c^2}\right)$$

Subtracting the first equation from the second, and then rearranging, gives

$$t_2 - t_1 = \frac{v}{c^2}(x_2 - x_1)$$

Note that the chasing clock (at x_2) leads the other (at x_1) by an amount that is proportional to their proper separation $L_p = x_2 - x_1$.

If two clocks are synchronized in the frame in which they are both at rest, in a frame in which they are moving along the line through both clocks, the chasing clock leads (shows a later time) by an amount

$$\Delta t_S = L_p \frac{v}{c^2} \qquad \text{39-17}$$

where L_p is the proper distance between the clocks.

CHASING CLOCK SHOWS LATER TIME

A numerical example should help clarify time dilation, clock synchronization, and the internal consistency of these results.

Example 39-6 Synchronizing Clocks

Observer A' in a spaceship that has a flashgun and a mirror is shown in Figure 39-3 (see page 1325). Observer A' is standing next to the flashgun. The distance from the gun to the mirror is 15 light-minutes (written 15 $c \cdot$ min) and the spaceship, at rest in frame S', travels with speed $v = 0.80c$ relative to a very long space platform that is at rest in frame S. The platform has two synchronized clocks, one clock at position x_1, the position of the spaceship when the observer explodes the flashgun, and the other clock at position x_2, the position of the spaceship when the light returns to the gun from the mirror. Find the time intervals between the events (exploding the flashgun and receiving the return flash from the mirror) (*a*) in the frame of the spaceship and (*b*) in the frame of the platform. Find (*c*) the distance traveled by the spaceship and (*d*) the amount by which the clocks on the platform are out of synchronization according to observers on the spaceship.

PICTURE The events occur at the same place on the spaceship, so the time between the events in frame S' is the proper time between the events.

SOLVE

(*a*) 1. In the frame of the spaceship, the light travels from the gun to the mirror and back, a total distance $D = 30\ c \cdot \text{min}$. The time required is D/c:

$$\Delta t' = \frac{D}{c} = \frac{30\ c \cdot \text{min}}{c} = \boxed{30\ \text{min}}$$

2. Because the two events happen at the same place in the spaceship, the time interval is proper time:

$$\Delta t_p = \boxed{30\ \text{min}}$$

(*b*) 1. In frame S, the time between the events is longer by the factor γ:

$$\Delta t = \gamma\, \Delta t_p = \gamma(30\ \text{min})$$

2. Calculate γ:

$$\gamma = \frac{1}{\sqrt{1 - (v^2/c^2)}} = \frac{1}{\sqrt{1 - (0.80)^2}} = \frac{1}{\sqrt{0.36}} = \frac{5}{3}$$

3. Use the value of γ to calculate the time between the events as observed in frame S:

$$\Delta t = \gamma\, \Delta t_p = \tfrac{5}{3}(30\ \text{min}) = \boxed{50\ \text{min}}$$

(*c*) In frame S, the distance traveled by the spaceship is $v\,\Delta t$: $x_2 - x_1 = v\,\Delta t = (0.80c)(50\text{ min}) = \boxed{40\,c\cdot\text{min}}$

(*d*) 1. The amount that the clocks on the platform are out of synchronization is related to the proper distance between the clocks L_p: $\Delta t_s = L_p \frac{v}{c^2}$

2. The Part-(*c*) result is the proper distance between the clocks on the platform: $L_p = x_2 - x_1 = 40\,c\cdot\text{min}$

so

$$\Delta t_s = L_p \frac{v}{c^2} = (40\,c\cdot\text{min})\frac{(0.80c)}{c^2} = \boxed{32\text{ min}}$$

TAKING IT FURTHER Observers on the platform would say that the spaceship's clock is running slow because it records a time of only 30 min between the events, whereas the time measured by observers on the platform is 50 min.

Figure 39-8 shows the situation in Example 39-6 viewed from the spaceship in S'. The platform is traveling past the ship with speed $0.8c$. There is a clock at point x_1, which coincides with the ship when the flashgun is exploded, and another at point x_2, which coincides with the ship when the return flash is received from the mirror. We assume that the clock at x_1 reads 12:00 noon at the time of the light flash. The clocks at x_1 and x_2 are synchronized in S but not in S'. In S', the clock at x_2, which is chasing the one at x_1, leads by 32 min; it would thus read 12:32 to an observer in S'. When the spaceship coincides with x_2, the clock there reads 12:50. The time between the events is therefore 50 min in S. Note that according to observers in S', this clock ticks off 50 min − 32 min = 18 min for a trip that takes 30 min in S'. Thus, observers in S' see this clock run slow by the factor 30/18 = 5/3.

Every observer in one frame sees the clocks in the other frame run slow. According to observers in S, who measure 50 min for the time interval, the time interval in S' (30 min) is too small, so they see the single clock in S' run too slow by the factor 5/3. According to the observers in S', the observers in S measure a time that is too *long* despite the fact that their clocks run too slow because the clocks in S are out of synchronization. The clocks tick off only 18 min, but the second clock leads the first clock by 32 min, so the time interval is 50 min.

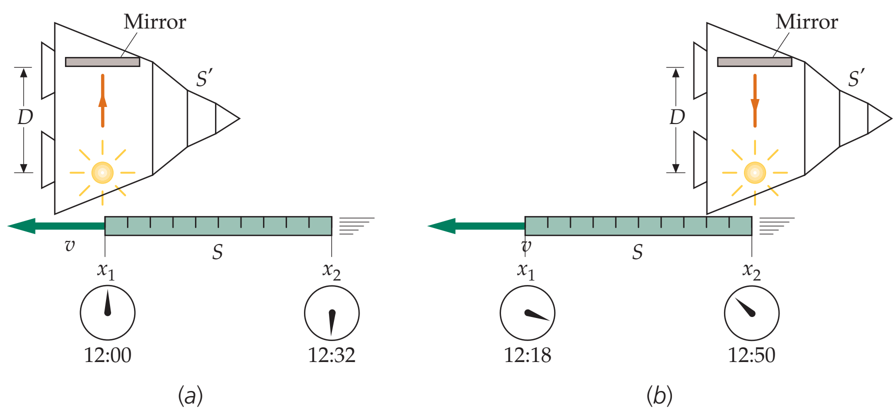

FIGURE 39-8 Clocks on a platform as observed from the spaceship's frame of reference S'. During the time $\Delta t' = 30$ min it takes for the platform to pass the spaceship, the clocks on the platform run slow and tick off (30 min)/γ = 18 min. But the clocks are unsynchronized, with the chasing clock leading by $L_p v/c^2$, which for this case is 32 min. The time it takes for the spaceship to go from x_1 to x_2, as measured on the platform, is therefore 32 min + 18 min = 50 min.

THE TWIN PARADOX

Homer and Ulysses are identical twins. Ulysses travels at high speed to a planet beyond the solar system and returns while Homer remains at home. When they are together again, which twin is older or are they the same age? The correct answer is that Homer, the twin who stays at home, is older. This problem, with variations, has been the subject of spirited debate for decades, though there are very few who disagree with the answer. The problem appears to be a paradox because of the seemingly symmetric roles played by the twins and the asymmetric result in their aging. The paradox is resolved when the asymmetry of the twins' roles is noted. The relativistic result conflicts with common sense based on our strong but incorrect belief in absolute simultaneity. We will consider a particular case with some numerical magnitudes that, though impractical, make the calculations easy.

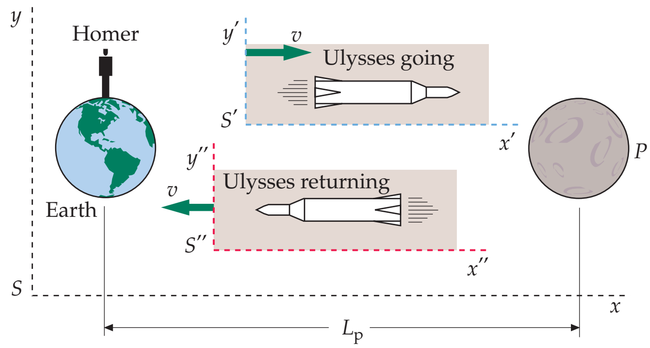

FIGURE 39-9 The twin paradox. Earth and a distant planet are fixed in frame S. Ulysses coasts in frame S' to the planet and then coasts back in frame S''. His twin Homer stays on Earth. When Ulysses returns, he is younger than his twin. The roles played by the twins are not symmetric. Homer remains at rest in one inertial reference frame, but Ulysses must go from being at rest in one inertial reference frame to another if he is to return home.

In reference frame S, Earth, planet P and Homer are at rest and Earth and planet P are a distance L_p apart (Figure 39-9). Homer is on Earth. Reference frames S' and S'' are moving with speed v toward and away from planet P, respectively. Ulysses quickly accelerates to speed v, then coasts, at rest in S', until he reaches the planet, where he quickly decelerates to a stop and is momentarily at rest in S. To return, Ulysses quickly accelerates to speed v toward Earth and then coasts, at rest in S'', until he reaches Earth, where he quickly decelerates to a stop. We can assume that the acceleration (and deceleration) times are negligible compared with the coasting times. We use the following values for illustration: $L_p = 8$ light-years ($8\,c\cdot y$) and $v = 0.8c$. Then $\sqrt{1-(v^2/c^2)} = 3/5$ and $\gamma = 5/3$.

It is easy to analyze the problem from Homer's point of view on Earth. According to Homer's clock, Ulysses coasts in S' for a time $L_p/v = 10$ y and in S'' for an equal time. Thus, Homer is 20 y older when Ulysses returns. The time interval in S' between Ulysses's leaving Earth and his arriving at the planet is shorter because it is proper time. The time it takes to reach the planet by Ulysses's clock is

$$\Delta t' = \frac{\Delta t}{\gamma} = \frac{10\text{ y}}{5/3} = 6\text{ y}$$

Because the same time is required for the return trip, Ulysses will have recorded 12 y for the round trip and will be 8 years younger than Homer upon his return.

From Ulysses's point of view, the distance between Earth and the planet is contracted and is only

$$L' = \frac{L_p}{\gamma} = \frac{8\,c\cdot\text{y}}{5/3} = 4.8\,c\cdot\text{y}$$

At $v = 0.8c$, it takes only $L'/v = 4.8\,c\cdot y/0.8\,c = 6$ y each way.

The real challenge in this problem is for Ulysses to understand why his twin aged 20 y during his absence. If we consider Ulysses as being at rest and Homer as moving away, Homer's clock should run slow and measure only $\frac{3}{5}(6\text{ y}) = 3.6$ y. Then why shouldn't Homer age only 7.2 y during the round trip? This, of course, is the paradox. The difficulty with the analysis from the point of view of Ulysses is that he does not remain in a single inertial reference frame. What happens while Ulysses is stopping and starting? To investigate this problem in detail, we would need to treat accelerated reference frames, a subject dealt with in the study of general relativity and beyond the scope of this book. However, we can get some insight into the problem by having the twins send regular signals to each other so that they can record the other's age continuously. If they arrange to send a signal once a year, each can determine the age of the other merely by counting the signals received. The arrival frequency of the signals will not be 1 per year because of the Doppler shift. The frequency observed will be given by Equations 39-16*a* and 39-16*b*.

Using $v/c = 0.8$ (so $v^2/c^2 = 0.64$), we have for the case in which the twins are receding from each other

$$f' = \frac{f_0}{1 + (v/c)}\sqrt{1 - (v^2/c^2)} = \frac{\sqrt{1 - 0.64}}{1 + 0.8} f_0 = \frac{1}{3} f_0$$

When they are approaching, Equation 39-16*a* gives $f' = 3f_0$.

Consider the situation first from the point of view of Ulysses. During the 6 y it takes him to reach the planet (remember that the distance is contracted in his frame), he receives signals at the rate of $\frac{1}{3}$ signal per year, and so he receives 2 signals. As soon as Ulysses turns around and starts back to Earth, he begins to receive 3 signals per year. In the 6 y it takes him to return he receives 18 signals, giving a total of 20 for the trip. He accordingly expects his twin to have aged 20 years.

We now consider the situation from Homer's point of view. He receives signals at the rate of $\frac{1}{3}$ signal per year not only for the 10 y it takes Ulysses to reach the planet but also for the time it takes for the last signal sent by Ulysses before he turns around to get back to Earth. (He cannot know that Ulysses has turned around until the signals begin reaching him with increased frequency.) Because the planet is 8 light-years away, there is an additional 8 y of receiving signals at the rate of $\frac{1}{3}$ signal per year. During the first 18 y, Homer receives 6 signals. In the final 2 y before Ulysses arrives, Homer receives 6 signals, or 3 per year. (The first signal sent after Ulysses turns around takes 8 y to reach Earth, whereas Ulysses, traveling at $0.8c$, takes 10 y to return and therefore arrives just 2 y after Homer begins to receive signals at the faster rate.) Thus, Homer expects Ulysses to have aged 12 y. In this analysis, the asymmetry of the twins' roles is apparent. When they are together again, both twins agree that the one who has been accelerated will be younger than the one who stayed home.

The predictions of the special theory of relativity concerning the twin paradox have been tested using small particles that can be accelerated to such large speeds that γ is appreciably greater than 1. Unstable particles can be accelerated and trapped in circular orbits in a magnetic field, for example, and their lifetimes can then be compared with those of identical particles at rest. In all such experiments, the accelerated particles live longer on the average than the particles at rest, as predicted. These predictions have also been confirmed by the results of an experiment in which high-precision atomic clocks were flown around the world in commercial airplanes, but the analysis of that experiment is complicated due to the necessity of including gravitational effects treated in the general theory of relativity.

39-5 THE VELOCITY TRANSFORMATION

We can find how velocities transform from one reference frame to another by differentiating the Lorentz transformation equations. Suppose a particle has velocity $u'_x = dx'/dt'$ in frame S', which is moving to the right with speed v relative to frame S. The particle's velocity in frame S is

$$u_x = \frac{dx}{dt}$$

From the Lorentz transformation equations (Equations 39-9 and 39-10), we have

$$dx = \gamma(dx' + v\,dt')$$

and

$$dt = \gamma\left(dt' + \frac{v\,dx'}{c^2}\right)$$

The velocity relative to frame S is thus

$$u_x = \frac{dx}{dt} = \frac{\gamma(dx' + v\,dt')}{\gamma\left(dt' + \dfrac{v\,dx'}{c^2}\right)} = \frac{\dfrac{dx'}{dt'} + v}{1 + \dfrac{v}{c^2}\dfrac{dx'}{dt'}} = \frac{u'_x + v}{1 + \dfrac{vu'_x}{c^2}}$$

If a particle has components of velocity along the y or z axes, we can use the same relation between dt and dt', with $dy = dy'$ and $dz = dz'$, to obtain

$$u_y = \frac{dy}{dt} = \frac{dy'}{\gamma\left(dt' + \dfrac{v\,dx'}{c^2}\right)} = \frac{\dfrac{dy'}{dt'}}{\gamma\left(1 + \dfrac{v}{c^2}\dfrac{dx'}{dt'}\right)} = \frac{u'_y}{\gamma\left(1 + \dfrac{vu'_x}{c^2}\right)}$$

and

$$u_z = \frac{u'_z}{\gamma\left(1 + \dfrac{vu'_x}{c^2}\right)}$$

The complete relativistic velocity transformation is

$$u_x = \frac{u'_x + v}{1 + \dfrac{vu'_x}{c^2}} \qquad \text{39-18}a$$

$$u_y = \frac{u'_y}{\gamma\left(1 + \dfrac{vu'_x}{c^2}\right)} \qquad \text{39-18}b$$

$$u_z = \frac{u'_z}{\gamma\left(1 + \dfrac{vu'_x}{c^2}\right)} \qquad \text{39-18}c$$

RELATIVISTIC VELOCITY TRANSFORMATION

The inverse velocity transformation equations are

$$u'_x = \frac{u_x - v}{1 - \dfrac{vu_x}{c^2}} \qquad \text{39-19}a$$

$$u'_y = \frac{u_y}{\gamma\left(1 - \dfrac{vu_x}{c^2}\right)} \qquad \text{39-19}b$$

$$u'_z = \frac{u_z}{\gamma\left(1 - \dfrac{vu_x}{c^2}\right)} \qquad \text{39-19}c$$

These equations differ from the classical and intuitive result $u_x = u'_x + v$, $u_y = u'_y$, and $u_z = u'_z$ because the denominators in the equations are not equal to 1. When v and u'_x are small compared with the speed of light c, $\gamma \approx 1$ and $vu'_x/c^2 \ll 1$. Then the relativistic and classical velocity transformation equations are the same.

Example 39-7 Relative Velocity at Nonrelativistic Speeds

A supersonic plane moves away from you, and in the $+x$ direction, at a speed of 1000 m/s (about 3 times the speed of sound) relative to you. A second plane, traveling in the same direction and ahead of the first plane, moves away from you, and away from the first plane, at a speed of 500 m/s relative to the first plane. How fast is the second plane moving relative to you?

PICTURE The speeds are so small compared with c that we expect the classical equations for combining velocities to be accurate. We show this by calculating the correction term in the denominator of Equation 39-18*a*. Let frame S be your rest frame and frame S' be the rest frame of the first plane. Then v, the velocity of S' relative to S, is 1000 m/s. The second plane has velocity $u'_x = 500$ m/s relative to S'.

SOLVE

1. Let S and S' be the reference frames of you and the first plane, respectively. Also, let u_x and u'_x be the velocities of the second plane relative to S and S', respectively. Equation 39-18*a* can be used to find u_x. The velocity of the second plane relative to you is v:

$$u_x = \frac{u'_x + v}{1 + \dfrac{vu'_x}{c^2}}$$

2. If the correction term in the denominator is negligible (compared to 1), Equation 39-18*a* gives the classical formula for combining velocities. Calculate the value of the correction term:

$$\frac{vu'_x}{c^2} = \frac{(1000)(500)}{(3.00 \times 10^8)^2} = 5.56 \times 10^{-12}$$

3. The correction term is so small that the classical and relativistic results are virtually the same:

$$u_x \approx u'_x + v = 500 \text{ m/s} + 1000 \text{ m/s} = \boxed{1500 \text{ m/s}}$$

Example 39-8 Relative Velocity at Relativistic Speeds

Work Example 39-7 if the first plane moves with speed $v = 0.80c$ relative to you and the second plane moves with the same speed $0.80c$ relative to the first plane.

PICTURE These speeds are not small compared with c, so we need to use the relativistic expression (Equation 39-18*a*). We again assume that you are at rest in frame S and the first plane is at rest in frame S' that is moving at $v = 0.80c$ relative to you. The velocity of the second plane relative to S' is $u'_x = 0.80c$.

SOLVE

Use Equation 39-18*a* to calculate the speed of the second plane relative to you:

$$u_x = \frac{u'_x + v}{1 + \dfrac{vu'_x}{c^2}} = \frac{0.80c + 0.80c}{1 + \dfrac{(0.80c)(0.80c)}{c^2}} = \frac{1.60c}{1.64} = \boxed{0.98c}$$

CHECK As expected, the result is less than c.

The result in Example 39-8 is quite different from the classically expected result of $0.80c + 0.80c = 1.60c$. In fact, it can be shown from Equations 39-18*a*–*c* that if the speed of an object is less than c in one frame, it is less than c in all other frames moving relative to that frame with a speed less than c. (See Problem 59.) We will see in Section 39-7 that it takes an infinite amount of energy to accelerate a particle to the speed of light. The speed of light c is thus an upper, unattainable limit for the speed of a particle with mass. (There are massless particles, such as photons, that always move at the speed of light.)

Example 39-9 Relative Speed of a Photon

A photon moves along the x' axis in frame S', with speed $u'_x = c$. What is its speed in frame S?

PICTURE Use Equation 39-18*a* to calculate the speed of the photon in S.

SOLVE

The speed in S is given by Equation 39-18*a*:

$$u_x = \frac{u'_x + v}{1 + \dfrac{vu'_x}{c^2}} = \frac{c + v}{1 + \dfrac{vc}{c^2}} = \frac{c + v}{1 + \dfrac{v}{c}} = \frac{c + v}{\dfrac{1}{c}(c + v)} = \boxed{c}$$

CHECK The speed in both frames is c, independent of v. This is in accord with Einstein's postulates.

Example 39-10 Rockets Passing in Opposite Directions

Two spaceships, each 100 m long when measured at rest, travel toward each other, each with a speed of $0.85c$ relative to Earth. (*a*) What is the length of each spaceship as measured by someone at rest relative to Earth? (*b*) How fast is each spaceship traveling as measured by an observer at rest relative to the other spaceship? (*c*) What is the length of one spaceship when measured by an observer at rest relative to the other spaceship? (*d*) At time $t = 0$ on Earth, the front ends of the ships are next to each other as they just begin to pass each other. At what time on Earth are their back ends next to each other?

PICTURE (*a*) The length of each spaceship as measured on Earth is the contracted length $\sqrt{1 - (u^2/c^2)}L_p$ (Equation 39-14), where u is the speed of either spaceship relative to Earth. To solve Part (*b*), let Earth be at rest in frame S, and let the spaceship on the left (spaceship 1) be at rest in frame S', which is moving at speed $v = 0.85c$ relative to S. Then the spaceship on the right (spaceship 2) moves with velocity $u_{1x} = -0.85c$ (Figure 39-10). (*c*) The length of spaceship 2 as seen by an observer at rest relative to spaceship 1 is $\sqrt{1 - (u_{2x}^2/c^2)}L_p$.

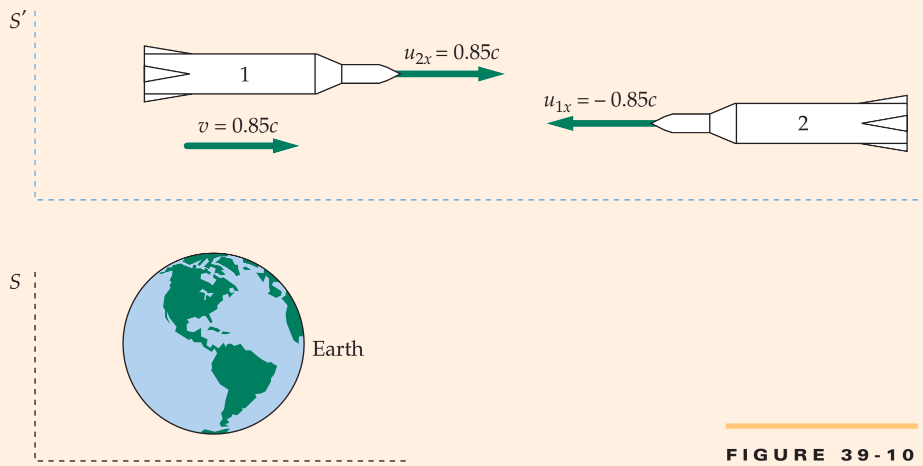

FIGURE 39-10

SOLVE

(*a*) The length of each spaceship in S, the reference frame of Earth, is the proper length divided by γ.

$$L = \frac{1}{\gamma}L_p = \sqrt{1 - \frac{|u_{2x}|^2}{c^2}}L_p = \sqrt{1 - \frac{(0.85c)^2}{c^2}}(100\text{ m}) = \boxed{53\text{ m}}$$

(*b*) Use the velocity transformation formula (Equation 39-19*a*) to find the velocity u'_{2x} of spaceship 2 as seen in frame S':

$$u'_{2x} = \frac{u_{2x} - v}{1 - \dfrac{vu_{2x}}{c^2}} = \frac{-0.85c - 0.85c}{1 - \dfrac{(0.85c)(-0.85c)}{c^2}} = \frac{-1.70c}{1.7225} = -0.987c$$

so

$$|u'_{2x}| = \boxed{0.99c}$$

(*c*) In the frame of spaceship 1, spaceship 2 is moving with speed $|u'| = 0.987c$. Use this to calculate the length of spaceship 2 as seen by an observer at rest relative to spaceship 1:

$$L = \frac{1}{\gamma}L_p = \sqrt{1 - \frac{|u_{2x}|^2}{c^2}}L_p = \sqrt{1 - \frac{(0.987c)^2}{c^2}}(100\text{ m}) = \boxed{16\text{ m}}$$

(*d*) If the front ends of the spaceships are together at $t = 0$ on Earth, their back ends will be together after the time it takes either spaceship to move the length of the spaceship in Earth's frame:

$$t = \frac{L}{u} = \frac{53\text{ m}}{0.85c} = \frac{53\text{ m}}{(0.85)(3.00 \times 10^8\text{ m/s})} = \boxed{2.1 \times 10^{-7}\text{ s}}$$

CHECK As expected, the Part (*c*) result is less than the Part (*a*) result, and both results are less than the proper length of 100 m.

39-6 RELATIVISTIC MOMENTUM

We have seen in previous sections that Einstein's postulates require important modifications in our ideas of simultaneity and in our measurements of time and length. Einstein's postulates also require modifications in our concepts of mass, momentum, and energy. In classical mechanics, the momentum of a particle is defined as the product of its mass and its velocity, $m\vec{u}$, where $\vec{u}$ is the velocity. In an isolated system of particles, with no net force acting on the system, the total momentum of the system remains constant.

The reason that the total momentum of a system is important in classical mechanics is that it is conserved when there are no external forces acting on the system, as is the case in collisions. But we have just seen that $\Sigma m_i\vec{u}_i$ is conserved only in the approximation that $u \ll c$. We will define the relativistic momentum $\vec{p}$ of a particle to have the following properties:

1. In collisions, $\vec{p}$ is conserved.
2. As u/c approaches zero, $\vec{p}$ approaches $m\vec{u}$.

We will show that the quantity

$$\vec{p} = \frac{m\vec{u}}{\sqrt{1 - \dfrac{u^2}{c^2}}} \qquad \text{39-20}$$

RELATIVISTIC MOMENTUM

is conserved in the elastic collision shown in Figure 39-11. Because this quantity also approaches $m\vec{u}$ as u/c approaches zero, we take this equation for the definition of the **relativistic momentum** of a particle.

One interpretation of Equation 39-20 is that the mass of an object increases with speed. Then the quantity $m_{\text{rel}} = m/\sqrt{1 - (u^2/c^2)}$ is called the *relativistic mass*. The relativistic mass of a particle when it is at rest in some reference frame is then called its *rest mass* m. In this chapter, we will treat the terms mass and rest mass as synonymous, and both terms will be labeled m.

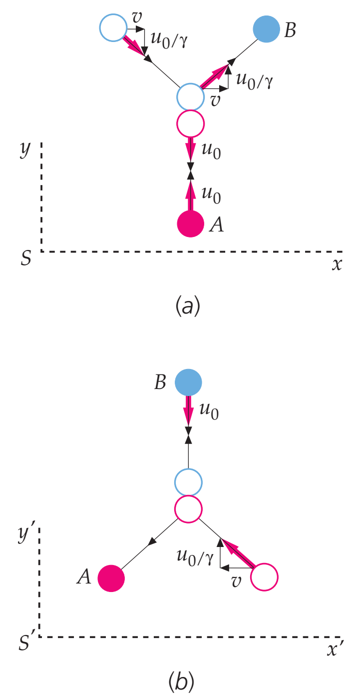

FIGURE 39-11 (*a*) Elastic collision of two identical pucks as seen in frame S. The vertical component of the velocity of puck B is u_0/γ in S if it is u_0 in S'. (*b*) The same collision as seen in S'. In this frame, puck A has a vertical component of velocity equal to u_0/γ.

ILLUSTRATION OF CONSERVATION OF THE RELATIVISTIC MOMENTUM

We consider two observers: one observer at rest in reference frame S, and the other observer at rest in frame S', which is moving to the right in the $+x$ direction with speed v relative to frame S. Each has a puck of mass m that can slide freely across a flat horizontal surface. The two pucks are identical when compared at rest. One observer launches puck A in the $+y$ direction with a speed u_0 relative to himself and the other launches puck B in the $-y$ direction with a speed u_0 relative to himself, so that each puck makes an elastic collision with the other puck, and returns to the person that launched it. Figure 39-11 shows how the collision looks in each reference frame.

We will compute the y component of the relativistic momentum of each puck in the reference frame S for the collision and show that the y component of the total relativistic momentum is zero. The speed of puck A in S is u_0, so the y component of its relativistic momentum is

$$p_{Ay} = \frac{mu_0}{\sqrt{1 - (u_0^2/c^2)}}$$

The speed of puck B in S is more complicated. Its x component is v and its y component is $-u_0/\gamma$ (Equation 39-18*b*). Thus,

$$u_B^2 = u_{Bx}^2 + u_{By}^2 = v^2 + \left[-u_0\sqrt{1 - (v^2/c^2)}\right]^2 = v^2 + u_0^2 - \frac{u_0^2 v^2}{c^2}$$

Using this result to compute $\sqrt{1-(u_B^2/c^2)}$ we obtain

$$1-\frac{u_B^2}{c^2}=1-\frac{v^2}{c^2}-\frac{u_0^2}{c^2}+\frac{u_0^2v^2}{c^4}=\left(1-\frac{v^2}{c^2}\right)\left(1-\frac{u_0^2}{c^2}\right)$$

and

$$\sqrt{1-(u_B^2/c^2)}=\sqrt{1-(v^2/c^2)}\,\sqrt{1-(u_0^2/c^2)}=\left(\frac{1}{\gamma}\right)\sqrt{1-(u_0^2/c^2)}$$

The y component of the relativistic momentum of puck B as seen in S is therefore

$$p_{By}=\frac{mu_{By}}{\sqrt{1-(u_B^2/c^2)}}=\frac{-mu_0/\gamma}{(1/\gamma)\sqrt{1-(u_0^2/c^2)}}=\frac{-mu_0}{\sqrt{1-(u_0^2/c^2)}}$$

Because $p_{By}=-p_{Ay}$, the y component of the total momentum of the two pucks is zero. If the y component of the momentum of each puck is reversed by the collision, the total momentum will remain zero and momentum will be conserved.

39-7 RELATIVISTIC ENERGY

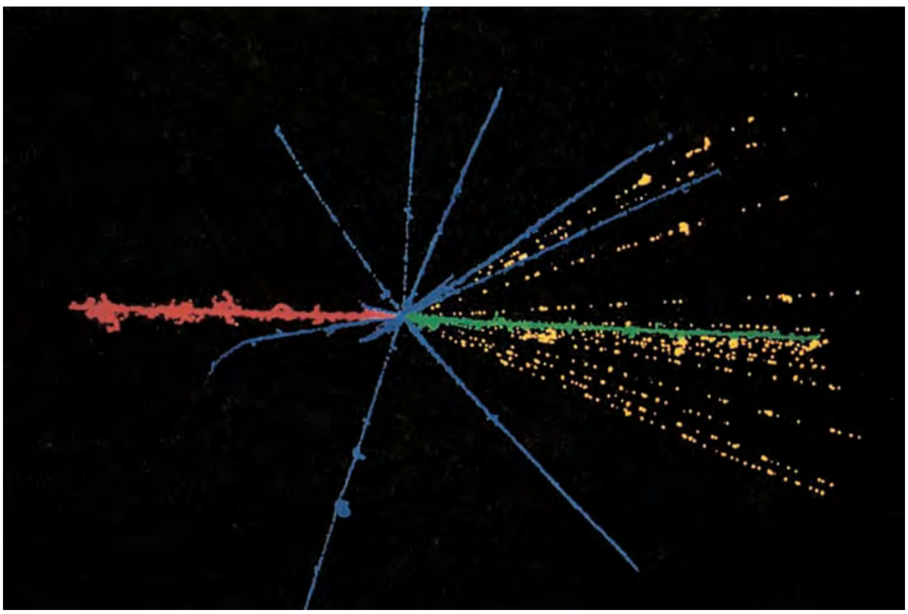
In classical mechanics, the work done by the net force acting on a particle equals the change in the kinetic energy of the particle. In relativistic mechanics, we equate the net force to the rate of change of the relativistic momentum. The work done by the net force can then be calculated and set equal to the change in kinetic energy.

As in classical mechanics, we will define kinetic energy as the work done by the net force in accelerating a particle from rest to some final velocity u_f. Considering one dimension only, we have

$$K=\int_{u=0}^{u=u_f}F_{\text{net}}\,ds=\int_{u=0}^{u=u_f}\frac{dp}{dt}\,ds=\int_{u=0}^{u=u_f}u\,dp=\int_{u=0}^{u=u_f}u\,d\left(\frac{mu}{\sqrt{1-(u^2/c^2)}}\right) \qquad 39\text{-}21$$

where we have used $u=ds/dt$. It is left as a problem (Problem 35) for you to show that

$$d\left(\frac{mu}{\sqrt{1-(u^2/c^2)}}\right)=m\left(1-\frac{u^2}{c^2}\right)^{-3/2}u\,du$$



The creation of elementary particles demonstrates the conversion of kinetic energy to rest energy. In this 1950 photograph of a cosmic ray shower, a high-energy sulfur nucleus (red) collides with a nucleus in a photographic emulsion and produces a spray of particles, including a fluorine nucleus (green), other nuclear fragments (blue), and approximately 16 pions (yellow). *(© C. Powell, P. Fowler, and D. Perkins. Science Photo Library/Photo Researchers.)*

If we substitute that expression into the integrand in Equation 39-21, we obtain

$$K = \int_{u=0}^{u=u_f} u\, d\left(\frac{mu}{\sqrt{1-(u^2/c^2)}}\right) = \int_0^{u_f} m\left(1-\frac{u^2}{c^2}\right)^{-3/2} u\, du$$

$$= mc^2\left(\frac{1}{\sqrt{1-(u_f^2/c^2)}} - 1\right)$$

or

$$K = \frac{mc^2}{\sqrt{1-(u^2/c^2)}} - mc^2 \qquad \text{39-22}$$

RELATIVISTIC KINETIC ENERGY

(In this expression the final speed u_f is arbitrary, so the subscript f is not needed.)

The expression for kinetic energy consists of two terms. The first term depends on the speed of the particle. The second term, mc^2, is independent of the speed. The quantity mc^2 is called the **rest energy** E_0 of the particle. The rest energy is the product of the mass and c^2:

$$E_0 = mc^2 \qquad \text{39-23}$$

REST ENERGY

The total **relativistic energy** E is then defined to be the sum of the kinetic energy and the rest energy:

$$E = K + mc^2 = \frac{mc^2}{\sqrt{1-(u^2/c^2)}} \qquad \text{39-24}$$

RELATIVISTIC ENERGY

Thus, the work done by an unbalanced force increases the energy from the rest energy mc^2 to the final energy $mc^2/\sqrt{1-(u^2/c^2)}$. We can obtain a useful expression for the velocity of a particle by multiplying Equation 39-20 for the relativistic momentum by c^2 and comparing the result with Equation 39-24 for the relativistic energy. We have

$$pc^2 = \frac{mc^2u}{\sqrt{1-(u^2/c^2)}} = Eu$$

Dividing both sides by cE gives

$$\frac{u}{c} = \frac{pc}{E} \qquad \text{39-25}$$

Energies in atomic and nuclear physics are usually expressed in units of electron volts (eV) or mega-electron volts (MeV):

$$1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$$

A convenient unit for the masses of atomic particles is eV/c^2 or MeV/c^2, which is the rest energy of the particle divided by c^2. The rest energies of some elementary particles and light nuclei are given in Table 39-1.

Table 39-1 Rest Energies of Some Elementary Particles and Light Nuclei

Particle	Symbol	Rest energy, MeV
Photon	γ	0
Electron (positron)	e or $e^-(e^+)$	0.5110
Muon	$\mu^\pm$	105.7
Pion	π^0	135.0
	$\pi^\pm$	139.6
Proton	^{1}H or p	938.272
Neutron	n	939.565
Deuteron	^{2}H or d	1875.613
Triton	^{3}H or t	2808.920
Helion	^{3}He or h	2808.391
Alpha particle	^{4}He or α	3727.379

Example 39-11 Total Energy, Kinetic Energy, and Momentum

An electron (rest energy 0.511 MeV) moves with speed $u = 0.800c$. Find (*a*) its total energy, (*b*) its kinetic energy, and (*c*) the magnitude of its momentum.

PICTURE This problem involves substituting into Equations 39-20 to 39-25.

SOLVE

(*a*) The total energy is given by Equation 39-24:

$$E = \frac{mc^2}{\sqrt{1-(u^2/c^2)}} = \frac{0.511\text{ MeV}}{\sqrt{1-0.64}} = \frac{0.511\text{ MeV}}{0.6} = \boxed{0.852\text{ MeV}}$$

(*b*) The kinetic energy is the total energy minus the rest energy:

$$K = E - mc^2 = 0.852\text{ MeV} - 0.511\text{ MeV} = \boxed{0.341\text{ MeV}}$$

(*c*) The magnitude of the momentum is found from Equation 39-20. We can simplify the momentum expression by multiplying both numerator and denominator by c^2 and using the Part-(*a*) result:

$$p = \frac{mu}{\sqrt{1-(u^2/c^2)}}$$

$$= \frac{mc^2}{\sqrt{1-(u^2/c^2)}}\frac{u}{c^2} = (0.852\text{ MeV})\frac{0.8c}{c^2} = \boxed{0.682\text{ MeV}/c}$$

CHECK The kinetic energy is less than the total energy as expected.

TAKING IT FURTHER The technique used to solve Part (*c*) (multiplying numerator and denominator by c^2) is equivalent to using Equation 39-25.

The expression for kinetic energy given by Equation 39-22 does not look much like the classical expression $\frac{1}{2}mu^2$. However, when u is much less than c, we can approximate $1/\sqrt{1-(u^2/c^2)}$ using the binomial expansion

$$(1+x)^n = 1 + nx + \frac{n(n-1)}{2}x^2 + \cdots \approx 1 + nx \qquad x \ll 1 \qquad \text{39-26}$$

Then

$$\frac{1}{\sqrt{1-(u^2/c^2)}} = \left(1 - \frac{u^2}{c^2}\right)^{-1/2} \approx 1 + \frac{1}{2}\frac{u^2}{c^2} \qquad u \ll c$$

See **Math Tutorial** *for more information on the* **Binomial Expansion**

From this result, when u is much less than c, the expression for relativistic kinetic energy becomes

$$K = mc^2\left[\frac{1}{\sqrt{1-(u^2/c^2)}} - 1\right] \approx mc^2\left[1 + \frac{1}{2}\frac{u^2}{c^2} - 1\right] = \frac{1}{2}mu^2 \qquad u \ll c$$

Thus, at low speeds, the relativistic expression is the same as the classical expression.

We note from Equation 39-24 that as the speed u approaches the speed of light c, the energy of the particle becomes very large (because $1/\sqrt{1-(u^2/c^2)}$ becomes very large). At $u = c$, the energy becomes infinite. A simple interpretation of the result is that it takes an infinite amount of energy to accelerate a particle (that has mass) to the speed of light.

In practical applications, the momentum or energy of a particle is often known rather than the speed. Equation 39-20 for the relativistic momentum and Equation 39-24 for the relativistic energy can be combined to eliminate the speed u. The result is

$$E^2 = p^2c^2 + (mc^2)^2 \qquad 39\text{-}27$$

RELATION FOR TOTAL ENERGY, MOMENTUM, AND REST ENERGY

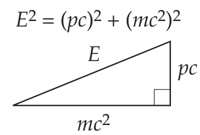


FIGURE 39-12 Right triangle to remember Equation 39-27.

This useful equation can be conveniently remembered from the right triangle shown in Figure 39-12.

PRACTICE PROBLEM 39-2

A proton (mass equal to 938 MeV/c^2) moving at speed u has a total energy of 1400 MeV. Find (*a*) $1/\sqrt{1-(u^2/c^2)}$, (*b*) the momentum of the proton, and (*c*) the speed u of the proton.

If the energy of a particle is much greater than its rest energy mc^2, the second term on the right side of Equation 39-27 can be neglected, giving the useful approximation

$$E \approx pc \qquad E \gg mc^2 \qquad 39\text{-}28$$

Equation 39-28 is an exact relation between energy and momentum for particles that do not have mass, such as photons.

MASS AND ENERGY

Einstein considered the relation $E_0 = mc^2$ (Equation 39-23) relating the energy of a particle to its mass to be the most significant result of the theory of relativity. Energy and inertia, which were formerly two distinct concepts, are related through this famous equation. As discussed in Chapter 7, the conversion of rest energy to kinetic energy with a corresponding decrease in mass is a common occurrence in radioactive decay and nuclear reactions, including nuclear fission and nuclear fusion. We illustrated this in Section 7-4 with the deuteron, whose mass is 2.22 MeV/c^2 less than the mass of its parts—a proton and a neutron. When a neutron and a proton combine to form a deuteron, 2.22 MeV of energy is released. The breaking up of a deuteron into a neutron and a proton requires 2.22 MeV of energy input. The proton and the neutron are thus bound together in a deuteron by a binding energy of 2.22 MeV. Any stable composite particle, such as a deuteron or an alpha particle (2 neutrons plus 2 protons), that is made up of other particles has a mass and rest energy that are less than the sum of the masses and rest energies of its parts. The difference in these rest energies is the binding energy of the composite particle. The binding energies of atoms and molecules are of the order of a few electron volts, which explains why there is only a negligible difference in mass between the composite particle and its parts. The binding energies of nuclei are of the order of several MeV, which explains why there is a noticeable difference in mass between the composite particle and its parts. Some very heavy nuclei, such as radium, are radioactive and decay into a less massive nucleus plus an alpha particle. In this case, the original nucleus has a rest energy greater than that of the decay particles. The excess energy appears as the kinetic energy of the decay products.

To further illustrate the connection between mass and energy, we consider a perfectly inelastic collision of two particles. Classically, kinetic energy is lost during such a collision. Relativistically, this loss in kinetic energy shows up as an increase in rest energy of the system; that is, the total energy of the system is conserved. Consider a particle of mass m_1 moving with initial speed u_1 that collides with a particle of mass m_2 moving with initial speed u_2. The particles collide and stick together, forming a particle of mass M that moves with speed u_f, as shown in Figure 39-13. The initial total energy of particle 1 is

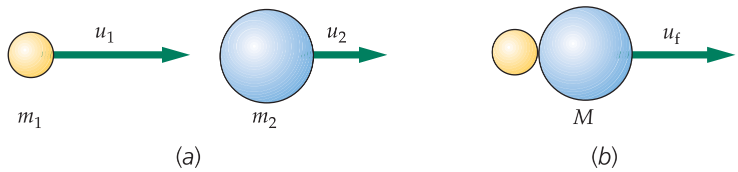

FIGURE 39-13 A perfectly inelastic collision between two particles. One particle of mass m_1 collides with another particle of mass m_2. After the collision, the particles stick together, forming a composite particle of mass M that moves with speed u_f so that relativistic momentum is conserved. Kinetic energy is lost in the process. If we assume that the total energy is conserved, the loss in kinetic energy must equal c^2 multiplied by the increase in the mass of the system.

$$E_1 = K_1 + m_1c^2$$

where K_1 is its initial kinetic energy. Similarly the initial total energy of particle 2 is

$$E_2 = K_2 + m_2c^2$$

The total initial energy of the system is

$$E_i = E_1 + E_2 = K_1 + m_1c^2 + K_2 + m_2c^2 = K_i + M_ic^2$$

where $K_i = K_1 + K_2$ and $M_i = m_1 + m_2$ are the initial kinetic energy and initial mass of the system. The final total energy of the system is

$$E_f = K_f + M_fc^2$$

If we set the final total energy equal to the initial total energy, we obtain

$$K_f + M_fc^2 = K_i + M_ic^2$$

Rearranging gives $K_f - K_i = -(M_f - M_i)c^2$, which can be expressed

$$\Delta K + (\Delta M)c^2 = 0 \qquad 39\text{-}29$$

where $\Delta M = M_f - M_i$ is the change in mass of the system.

Example 39-12 Totally Inelastic Collision

A particle of mass 2.00 MeV/c^2 and kinetic energy 3.00 MeV collides with a stationary particle of mass 4.00 MeV/c^2. After the collision, the two particles stick together. Find (*a*) the magnitude of the initial momentum of the system, (*b*) the final velocity of the two-particle system, and (*c*) the mass of the two-particle system.

PICTURE (*a*) The initial momentum of the system is the initial momentum of the incoming particle, which can be found from the total energy of the particle. (*b*) The final velocity of the system can be found from its total energy and momentum using $u/c = pc/E$ (Equation 39-25). The energy is found from conservation of energy, and the momentum from conservation of momentum. (*c*) Because the final energy and momentum are known, the final mass can be found using $E^2 = p^2c^2 + (mc^2)^2$.

SOLVE

(*a*) 1. The initial momentum of the system is the initial momentum of the incoming particle. The momentum of a particle is related to its energy and mass (Equation 39-27):

$$E_1^2 = p_1^2c^2 + (m_1c^2)^2$$

$$p_1c = \sqrt{E_1^2 - (m_1c^2)^2}$$

2. The total energy of the moving particle is the sum of its kinetic energy and its rest energy:

$$E_1 = 3.00\text{ MeV} + 2.00\text{ MeV} = 5.00\text{ MeV}$$

3. Use the total energy to calculate the magnitude of the momentum:

$$p_1c = \sqrt{E_1^2 - (m_1c^2)^2} = \sqrt{(5.00\text{ MeV})^2 - (2.00\text{ MeV})^2} = \sqrt{21.0}\text{ MeV}$$

$$p_1 = \boxed{4.58\text{ MeV}/c}$$

(*b*) 1. We can find the final velocity of the system from its total energy E_f and its momentum p_f using Equation 39-25:

$$\frac{u_f}{c} = \frac{p_fc}{E_f}$$

2. By the conservation of total energy, the final energy of the system equals the initial total energy of the two particles:

$$E_f = E_i = E_1 + E_2 = 5.00\text{ MeV} + 4.00\text{ MeV} = 9.00\text{ MeV}$$

3. By the conservation of momentum, the final momentum of the two-particle system equals the initial momentum:

$$p_f = 4.58\text{ MeV}/c$$

4. Calculate the velocity of the two-particle system from its total energy and momentum using $u/c = pc/E$:

$$\frac{u_f}{c} = \frac{p_fc}{E_f} = \frac{4.58\text{ MeV}}{9.00\text{ MeV}} = 0.509$$

$$u_f = \boxed{0.509c}$$

(*c*) We can find the mass M_f of the final two-particle system from Equation 39-27 using $pc = 4.58$ MeV and $E = 9.00$ MeV:

$$E_f^2 = (p_fc)^2 + (M_fc^2)^2$$

$$(9.00\text{ MeV})^2 = (4.58\text{ MeV})^2 + (M_fc^2)^2$$

$$M_f = \boxed{7.75\text{ MeV}/c^2}$$

TAKING IT FURTHER Note that the mass of the system increased from 6.00 MeV/c^2 to 7.75 MeV/c^2. This mass increase, multiplied by c^2, equals the loss in kinetic energy of the system, as you will show in the following exercise.

PRACTICE PROBLEM 39-3 (*a*) Find the final kinetic energy of the two-particle system in Example 39-12. (*b*) Find the loss in kinetic energy, K_{loss}, in the collision. (*c*) Show that $K_{loss} = (\Delta M)c^2$, where ΔM is the change in mass of the system.

Example 39-13 Momentum and Total-Energy Conservation

A 1.00×10^6-kg rocket has 1.00×10^3 kg of fuel on board. The rocket is parked in space when it suddenly becomes necessary to accelerate. The rocket engines ignite, and the 1.00×10^3 kg of fuel are consumed. The exhaust (spent fuel) is ejected during a very short time interval at a speed of 0.500c relative to S—the inertial reference frame in which the rocket is initially at rest. (*a*) Calculate the change in the mass of the rocket–fuel system. (*b*) Calculate the final speed of the rocket u_R relative to S. (*c*) Again, calculate the final speed of the rocket relative to S, this time using classical (Newtonian) mechanics.

PICTURE The speed of the rocket and the change in the mass of the system can be calculated using conservation of momentum and conservation of energy. In reference frame S, the total momentum of the rocket plus fuel remains zero. After the burn, the magnitude of the momentum of the rocket equals that of the ejected fuel. Let $m_R = 1.00 \times 10^6$ kg be the mass of the rocket, not including the mass of the fuel, let $m_{Fi} = 1.00 \times 10^3$ kg be the mass of the fuel *before* the burn, and let m_{Ff} be the mass of the fuel *after* the burn. The mass of the rocket, m_R, remains fixed, but during the burn the mass of the fuel decreases. (The fuel has less chemical energy after the burn, and so has less mass as well.)

SOLVE

(*a*) 1. The magnitudes of the momentum of the rocket and the momentum of the ejected fuel are equal. For the reasons stated above, the mass of the rocket, not including the 1.00×10^3 kg of fuel, does not change during the burn:

$$p_R = p_F = p$$

$$\frac{m_R u_R}{\sqrt{1 - (u_R^2/c^2)}} = \frac{m_{Ff} u_F}{\sqrt{1 - (u_F^2/c^2)}} = p$$

$m_R = 1.00 \times 10^6$ kg, $u_F = 0.500c$, and u_R is the final speed of the rocket.

2. The total energy of the system does not change:

$$E_f = E_i$$

3. The initial energy is the rest energy of the rocket and fuel before the burn. The final energy is the energy of the rocket plus energy of the fuel. The energy of each is related to its momentum by Equation 39-27:

$$E_i = m_R c^2 + m_{Fi} c^2 = (m_R + m_{Fi})c^2$$

$$E_{Rf}^2 = p^2c^2 + (m_R c^2)^2$$

$$E_{Ff}^2 = p^2c^2 + (m_{Ff} c^2)^2$$

so

$$E_f = E_{Rf} + E_{Ff}$$

$$E_f = \sqrt{p^2c^2 + (m_R c^2)} + \sqrt{p^2c^2 + (m_{Ff} c^2)^2}$$

4. Equate the initial and final energies:

$$\sqrt{p^2c^2 + (m_R c^2)^2} + \sqrt{p^2c^2 + (m_{Ff} c^2)^2} = (m_R + m_{Fi})c^2$$

5. The step-4 result and $p = \dfrac{m_{Ff} u_F}{1 - (u_F^2/c^2)}$ (the step-1 result) constitute two simultaneous equations with unknowns p and m_{Ff}. Solving for m_{Ff} gives:

$$m_{Ff} = 866 \text{ kg}$$

so

$$m_{\text{loss}} = m_{Fi} = 1000 \text{ kg} - 866 \text{ kg} = \boxed{134 \text{ kg}}$$

(*b*) 1. To solve for u_R, we use Equation 39-25:

$$\frac{u_R}{c} = \frac{pc}{E_{Rf}}$$

2. To solve for p, we substitute the value for m_{Ff} into the Part (*a*), step-1 result:

$$p = \frac{m_{Ff} u_F}{\sqrt{1 - (u_F^2/c^2)}} = \frac{(866 \text{ kg})0.500c}{\sqrt{1 - 0.250}}$$

$$= (5.00 \times 10^2 \text{ kg})c$$

3. We use the value for p to solve for E_{Rf}:

$$E_{Rf}^2 = p^2c^2 + (m_R c^2)^2$$

$$= (5.00 \times 10^2 \text{ kg})^2 c^4 + (1.00 \times 10^6 \text{ kg})^2 c^4$$

$$= (1.00 \times 10^{12} \text{ kg}^2)c^4$$

so

$$E_{Rf} = (1.00 \times 10^6 \text{ kg})c^2$$

4. Using our Part (*b*), step-1 result, we solve for u_R:

$$u_R = \frac{pc^2}{E_{Rf}} = \frac{(5.00 \times 10^2 \text{ kg})c^3}{(1.00 \times 10^6 \text{ kg})c^2}$$

$$= \boxed{5.00 \times 10^{-4} c = 1.50 \times 10^{-5} \text{ m/s}}$$

(*c*) Equate the magnitude of the classical expressions for the momentum of the rocket and burned fuel and solve for u_R:

$$m_R m_R = m_F u_F$$

$$u_R = \frac{m_F}{m_R} u_F = \frac{1.00 \times 10^3 \text{ kg}}{1.00 \times 10^6 \text{ kg}} 0.500c$$

$$= 5.00 \times 10^{-4} c$$

$$= \boxed{1.50 \times 10^5 \text{ m/s}}$$

CHECK We find the result of the relativistic calculation of the final rocket speed to differ from the classical result. If carried out to five figures, the relativistic calculation gives $u_R = 4.9994 \times 10^{-4}\, c$ for the final speed of the rocket. However, the classical calculation gives $u_R = 5.0000 \times 10^{-4}\, c$. These two values differ by less than one part in 8000.

CONCEPT CHECK 39-1

If the matter being ejected were a 1.00×10^3-kg rigid block launched by a spring with one end attached to the rocket, would the mass of the block change or would the mass of the spring change?

39-8 GENERAL RELATIVITY

The generalization of the theory of relativity to noninertial reference frames by Einstein in 1916 is known as the general theory of relativity. It is much more difficult mathematically than the special theory of relativity, and there are fewer situations in which it can be tested. Nevertheless, its importance calls for a brief qualitative discussion.

The basis of the general theory of relativity is the **principle of equivalence:**

> A homogeneous gravitational field is completely equivalent to a uniformly accelerated reference frame.
>
> PRINCIPLE OF EQUIVALENCE

This principle arises in Newtonian mechanics because of the apparent identity of gravitational mass and inertial mass. In a uniform gravitational field, all objects fall with the same acceleration $\vec{g}$ independent of their masses because the gravitational force is proportional to the (gravitational) mass, whereas the acceleration varies inversely with the (inertial) mass. Consider a compartment in space undergoing a uniform acceleration $\vec{a}$, as shown in Figure 39-14*a*. No mechanics experiment can be performed inside the compartment that will distinguish whether the compartment is actually accelerating in space or is at rest (or is moving with uniform velocity) in the presence of a uniform gravitational field $\vec{g} = -\vec{a}$, as shown in Figure 39-14*b*. If objects are dropped in the compartment, they will fall to the floor with an acceleration $\vec{g} = -\vec{a}$. If people stand on a spring scale, it will read their weight of magnitude $ma = mg$.

Einstein assumed that the principle of equivalence applies to all physics and not just to mechanics. In effect, he assumed that there is no experiment of any kind that can distinguish uniformly accelerated motion from the presence of a gravitational field.

One consequence of the principle of equivalence—the deflection of a light beam in a gravitational field—was one of the first to be tested experimentally. In a region that has no gravitational field, a light beam will travel in a straight line at speed c. The principle of equivalence tells us that a region that has no gravitational field exists only in a compartment that is in free fall. Figure 39-15 shows a beam of light entering a compartment that is accelerating relative to a nearby reference frame in free fall. Successive positions of the compartment at equal time intervals are shown in Figure 39-15*a*. Because the compartment is accelerating, the distance it moves in each time interval increases with time. The path of the beam of light as observed from inside the compartment is therefore a parabola, as shown in Figure 39-15*b*.

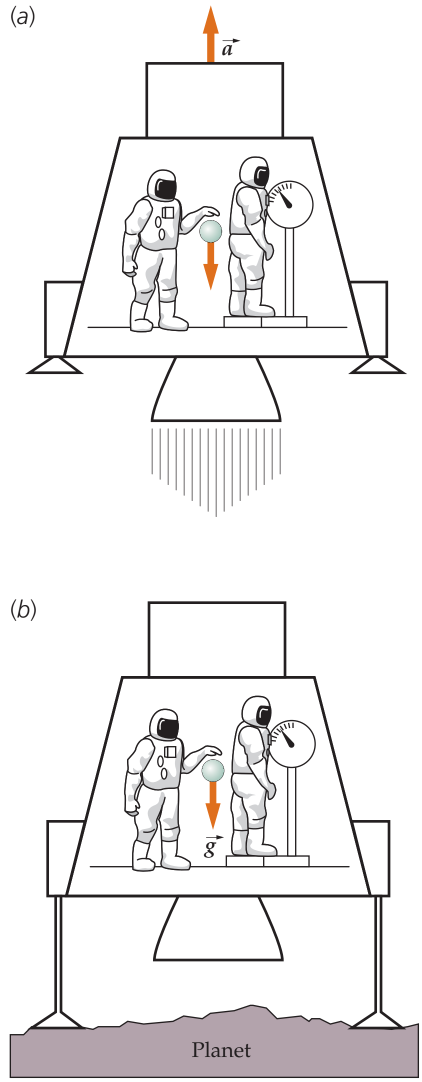

FIGURE 39-14 The results of experiments in a uniformly accelerated reference frame (*a*) cannot be distinguished from those in a uniform gravitational field (*b*) if the acceleration $\vec{a}$ and the gravitational field $\vec{g}$ have the same magnitude.

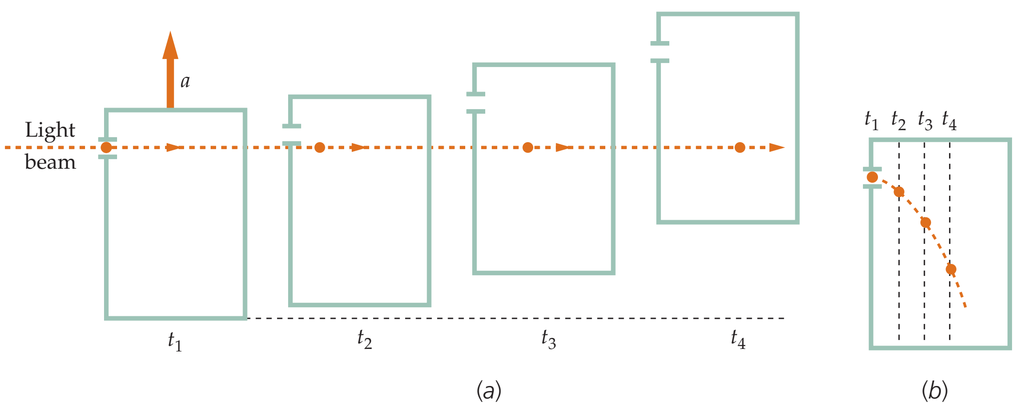

FIGURE 39-15 (*a*) A light beam moving in a straight line through a compartment that is undergoing uniform acceleration relative to a nearby reference frame in free fall. The position of the beam is shown at equally spaced times t_1, t_2, t_3, and t_4. (*b*) In the reference frame of the compartment, the light travels in a parabolic path as a ball would if it were projected horizontally. The vertical displacements are greatly exaggerated for emphasis.

But according to the principle of equivalence, there is no way to distinguish between an accelerating compartment and one moving with uniform velocity in a uniform gravitational field. We conclude, therefore, that a beam of light will accelerate in a gravitational field, just like objects that have mass. For example, near the surface of Earth, light will fall with an acceleration of 9.81 m/s^2. This is difficult to observe because of the enormous speed of light. In a distance of 3000 km, which takes light about 0.01 s to traverse, a beam of light should fall approximately 0.5 mm. Einstein pointed out that the deflection of a light beam in a gravitational field might be observed when light from a distant star passes close to the Sun, as illustrated in Figure 39-16. Because of the brightness of the Sun, this cannot ordinarily be seen. Such a deflection was first observed in 1919 during an eclipse of the Sun. This well-publicized observation brought instant worldwide fame to Einstein.

A second prediction from Einstein's theory of general relativity, which we will not discuss in detail, is the excess precession of the perihelion of the orbit of Mercury of about 0.01° per century. This effect had been known and unexplained for some time, so, in a sense, explaining it constituted an immediate success of the theory.

A third prediction of general relativity concerns the change in time intervals and frequencies of light in a gravitational field. In Chapter 11, we found that the gravitational potential energy between two masses M and m a distance r apart is

$$U = -\frac{GMm}{r}$$

where G is the universal gravitational constant, and the point of zero potential energy has been chosen to be when the separation of the masses is infinite. The potential energy per unit mass near a mass M is called the *gravitational potential* ϕ:

$$\phi = -\frac{GM}{r} \qquad 39\text{-}30$$

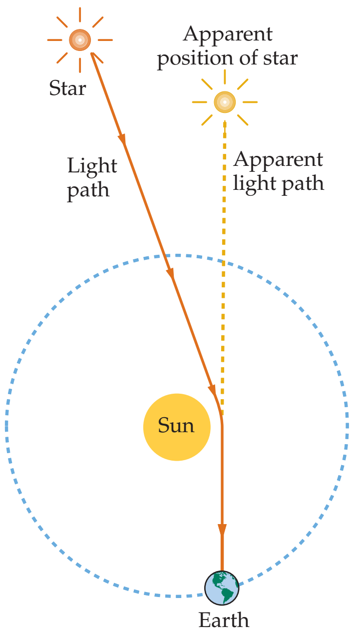

FIGURE 39-16 The deflection (greatly exaggerated) of a beam of light due to the gravitational attraction of the Sun.

The quartz sphere in the top part of the container is probably the world's most perfectly round object. It is designed to spin as a gyroscope in a satellite orbiting Earth. General relativity predicts that the rotation of Earth will cause the axis of rotation of the gyroscope to precess in a circle at a rate of approximately 1 revolution in 100 000 years. *(Michael Freeman.)*

According to the general theory of relativity, clocks run more slowly in regions of lower gravitational potential. (Because the gravitational potential is negative, as can be seen from Equation 39-30, the nearer the mass the more negative, and therefore, the lower the gravitational potential.) If Δt_1 is a time interval between two events measured by a clock where the gravitational potential is ϕ_1 and Δt_2 is the interval between the same two events as measured by a clock where the gravitational potential is ϕ_2, general relativity predicts that the fractional difference between the times will be approximately*

$$\frac{\Delta t_2 - \Delta t_1}{\Delta t} = \frac{1}{c^2}(\phi_2 - \phi_1) \qquad \text{39-31}$$

A clock in a region of low gravitational potential will therefore run more slowly than a clock in a region of higher gravitional potential. Because a vibrating atom can be considered to be a clock, the frequency of vibration of an atom in a region of low potential, such as near the Sun, will be lower than the frequency of vibration of the same atom on Earth. This shift toward a lower frequency, and therefore a longer wavelength, is called the **gravitational redshift.**

As our final example of the predictions of general relativity, we mention **black holes,** which were first predicted by J. Robert Oppenheimer and Hartland Snyder in 1939. According to the general theory of relativity, if the density of an object such as a star is great enough, its gravitational attraction will be so great that once inside a critical radius, nothing can escape, not even light or other electromagnetic radiation. (The effect of a black hole on objects outside the critical radius is the same as that of any other mass.) A remarkable property of such an object is that nothing that happens inside it can be communicated to the outside. As sometimes occurs in physics, a simple but incorrect calculation gives the correct results for the relation between the mass and the critical radius of a black hole. In Newtonian mechanics, the speed needed for a particle to escape from the surface of a planet or a star of mass M and radius R is given by Equation 11-21:

$$v_e = \sqrt{\frac{2GM}{R}}$$

If we set the escape speed equal to the speed of light and solve for the radius, we obtain the critical radius R_S, called the **Schwarzschild radius:**

$$R_S = \frac{2GM}{c^2} \qquad \text{39-32}$$

For an object that has a mass equal to five times that of our Sun (theoretically the minimum mass for a black hole) to be a black hole, its radius would have to be approximately 15 km. Because no radiation is emitted from a black hole and its radius is expected to be small, the detection of a black hole is not easy. The best chance of detection occurs in a binary-star system in which a black hole is a close companion to a normal star. Then both stars revolve around their center of mass and the gravitational field of the black hole will pull gas from the normal star into the black hole. However, to conserve angular momentum, the gas does not go straight into the black hole. Instead, the gas orbits around the black hole in a disk, called an accretion disk, while slowly being pulled closer to the black hole. The gas in this disk emits X rays because the temperature of the gas being pulled inward reaches several million kelvins. The mass of a black-hole candidate can often be estimated. An estimated mass of at least five solar masses, along with the emission of X rays, establishes a strong inference that the candidate is, in fact, a black hole. In addition to the black holes just described, there are supermassive black holes that exist at the centers of galaxies. At the center of the Milky Way is a supermassive black hole that has a mass of about two million solar masses.

This extremely accurate hydrogen maser clock was launched in a satellite in 1976, and its time was compared to that of an identical clock on Earth. In accordance with the prediction of general relativity, the clock on Earth, where the gravitational potential was lower, lost approximately 4.3×10^{-10} s each second compared with the clock orbiting Earth at an altitude of approximately 10 000 km. *(NASA.)*

* Because this shift is usually very small, it does not matter by which interval we divide on the left side of the equation.

Summary

TOPIC	RELEVANT EQUATIONS AND REMARKS
1. Einstein's Postulates	The special theory of relativity is based on two postulates of Albert Einstein. All of the results of special relativity can be derived from these postulates. Postulate 1: Absolute uniform motion cannot be detected. Postulate 2: The speed of light is independent of the motion of the source. An important implication of these postulates is Postulate 2 (alternate): Every observer measures the same value c for the speed of light.
2. The Lorentz Transformation	$x = \gamma(x' + vt'), \quad y = y', \quad z = z'$ 39-9 $t = \gamma\left(t' + \frac{vx'}{c^2}\right)$ 39-10 $\gamma = \frac{1}{\sqrt{1 - (v^2/c^2)}}$ 39-7
Inverse transformation	$x' = \gamma(x - vt), \quad y' = y, \quad z' = z$ 39-11 $t' = \gamma\left(t - \frac{vx}{c^2}\right)$ 39-12
3. Time Dilation	The time interval measured between two events that occur at the same point in space in some reference frame is called the proper time interval Δt_p between those two events. In another reference frame in which the same two events occur at different places, the time interval Δt between the events is longer by the factor γ. $\Delta t = \gamma\,\Delta t_p$ 39-13
4. Length Contraction	The length of an object measured in the reference frame in which the object is at rest is called its proper length L_p. When measured in another reference frame, the length of the object along the direction parallel to the velocity of the object is $L = \frac{L_p}{\gamma}$ 39-14
5. The Relativistic Doppler Effect	$f' = \frac{\sqrt{1 - (v^2/c^2)}}{1 - (v/c)} f_0$ approaching 39-16*a* $f' = \frac{\sqrt{1 - (v^2/c^2)}}{1 + (v/c)} f_0$ receding 39-16*b*
6. Clock Synchronization and Simultaneity	Two events that are simultaneous in one reference frame typically are not simultaneous in another frame that is moving relative to the first. If two clocks are synchronized in the frame in which they are at rest, they will be out of synchronization in another frame. In the frame in which they are moving, the chasing clock leads by an amount $\Delta t_S = L_p \frac{v}{c^2}$ 39-17 where L_p is the proper distance between the clocks.
7. The Velocity Transformation	$u_x = \frac{u'_x + v}{1 + (vu'_x/c^2)}$ 39-18*a* $u_y = \frac{u'_y}{\gamma[1 + (vu'_x/c^2)]}$ 39-18*b* $u_z = \frac{u'_z}{\gamma[1 + (vu'_x/c^2)]}$ 39-18*c*

TOPIC	RELEVANT EQUATIONS AND REMARKS	
Inverse velocity transformation	$u'_x = \dfrac{u_x - v}{1 - (vu_x/c^2)}$	39-19*a*
	$u'_y = \dfrac{u_y}{\gamma[1 - (vu_x/c^2)]}$	39-19*b*
	$u'_z = \dfrac{u_z}{\gamma[1 - (vu_x/c^2)]}$	39-19*c*
8. Relativistic Momentum	$\vec{p} = \dfrac{m\vec{u}}{\sqrt{1 - (u^2/c^2)}}$	39-20
	where m is the mass of the particle.	
9. Relativistic Energy		
Kinetic energy	$K = \dfrac{mc^2}{\sqrt{1 - (u^2/c^2)}} - mc^2$	39-22
Rest energy	$E_0 = mc^2$	39-23
Total Relativistic energy	$E = K + E_0 = \dfrac{mc^2}{\sqrt{1 - (u^2/c^2)}}$	39-24
10. Useful Formulas for Speed, Energy, and Momentum	$\dfrac{u}{p} = \dfrac{pc}{E}$	39-25
	$E^2 = p^2c^2 + (mc^2)^2$	39-27
	$E \approx pc \qquad E \gg mc^2$	39-28

Answer to Concept Check

39-1 Only the rest mass of the spring would change.

Answers for Practice Problems

39-1 1.67 h

39-2 (*a*) 1.49, (*b*) $p = 1.04 \times 10^3$ MeV/c, and (*c*) $u = 0.74c$

39-3 (*a*) $K_f = E_f - M_fc^2 = 9.00\text{ MeV} - 7.75\text{ MeV} = 1.25\text{ MeV}$,

(*b*) $K_{loss} = K_i - K_f = 3.00\text{ MeV} - 1.25\text{ MeV} = 1.75\text{ MeV}$, and

(*c*) $(\Delta M)c^2 = (M_f - M_i)c^2 = 7.75\text{ MeV} - (2.00\text{ MeV} + 4.00\text{ MeV}) = 1.75\text{ MeV} = K_{loss}$

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • The approximate total energy of a particle of mass m moving at speed $u \ll c$ is (*a*) $mc^2 + \frac{1}{2}mu^2$, (*b*) $\frac{1}{2}mu^2$, (*c*) cmu, (*d*) mc^2, (*e*) $\frac{1}{2}cmu$. SSM

2 • A set of twins work in an office building. One twin works on the top floor and the other twin works in the basement. Considering general relativity, which twin will age more quickly? (*a*) They will age at the same rate. (*b*) The twin who works on the top floor will age more quickly. (*c*) The twin who works in the basement will age more quickly. (*d*) It depends on the speed of the office building. (*e*) None of the above.

3 • True or false:
(*a*) The speed of light is the same in all reference frames.
(*b*) The time interval between two events is never shorter than the proper time interval between the two events.
(*c*) Absolute motion can be determined by means of length contraction.
(*d*) The light-year is a unit of distance.
(*e*) Simultaneous events must occur at the same place.
(*f*) If two events are not simultaneous in one frame, they cannot be simultaneous in any other frame.
(*g*) The mass of a system that consists of two particles tightly bound together by attractive forces is less than the sum of the masses of the individual particles when separated.

4 • An observer sees a system moving past her that consists of a mass oscillating on the end of a spring and measures the period T of the oscillations. A second observer, who is moving with the mass–spring system, also measures its period. The second observer will find a period that is (*a*) equal to T, (*b*) less than T, (*c*) greater than T, (*d*) either (*a*) or (*b*) depending on whether the system was approaching or receding from the first observer, (*e*) Not enough information is given to answer the question.

5 • The Lorentz transformation for y and z is the same as the classical result: $y = y'$ and $z = z'$. Yet the relativistic velocity transformation does not give the classical result $u_y = u'_y$ and $u_z = u'_z$. Explain why this result occurs.

ESTIMATION AND APPROXIMATION

6 •• The Sun radiates energy at the rate of approximately 4×10^{26} W. Assume that this energy is produced by a reaction whose net result is the fusion of four protons to form a single ^{4}He nucleus and the release of 25 MeV of energy that is radiated into space. Calculate the Sun's loss of mass per day.

7 •• The most distant galaxies that can be seen by the Hubble telescope are moving away from us and have a redshift parameter of about $z = 5$. [The redshift parameter z is defined as $(f - f')/f'$, where f is the frequency measured in the rest frame of the emitter and f' is the frequency measured in the rest frame of the receiver.] (*a*) What is the speed of the galaxies relative to us (expressed as a fraction of the speed of light)? (*b*) *Hubble's law* states that the recession speed is given by the expression $v = Hx$, where v is the speed of recession, x is the distance, and H, the Hubble constant, is equal to 75 km/s/Mpc, where 1 pc = 3.26 $c \cdot$y. (The abbreviation for parsec is pc.) Estimate the distance of such a galaxy from us using the information given. SSM

TIME DILATION AND LENGTH CONTRACTION

8 • The proper mean lifetime of a muon is 2.2 μs. Muons in a beam are traveling through a laboratory at 0.95c. (*a*) What is their mean lifetime as measured in the laboratory? (*b*) How far do they travel, on average, before they decay?

9 •• In the Stanford linear collider, small bundles of electrons and positrons are fired at each other. In the laboratory's frame of reference, each bundle is approximately 1.0 cm long and 10 μm in diameter. In the collision region, each particle has an energy of 50 GeV, and the electrons and the positrons are moving in opposite directions. (*a*) How long and how wide is each bundle in its own reference frame? (*b*) What must be the minimum proper length of the accelerator for a bundle to have both its ends simultaneously in the accelerator in its own reference frame? (The actual proper length of the accelerator is less than 1000 m.) (*c*) What is the length of a positron bundle in a reference frame that moves with the electron bundle?

10 • Use the binomial expansion equation

$$(1 + x)^n = 1 + nx + \frac{n(n-1)}{2}x^2 + \ldots \approx 1 + nx \qquad x \ll 1$$

to derive the following results for the case when v is much less than c.

$$(a)\ \gamma \approx 1 + \frac{1}{2}\frac{v^2}{c^2}$$

$$(b)\ \frac{1}{\gamma} \approx 1 - \frac{1}{2}\frac{v^2}{c^2}$$

$$(c)\ \gamma - 1 \approx 1 - \frac{1}{\gamma} \approx \frac{1}{2}\frac{v^2}{c^2}$$

11 •• Star A and Star B are at rest relative to Earth. Star A is 27 $c \cdot$y from Earth, and as viewed from Earth, Star B is located beyond (behind) Star A. (*a*) A spaceship is making a trip from Earth to Star A at a speed such that the trip from Earth to Star A takes 12 y according to clocks on the spaceship. At what speed, relative to Earth, must the spaceship travel? (Assume that the times for the accelerations are very short compared to the overall trip time.) (*b*) Upon reaching Star A, the spaceship speeds up and departs for Star B at a speed such that the gamma factor, γ, is twice that of Part (*a*). The trip from Star A to Star B takes 5.0 y (spaceship's time). How far, in $c \cdot$y, is Star B from Star A in the rest frame of Earth and the two stars? (*c*) Upon reaching Star B, the spaceship departs for Earth at the same speed as in Part (*b*). It takes it 10 y (spaceship's time) to return to Earth. If you were born on Earth the day the ship left Earth and you remain on Earth, how old are you on the day the ship returns to Earth?

12 • A spaceship travels to a star 35 $c \cdot$y away at a speed of 2.7×10^8 m/s. How long does the spaceship take to get to the star (*a*) as measured on Earth and (*b*) as measured by a passenger on the spaceship?

13 •• Unobtainium (Un) is an unstable particle that decays into normalium (Nr) and standardium (St) particles. (*a*) An accelerator produces a beam of Un that travels to a detector located 100 m away from the accelerator. The particles travel with a velocity of $v = 0.866c$. How long do the particles take (in the laboratory frame) to get to the detector? (*b*) By the time the particles get to the detector, half of the particles have decayed. What is the half-life of Un? (*Note:* half-life as it would be measured in a frame moving with the particles) (*c*) A new detector is going to be used, which is located 1000 m away from the accelerator. How fast should the particles be moving if half of the particles are to make it to the new detector? SSM

14 •• A clock on Spaceship A measures the time interval between two events, both of which occur at the location of the clock. You are on Spaceship B. According to your careful measurements, the time interval between the two events is 1.00 percent longer than that measured by the two clocks on Spaceship A. How fast is Spaceship A moving relative to Spaceship B. (*Hint: Use one or more of the results of Problem 10.*)

15 •• If a plane flies at a speed of 2000 km/h, how long must the plane fly before its clock loses 1.00 s because of time dilation? (*Hint: Use one or more of the results of Problem 10.*)

THE LORENTZ TRANSFORMATION, CLOCK SYNCHRONIZATION, AND SIMULTANEITY

16 •• Show that when $v \ll c$ the relativistic transformation equations for x, t, and u_x reduce to the classical transformation equations.

17 •• A spaceship of proper length $L_p = 400$ m moves past a transmitting station at a speed of $0.760c$. (The transmitting station broadcasts signals that travel at the speed of light.) A clock is attached to the nose of the spaceship and a second clock is attached to the transmitting station. The instant that the nose of the spaceship passes the transmitter, the clock attached to the transmitter and the clock attached to the nose of the spaceship are set equal to zero. The instant that the tail of the spaceship passes the transmitter a signal is sent by the transmitter that is subsequently detected by a receiver in the nose of the spaceship. (*a*) When, according to the clock attached to the nose of spaceship, is the signal sent? (*b*) When, according to the clocks attached to the nose of spaceship, is the signal received? (*c*) When, according to the clock attached to the transmitter, is the signal received by the spaceship? (*d*) According to an observer that works at the transmitting station, how far from the transmitter is the nose of the spaceship when the signal is received? SSM

18 •• In frame S, event B occurs 2.0 μs after event A, and event A occurs at the origin whereas event B occurs on the x axis at $x = 1.5$ km. How fast and in what direction must an observer be traveling along the x axis so that events A and B occur simultaneously? Is it possible for event B to precede event A for some observer?

19 •• Observers in reference frame S see an explosion located on the x axis at $x_1 = 480$ m. A second explosion occurs, 5.0 μs later, at $x_2 = 1200$ m. In reference frame S', which is moving along the x axis in the $+x$ direction at speed v, the two explosions occur at the same point in space. What is the separation in time between the two explosions as measured in S'?

20 ••• In reference frame S, events 1 and 2 are separated by a distance $D = x_2 - x_1$ and a time $T = t_2 - t_1$. (*a*) Use the Lorentz transformation to show that in frame S', which is moving along the x axis with speed v relative to S, the time separation is $t_2' - t_1' = \gamma(T - vD/c^2)$. (*b*) Show that the events can be simultaneous in frame S' only if D is greater than cT. (*c*) If one of the events is the *cause* of the other, the separation D must be less than cT, because D/c is the smallest time that a signal can take to travel from x_1 to x_2 in frame S. Show that if D is less than cT, t_2' is greater than t_1' in all reference frames. This shows that if the cause precedes the effect in one frame, it must precede it in all reference frames. (*d*) Suppose that a signal could be sent with speed $c' > c$ so that in frame S the cause precedes the effect by the time $T = D/c'$. Show that there is then a reference frame moving with speed v less than c in which the effect precedes the cause.

21 ••• A rocket that has a proper length of 700 m is moving to the right at a speed of $0.900c$. It has two clocks—one in the nose and one in the tail—that have been synchronized in the frame of the rocket. A clock on the ground and the clock in the nose of the rocket both read zero as they pass by each other. (*a*) At the instant the clock on the ground reads zero, what does the clock in the tail of the rocket read according to observers on the ground? When the clock in the tail of the rocket passes the clock on the ground, (*b*) what does the clock in the tail read according to observers on the ground, and (*c*) what does the clock in the nose read according to observers on the ground, and (*d*) what does the clock in the nose read according to observers on the rocket? (*e*) At the instant the clock in the nose of the rocket reads 1.00 h, a light signal is sent from the nose of the rocket to an observer standing by the clock on the ground. What does the clock on the ground read when the observer on the ground receives the signal? (*f*) When the observer on the ground receives the signal, he immediately sends a return signal to the nose of the rocket. What is the reading of the clock in the nose of the rocket when that signal is received at the nose of the rocket?

THE VELOCITY TRANSFORMATION AND THE RELATIVISTIC DOPPLER EFFECT

22 •• **SPREADSHEET** A spaceship, at rest in a certain reference frame S, is given a speed increase of $0.50c$ (call this increase boost 1). Relative to its new rest frame, the spaceship is given a further $0.50c$ increase 10 seconds later (as measured in its new rest frame; call this increase boost 2). This process is continued indefinitely, at 10-s intervals, as measured in the rest frame of the spaceship. (Assume that the boosts take a very short time compared to 10 s.) (*a*) Using a spreadsheet program, calculate and graph the speed of the spaceship in reference frame S as a function of the boost number for boost 1 to boost 10. (*b*) Graph the gamma factor in the same manner. (*c*) How many boosts does it take until the speed of the ship in S is greater than $0.999c$? (*d*) How far does the spaceship move between boost 1 and boost 6, as measured in reference frame S? What is the average speed of the spaceship between boost 1 and boost 6, as measured in S?

23 • Light is emitted by a sodium sample that is moving toward Earth with speed v. The wavelength of the light is 589 nm in the rest frame of the sample. The wavelength measured in the frame of Earth is 547 nm. Find v.

24 • A distant galaxy is moving away from us at a speed of 1.85×10^7 m/s. Calculate the fractional redshift $(\lambda' - \lambda_0)/\lambda_0$ that we observe the light from the galaxy to have.

25 •• Derive $f' = f_0\sqrt{1 - (v^2/c^2)}/[1 - (v/c)]$ (Equation 39-16*a*) for the frequency received by an observer moving with speed v toward a stationary source of electromagnetic waves.

26 • Show that if v is much less than c, the Doppler shift is given approximately by

$$\Delta f/f \approx \pm v/c$$

27 •• A clock is placed in a satellite that orbits Earth with an orbital period of 90 min. By what time interval will this clock differ from an identical clock on Earth after 1.0 y? (Assume that special relativity applies and neglect general relativity.) SSM

28 •• For light that is Doppler-shifted with respect to an observer, we define the redshift parameter $z = (f - f')/f'$, where f is the frequency of the light measured in the rest frame of the emitter and f' is the frequency measured in the rest frame of the receiver. If the emitter is moving directly away from the receiver, show that the relative velocity between the emitter and the receiver is $v = c(u^2 - 1)/(u^2 + 1)$, where $u = z + 1$.

29 • A light beam moves along the y' axis with speed c in frame S', which is moving in the $+x$ direction with speed v relative to frame S. (*a*) Find the x and y components of the velocity of the light beam in frame S. (*b*) Show that, according to the velocity transformation equations, the magnitude of the velocity of the light beam in S is c.

30 •• A spaceship is moving east at speed $0.90c$ relative to Earth. A second spaceship is moving west at speed $0.90c$ relative to Earth. What is the speed of one spaceship relative to the other spaceship?

31 •• A particle moves with speed $0.800c$ in the $+x''$ direction along the x'' axis of frame S'', which moves with the same speed and in the same direction along the x' axis relative to frame S'. Frame S' moves with the same speed and in the same direction along the x axis relative to frame S. (*a*) Find the speed of the particle relative to frame S'. (*b*) Find the speed of the particle relative to frame S. SSM

RELATIVISTIC MOMENTUM AND RELATIVISTIC ENERGY

32 • A proton that has a rest energy equal to 938 MeV has a total energy of 2200 MeV. (*a*) What is its speed? (*b*) What is its momentum?

33 • If the kinetic energy of a particle equals twice its rest energy, what percentage error is made by using $p = mu$ for the magnitude of its momentum?

34 •• In a certain reference frame, a particle has momentum of 6.00 MeV/c and total energy of 8.00 MeV. (*a*) Determine the mass of the particle. (*b*) What is the total energy of the particle in a reference frame in which its momentum is 4.00 MeV/c? (*c*) What is the relative speed of the two reference frames?

35 •• Show that

$$d\left(\frac{mu}{1-(u^2/c^2)}\right) = m\left(1-\frac{u^2}{c^2}\right)^{-3/2} du$$

Note: This relation was used to derive the relativistically correct expression for kinetic energy (Equation 39-22).

36 •• The K^0 particle has a mass of 497.7 MeV/c^2. It decays into a π^- and π^+, each having mass 139.6 MeV/c^2. Following the decay of a K^0, one of the pions is at rest in the laboratory. Determine the kinetic energy of the other pion after the decay and of the K^0 prior to the decay.

37 •• In reference frame S', two protons, each moving at $0.500c$, approach each other head-on. (*a*) Calculate the total kinetic energy of the two protons in frame S'. (*b*) Calculate the total kinetic energy of the protons as seen in reference frame S, which is moving with one of the protons. SSM

38 •• An antiproton $\bar{p}$ has the same mass m as a proton p. The antiproton is created during the reaction $p + p \rightarrow p + p + p + \bar{p}$. During an experiment, protons at rest in the laboratory are bombarded with protons of kinetic energy K_L, which must be great enough so that an amount of kinetic energy equal to $2mc^2$ can be converted into the rest energy of the two particles. In the frame of the laboratory, the total kinetic energy cannot be converted into rest energy because of conservation of momentum. However, in the zero-momentum reference frame in which the two initial protons are moving toward each other with equal speed u, the total kinetic energy can be converted into rest energy. (*a*) Find the speed of each proton u so that the total kinetic energy in the zero-momentum frame is $2mc^2$. (*b*) Transform to the laboratory's frame in which one proton is at rest, and find the speed u' of the other proton. (*c*) Show that the kinetic energy of the moving proton in the laboratory's frame is $K_L = 6mc^2$.

39 ••• A particle of mass 1.00 MeV/c^2 and kinetic energy 2.00 MeV collides with a stationary particle of mass 2.00 MeV/c^2. After the collision, the particles stick together. Find (*a*) the speed of the first particle before the collision, (*b*) the total energy of the first particle before the collision, (*c*) the initial total momentum of the system, (*d*) the total kinetic energy after the collision, and (*e*) the mass of the system after the collision.

GENERAL RELATIVITY

40 •• Light traveling in the direction of increasing gravitational potential undergoes a frequency redshift. Calculate the shift in wavelength if a beam of light of wavelength $\lambda = 632.8$ nm is sent up a vertical shaft of height $L = 100$ m.

41 •• Let us revisit a problem from Chapter 3: Two cannons are pointed directly toward each other, as shown in Figure 39-17. When fired, the cannonballs will follow the trajectories shown. Point P is the point where the trajectories cross each other. Ignore any effects due to air resistance. Using the principle of equivalence, show that if the cannons are fired simultaneously (in the rest frame of the cannons), the cannonballs will hit each other at point P.

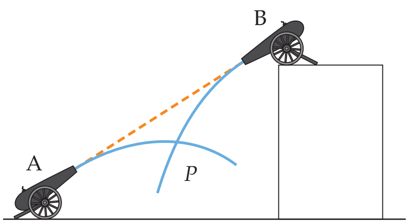

FIGURE 39-17
Problem 41

42 ••• A horizontal turntable rotates with angular speed ω. There is a clock at the center of the turntable and an identical clock mounted on the turntable a distance r from the center. In an inertial reference frame, in which the clock at the center is at rest, the clock at distance r is moving with speed $u = r\omega$. (*a*) Show that from time dilation according to special relativity, the time between ticks, Δt_0 for the clock at rest and Δt_R for the moving clock, are related by

$$\frac{\Delta t_R - \Delta t_0}{\Delta t_0} = -\frac{r^2\omega^2}{2c^2} \qquad r\omega \ll c$$

(*b*) In a reference frame rotating with the table, both clocks are at rest. Show that the clock at distance r experiences a pseudoforce $F_r = mr\omega^2$ in the rotating frame and that this is equivalent to a difference in gravitational potential between r and the origin of $\phi_r - \phi_0 = -\frac{1}{2}r^2\omega^2$. (*c*) Use the difference in gravitational potential given in Part (*b*) to show that in this frame the difference in time intervals is the same as in the inertial frame.

GENERAL PROBLEMS

43 • How fast must a muon travel so that its mean lifetime is 46 μs if its mean lifetime at rest is 2.2 μs?

44 • A distant galaxy is moving away from Earth with a speed that results in each wavelength received on Earth being shifted so that $\lambda' = 2\lambda_0$. Find the speed of the galaxy relative to Earth.

45 •• Frames S and S' are moving relative to each other along the x and x' axes (which superpose). Observers at rest in the two frames set their clocks to $t = 0$ when the two origins coincide. In frame S, event 1 occurs at $x_1 = 1.0\,c\cdot$y and $t_1 = 1.00$ y and event 2 occurs at $x_2 = 2.0\,c\cdot$y and $t_2 = 0.50$ y. The events occur simultaneously in frame S'. (*a*) Find the magnitude and direction of the velocity of S' relative to S. (*b*) At what time do both events occur as measured in S'? SSM

46 •• An interstellar spaceship travels from Earth to a star system 12 light-years away (as measured in Earth's frame). The trip takes 15 y as measured by clocks on the spaceship. (*a*) What is the speed of the spaceship relative to Earth? (*b*) When the spaceship arrives, it sends an electromagnetic signal to Earth. How long after the spaceship leaves Earth will observers on Earth receive the signal?

47 •• The neutral pion π^0 has a mass of 135.0 MeV/c^2. This particle can be created in a proton–proton collision:

$$\mathrm{p} + \mathrm{p} \rightarrow \mathrm{p} + \mathrm{p} + \pi^0$$

Determine the threshold kinetic energy for the creation of a π^0 in a collision of a moving proton and a stationary proton. (See Problem 38.)

48 •• A rocket that has a proper length of 1000 m moves away from a space station and in the $+x$ direction at $0.60c$ relative to an observer on the station. An astronaut stands at the rear of the rocket and fires a dart toward the front of the rocket at $0.80c$ relative to the rocket. How long does it take the dart to reach the front of the rocket (*a*) as measured in the frame of the rocket, (*b*) as measured in the frame of the space station, and (*c*) as measured in the frame of the dart?

49 ••• Using a simple thought experiment, Einstein showed that there is mass associated with electromagnetic radiation. Consider a box of length L and mass M resting on a frictionless surface. Attached to the left wall of the box is a light source that emits a directed pulse of radiation of energy E, which is completely absorbed at the right wall of the box. According to classical electromagnetic theory, the radiation carries momentum of magnitude $p = E/c$ (Equation 30-24). The box recoils when the pulse is emitted by the light source. (*a*) Find the recoil velocity of the box so that momentum is conserved when the light is emitted. (Because p is small and M is large, you may use classical mechanics.) (*b*) When the light is absorbed at the right wall of the box the box stops, so the total momentum of the system remains zero. If we neglect the very small velocity of the box, the time it takes for the radiation to travel across the box is $\Delta t = L/c$. Find the distance moved by the box in that time. (*c*) Show that if the center of mass of the system is to remain at the same place, the radiation must carry mass $m = E/c^2$. SSM

50 ••• Using the relativistic conservation of momentum and energy and the relation between energy and momentum for a photon $E = pc$, prove that a free electron (an electron not bound to an atomic nucleus) cannot absorb or emit a photon.

51 ••• When a moving particle that has a kinetic energy greater than the threshold kinetic energy K_{th} strikes a stationary target particle, one or more particles may be created in the inelastic collision. Show that the threshold kinetic energy of the moving particle is given by

$$K_{\mathrm{th}} = \frac{(\Sigma m_{\mathrm{in}} + \Sigma m_{\mathrm{fin}})(\Sigma m_{\mathrm{fin}} + \Sigma m_{\mathrm{in}})c^2}{2m_{\mathrm{target}}}$$

Here Σm_{in} is the sum of the masses of the particles prior to the collision, Σm_{fin} is the sum of the masses of the particles following the collision, and m_{target} is the mass of the target particle. Use this expression to determine the threshold kinetic energy of protons incident on a stationary proton target for the production of a proton–antiproton pair; compare your result with the result of Problem 38. SSM

52 ••• A particle of mass M decays into two identical particles, each of mass m, where $m = 0.30M$. Prior to the decay, the particle of mass M has a total energy of $4.0mc^2$ in the laboratory reference frame. The velocities of the decay products are along the direction of motion of M. Find the velocities of the decay products in the laboratory reference frame.

53 ••• A rod of proper length L_{p} makes an angle θ with the x axis in frame S. Show that the angle θ' made with the x' axis in frame S', which is moving in the $+x$ direction with speed v, is given by $\tan\theta' = \gamma \tan\theta$ and that the length of the stick in S' is $L' = L_{\mathrm{p}}(\gamma^{-2}\cos^2\theta + \sin^2\theta)^{1/2}$.

54 ••• Show that if a particle moves at an angle θ with the x axis with speed u in frame S, it moves at an angle θ' with the x' axis in S' given by

$$\tan\theta' = \gamma^{-1}\sin\theta/[\cos\theta - (v/u)].$$

55 ••• For the special case of a particle moving with speed u along the y axis in frame S, show that its momentum and energy in frame S', a frame that is moving along the x axis with velocity v, are related to its momentum and energy in S by the transformation equations

$$p'_x = \gamma\left(p_x - \frac{vE}{c^2}\right) \qquad p'_y = p_y \qquad p'_z = p_z \qquad \frac{E'}{c} = \gamma\left(\frac{E}{c} - \frac{vp_x}{c}\right)$$

Compare these equations with the Lorentz transformation equations for x', y', z', and t'. Notice that the quantities p_x, p_y, p_z and E/c transform in the same way as do x, y, z, and ct. SSM

56 ••• The equation for the spherical wavefront of a light pulse that begins at the origin at time $t = 0$ is $x^2 + y^2 + z^2 - (ct)^2 = 0$. Frame S' moves with velocity v along the x axis. Using the Lorentz transformation, show that such a light pulse also has a spherical wavefront in frame S' by showing that $x'^2 + y'^2 + z'^2 - (ct')^2 = 0$.

57 ••• In Problem 56, you showed that the quantity $x^2 + y^2 + z^2 - (ct)^2$ has the same value (zero) in both S and S'. A quantity that has the same value in all inertial frames is called a *Lorentz invariant*. From the results of Problem 55, the quantity $p_x^2 + p_y^2 + p_z^2 - E^2/c^2$ must also be a Lorentz invariant. Show that this quantity has the value $-m^2c^2$ in both the S and S' reference frames.

58 ••• A long rod that is parallel to the x axis is released from rest. Subsequently, it is in free fall with an acceleration of magnitude g in the $-y$ direction. An observer in a rocket ship moving with speed v parallel to the x axis passes by. Using the Lorentz transformations, show that the observer on the rocket ship will measure the rod to be bent into a parabolic shape. Is the parabola concave upward or concave downward?

59 •• Show that if u'_x and v in $u_x = (u'_x + v)/[1 + (vu'_x/c^2)]$ (Equation 39-18*a*) are both positive and less than c, then u_x is positive and less than c. (*Hint: Let* $u'_x = (1 - \varepsilon_1)c$ *and* $v = (1 - \varepsilon_2)c$, *where* ε_1 *and* ε_2 *are positive numbers that are less than 1.*)

60 ••• In reference frame S, the acceleration of a particle is $\vec{a} = a_x\hat{\imath} + a_y\hat{\jmath} + a_z\hat{k}$. Derive expressions for the acceleration components a'_x, a'_y, and a'_z of the particle in reference frame S' that is moving relative to S in the x direction with velocity v.

CHAPTER 40

THE DIABLO CANYON NUCLEAR POWER PLANT NEAR SAN LUIS OBISPO, CALIFORNIA. *(Tony Hertz/Alamy.)*

? How much energy is released during the fission of one gram of ^{235}U? (See Example 40-6).

Nuclear Physics

To many chemists, the atomic nucleus is modeled as a point charge that has most of the mass of the atom. In this chapter, we will look at the nucleus from the physicist's perspective and see how the protons and neutrons that make up the nucleus have played important roles in our everyday life as well as in the history and structure of the universe.

In this chapter, we study the properties of atomic nuclei, examine radioactivity, and explore nuclear reactions. We also discuss fission and fusion. The fission of very heavy nuclei, such as uranium, is a major source of power today, while the fusion of very light nuclei is the energy source that powers the stars, including our Sun, and may hold the key to our energy needs of the future.

40-1 PROPERTIES OF NUCLEI

The nucleus of an atom has just two kinds of particles, protons and neutrons,* which have approximately the same mass (the neutron is approximately 0.2 percent more massive). The proton has a charge of $+e$, and the neutron is uncharged.

* The most prevalent hydrogen nucleus has a single proton.

The number of protons, Z, is the atomic number of the atom, which also equals the number of electrons in the atom. The number of neutrons that a nucleus has, N, is approximately equal to Z for light nuclei. For heavier nuclei, the number of neutrons is increasingly greater than Z. The total number of nucleons* $A = N + Z$ is called the **nucleon number** or **mass number** of the nucleus. A particular nuclear species is called a **nuclide.** Two or more nuclides that have the same atomic number Z but have different values for N and A are called **isotopes.** A particular nuclide is designated by its atomic symbol (for example, H for hydrogen and He for helium) and its mass number A as a superscript. The lightest element, hydrogen, has three isotopes: protium, ^1H, whose nucleus is just a single proton; deuterium, ^2H, whose nucleus is composed of one proton and one neutron; and tritium, ^3H, whose nucleus is composed of one proton and two neutrons. Although the mass of the deuterium atom is about twice the mass of the protium atom and the mass of the tritium atom is about three times the mass of protium, these three atoms have nearly identical chemical properties because they each have one electron. On the average, there are about three stable isotopes for each element, although some atoms have only one stable isotope while others have five or six. The most common isotope of the second lightest element, helium, is ^4He. The ^4He nucleus is also known as an α particle. Another isotope of helium is ^3He, and the ^3He nucleus is also known as helion.

Nucleons exert a strong attractive force on other nucleons. This force, called the **strong nuclear force** or the **hadronic force,** is much stronger than the electrostatic force of repulsion between the protons and is very much stronger than the gravitational forces between the nucleons. (Gravity is so comparably weak that it can always be neglected in nuclear physics.) The strong nuclear force is roughly the same between two neutrons, two protons, or a neutron and a proton. Two protons, of course, also exert a repulsive electrostatic force on each other due to their charges, which tends to weaken the attraction between them somewhat. The strong nuclear force decreases rapidly with distance, and it is negligible when two nucleons are more than a few femtometers apart.

SIZE, SHAPE, AND DENSITY

The size and shape of the nucleus can be determined by bombarding it with high-energy particles and observing the scattering. The results depend somewhat on the kind of experiment. For example, a scattering experiment using electrons measures the charge distribution of the nucleus, whereas a scattering experiment using neutrons determines the region of influence of the strong nuclear force. A wide variety of experiments suggest that most nuclei are approximately spherical, with radii given approximately by

$$R = R_0 A^{1/3} \tag{40-1}$$

NUCLEAR RADIUS

where R_0 is approximately 1.2 fm. The fact that the radius of a spherical nucleus is proportional to $A^{1/3}$ implies that the volume of the nucleus is proportional to A. Because the mass of the nucleus is also approximately proportional to A, the densities of all nuclei are approximately the same. This is analogous to a drop of liquid, which also has constant density independent of its size. The **liquid-drop model** of the nucleus has proved quite successful in explaining nuclear behavior, especially the fission of heavy nuclei.

---

* The word *nucleon* refers to either a neutron or a proton that is part of a nucleus.

N AND *Z* Numbers

For light nuclei, the greatest stability is achieved when the numbers of protons and neutrons are approximately equal, $N \approx Z$. For heavier nuclei, instability caused by the electrostatic repulsion between the protons is minimized when there are more neutrons than protons. We can see this by looking at the N and Z numbers for the most abundant isotopes of some representative elements: for ${}^{16}_{8}\mathrm{O}$, $N = 8$ and $Z = 8$; for ${}^{40}_{20}\mathrm{Ca}$, $N = 20$ and $Z = 20$; for ${}^{56}_{26}\mathrm{Fe}$, $N = 30$ and $Z = 26$; for ${}^{207}_{82}\mathrm{Pb}$, $N = 125$ and $Z = 82$; and for ${}^{238}_{92}\mathrm{U}$, $N = 146$ and $Z = 92$. (The atomic number Z has been included here as a subscript of the atomic symbol for emphasis. It is not actually needed because the atomic number is implied by the atomic symbol.)

Figure 40-1 shows a plot of N versus Z for the known stable nuclei. The curve follows the straight line $N = Z$ for small values of N and Z. We can understand this tendency for N and Z to be equal by considering the total energy of A particles in a one-dimensional box. For $A = 8$, Figure 40-2 shows the energy levels for eight neutrons and for four neutrons and four protons. Because of the exclusion principle, only two identical particles (that have opposite spins) can be in the same space state. Because protons and neutrons are not identical, we can put two each in a state, as shown in Figure 40-2*b*. Thus, the total energy for four protons and four neutrons is less than the total energy for eight neutrons (or eight protons), as shown in Figure 40-2*a*. When the Coulomb energy of repulsion, which is proportional to Z^2, is included, this result changes somewhat. For large values of A and Z, the total energy may be increased less by adding two neutrons than by adding one neutron and one proton because of the electrostatic repulsion involved in the latter case. This explains why $N > Z$ for the larger values of A (for the heavier nuclei).

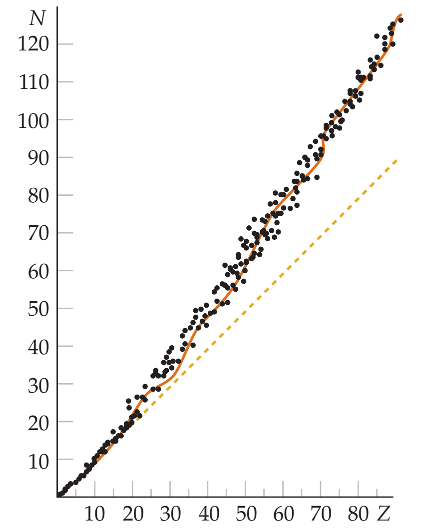

FIGURE 40-1 Plot of number of neutrons N versus number of protons Z for the stable nuclides. The dashed line is $N = Z$.

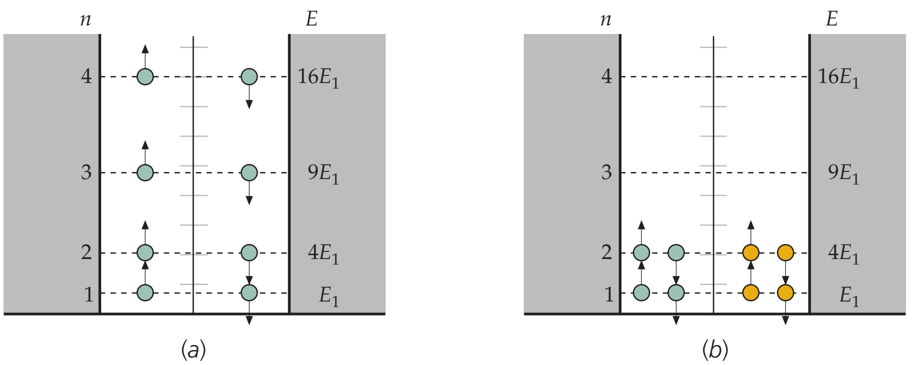

FIGURE 40-2 (*a*) Eight neutrons in a one-dimensional box. In accordance with the exclusion principle, only two neutrons (that have opposite spins) can be in a given energy level. (*b*) Four neutrons and four protons in a one-dimensional box. Because protons and neutrons are not identical particles, two of each can be in the same energy level. The total energy is much less for this case than for the case shown in Figure 40-2*a*.

PRACTICE PROBLEM 40-1

(*a*) Calculate the total energy of the eight neutrons in the one-dimensional box shown in Figure 40-2*a*. (*b*) Calculate the total energy of the four neutrons and four protons in the one-dimensional box shown in Figure 40-2*b*.

MASS AND BINDING ENERGY

The mass of a nucleus is less than the sum of the masses of its parts by E_b/c^2, where E_b is the binding energy and c is the speed of light. When two or more nucleons fuse together to form a nucleus, the total mass decreases and energy is released. Conversely, to break up a nucleus into its parts, energy is absorbed by the system and the mass of the system increases.

Atomic masses and nuclear masses are often given in unified atomic mass units (u), defined as one-twelfth the mass of a ^{12}C atom. The rest energy of one such mass unit is

$$(1\ \mathrm{u})c^2 = 931.5\ \mathrm{MeV} \tag{40-2}$$

Consider ^{4}He, for example, which consists of two protons and two neutrons. The mass of an atom can be accurately measured in a mass spectrometer. The mass of the ^{4}He atom is 4.002 603 u and the mass of the ^{1}H atom is 1.007 825 u. These values include the masses of the electrons in the atom. The mass of the neutron is 1.008 665 u. The sum of the masses of two ^{1}H atoms and two neutrons is $2(1.007\,825\ \mathrm{u}) + 2(1.008\,665\ \mathrm{u}) = 4.032\,980\ \mathrm{u}$, which is greater than the mass of the ^{4}He atom by 0.030 377 u.* We can find the binding energy of the ^{4}He nucleus from this mass difference of 0.030 377 u by using the mass conversion factor $(1\ \mathrm{u})c^2 = 931.5\ \mathrm{MeV}$ from Equation 40-2. Then

$$(0.030\,377\ \mathrm{u})c^2 = (0.030\,377\ \mathrm{u})c^2 \times \frac{931.5\ \mathrm{MeV}/c^2}{1\ \mathrm{u}} = 28.30\ \mathrm{MeV}$$

The total binding energy of ^{4}He is thus 28.30 MeV. In general, the binding energy of a nucleus of an atom of atomic mass M_A having Z protons and N neutrons is found by calculating the difference between the sum of the masses of the nucleons and the mass of the nucleus and then multiplying by c^2:

$$E_b = (ZM_H + Nm_n - M_A)c^2 \tag{40-3}$$

TOTAL NUCLEAR BINDING ENERGY

where M_H is the mass of the ^{1}H atom and m_n is the mass of the neutron. (Note that the mass of the Z electrons in the term ZM_H is canceled by the mass of the Z electrons in the term M_A.†) The atomic masses of the neutron and of some selected isotopes are listed in Table 40-1.

Example 40-1 Binding Energy of the Last Neutron

Find the binding energy of the last neutron in a ^{4}He nucleus.

PICTURE The binding energy is energy equivalent of the mass of a ^{3}He atom plus the mass of a neutron minus the mass of a ^{4}He atom. We find the masses from Table 40-1 and multiply by c^2 to obtain the energy equivalents.

---

* Note that by using the masses of two ^{1}H atoms rather than two protons, the masses of the electrons in the atom are accounted for. We do this because it is atomic masses, not nuclear masses, that are measured directly and listed in mass tables.

† The mass associated with the binding energies of the electrons are not accounted for in this calculation.

SOLVE

1. Add the mass of the neutron to that of ^{3}He:

$$m_{^3\text{He}} + m_\text{n} = 3.016\,030\text{ u} + 1.008\,665\text{ u}$$
$$= 4.024\,695\text{ u}$$

2. Subtract the mass of ^{4}He from the result:

$$\Delta m = (m_{^3\text{He}} + m_\text{n}) - m_{^4\text{He}}$$
$$= 4.024\,695\text{ u} - 4.002\,603\text{ u} = 0.022\,092\text{ u}$$

3. Multiply this mass difference by c^2 and convert to MeV:

$$E_\text{b} = (\Delta m)c^2$$
$$= (0.022\,092\text{ u})c^2 \times \frac{931.5\text{ MeV}/c^2}{1\text{ u}}$$
$$= \boxed{20.58\text{ MeV}}$$

CHECK As expected, the step-3 result of 20.58 MeV is less than the total binding energy of a ^{4}He nucleus. (The total binding energy of a ^{4}He nucleus is 28.30 MeV, a value that is calculated preceding Equation 40-3.)

Table 40-1 Atomic Masses of the Neutron and Selected Isotopes*

Element	Symbol	Z	Atomic mass, u
Neutron	n	0	1.008 665
Hydrogen			
Protium	^{1}H	1	1.007 825
Deuterium	^{2}H or D	1	2.014 102
Tritium	^{3}H or T	1	3.016 050
Helium	^{3}He	2	3.016 030
	^{4}He	2	4.002 603
Lithium	^{6}Li	3	6.015 125
	^{7}Li	3	7.016 004
Boron	^{10}B	5	10.012 939
Carbon	^{12}C	6	12.000 000
	^{13}C	6	13.003 354
	^{14}C	6	14.003 242
Nitrogen	^{13}N	7	13.005 738
	^{14}N	7	14.003 074
Oxygen	^{16}O	8	15.994 915
Sodium	^{23}Na	11	22.989 771
Potassium	^{39}K	19	38.963 710
Iron	^{56}Fe	26	55.939 395
Copper	^{63}Cu	29	62.929 592

Radon	^{222}Rn	86	222.017 531
Radium	^{226}Ra	88	226.025 360
Uranium	^{238}U	92	238.048 608
Plutonium	^{242}Pu	94	242.058 725

*Mass values obtained at <http://physics.nist.gov/PhysRefData/Compositions/index.html>.

Figure 40-3 shows the binding energy per nucleon E_b/A versus A. The mean value is approximately 8.3 MeV. The flatness of the curve for $A > 50$ shows that E_b is approximately proportional to A. This indicates that there is saturation of nuclear forces in the nucleus as would be the case if each nucleon were attracted only to its nearest neighbors. Such a situation also leads to a constant nuclear density consistent with the measurements of the radius. If, for example, there were no saturation and each nucleon bonded to each other nucleon, there would be $A - 1$ bonds for each nucleon and a total of $A(A - 1)$ bonds altogether. The total binding energy, which is a measure of the energy needed to break all these bonds, would then be proportional to $A(A - 1)$, and E_b/A would not be approximately constant. The steep rise in the curve for low A is due to the increase in the number of nearest neighbors and therefore to the increased number of bonds per nucleon. The gradual decrease at high A is due to the Coulomb repulsion of the protons, which increases as Z^2 and decreases the binding energy. For very large A, this Coulomb repulsion is so great that a nucleus that has an A greater than approximately 300 is unstable and undergoes spontaneous fission.

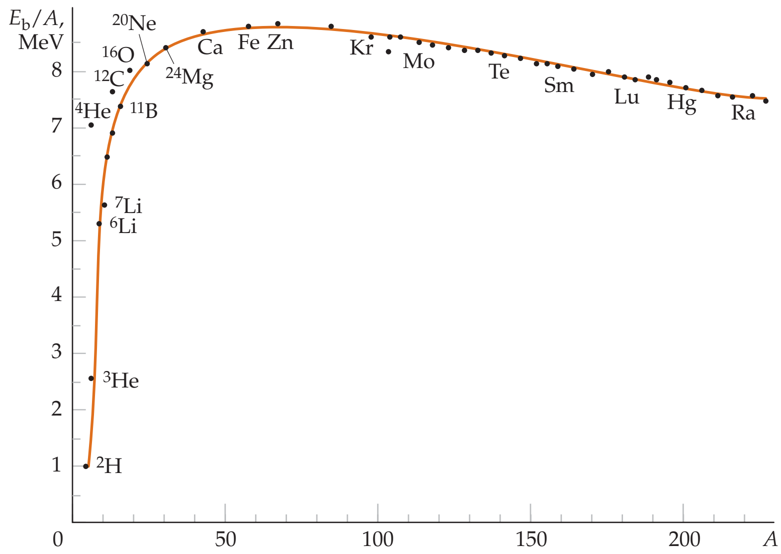

FIGURE 40-3 The binding energy per nucleon versus the nucleon number A. For nuclei that have values of A greater than 50, the curve is approximately constant, indicating that the total binding energy is approximately proportional to A.

40-2 RADIOACTIVITY

Many nuclei are radioactive; that is, they decay into other nuclei by the emission of particles such as photons, electrons, neutrons, or α particles. The terms α decay, β decay, and γ decay were used before it was discovered that α particles are ^{4}He nuclei, β particles are either electrons (β^-) or positrons* (β^+), and γ rays are photons. The rate of decay of a radioactive sample decreases exponentially with increasing time. *This exponential time dependence is characteristic of all radioactivity and indicates that radioactive decay is a statistical process.* Because each nucleus is well shielded from others by the atomic electrons, pressure and temperature changes have little or no effect on the rate of radioactive decay or other nuclear properties.

* The positron has the same mass as an electron and it has a charge of $+e$.

Let N be the number of radioactive nuclei at some time t. If the decay of an individual nucleus is a random event, we expect the number of nuclei that decay in some time interval dt to be proportional both to N and to dt. Because of these decays, the number N will decrease. The change in N between time t and time $t + dt$ is given by

$$dN = -\lambda N\, dt \tag{40-4}$$

where λ is a constant of proportionality called the **decay constant.** The rate of change of N, dN/dt, is proportional to N. This is characteristic of exponential decay. To solve Equation 40-4 for N, we first divide each side by N, thus separating the variables N and t:

$$\frac{dN}{N} = -\lambda\, dt$$

Integrating, we obtain

$$\int_{N_0}^{N'} \frac{dN}{N} = -\lambda \int_0^{t'} dt$$

or

$$\ln \frac{N'}{N_0} = -\lambda t' \tag{40-5}$$

where N' is the number of nuclei that remain at time t'. For convenience, we drop the primes from N' and t'. This introduces no ambiguity because the parameters N and t have been integrated out of the equation. Taking the exponential of each side, we obtain

$$\frac{N}{N_0} = e^{-\lambda t}$$

or

$$N = N_0 e^{-\lambda t} \tag{40-6}$$

See **Math Tutorial** *for more information on*
Exponential Functions

The number of radioactive decays per second is called the **decay rate** R:

$$R = -\frac{dN}{dt} = \lambda N = \lambda N_0 e^{-\lambda t} = R_0 e^{-\lambda t} \tag{40-7}$$

DECAY RATE

where

$$R_0 = \lambda N_0 \tag{40-8}$$

is the decay rate at time $t = 0$. The decay rate R is the quantity that is determined experimentally. The decay rate is also called the **activity** of the sample.

The average or **mean lifetime** τ is equal to the reciprocal of the decay constant (see Problem 40):

$$\tau = \frac{1}{\lambda} \tag{40-9}$$

The mean lifetime is analogous to the time constant in the exponential decrease in the charge on a capacitor in an RC circuit that we discussed in Section 25-6. After a time equal to the mean lifetime, the number of radioactive nuclei and the decay rate are each equal to $e^{-1} = 37$ percent of their original values. The **half-life** $t_{1/2}$ is defined as the time it takes for the number of nuclei and the decay rate to decrease by half. Setting $t = t_{1/2}$ and $N = N_0/2$ in Equation 40-6 gives

$$\frac{N_0}{2} = N_0 e^{-\lambda t_{1/2}} \qquad 40\text{-}10$$

or

$$e^{+\lambda t_{1/2}} = 2$$

Solving for $t_{1/2}$ gives

$$t_{1/2} = \frac{\ln 2}{\lambda} = (\ln 2)\tau = 0.693\tau \qquad 40\text{-}11$$

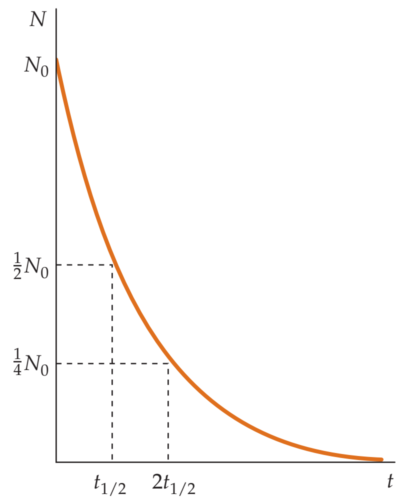

FIGURE 40-4 Exponential radioactive decay. After each half-life $t_{1/2}$, the number of nuclei remaining has decreased by one-half. The decay rate $R = \lambda N$ has the same time dependence as does N.

Figure 40-4 shows a plot of N versus t. If we multiply the numbers on the N axis by λ, this graph becomes a plot of R versus t. After each time interval of one half-life, both the number of nuclei left and the decay rate have decreased to half of their previous values. For example, if the decay rate is R_0 initially, it will be $\frac{1}{2}R_0$ after one half-life, $\left(\frac{1}{2}\right)\left(\frac{1}{2}\right)R_0$ after two half-lives, and so forth. After n half-lives, the decay rate will be

$$R = \left(\tfrac{1}{2}\right)^n R_0 \qquad 40\text{-}12$$

The half-lives of radioactive nuclei vary from very small times (less than 1 μs) to very large times (greater than 10^{10} y).

Example 40-2 Counting Rate for Radioactive Decay

A radioactive source has a half-life of 1.0 min. At time $t = 0$, the radioactive source is placed near a detector, and the counting rate (the number of decay particles detected per unit time) is observed to be 2000 counts/s. Find the counting rate at times $t = 1.0$ min, $t = 2.0$ min, $t = 3.0$ min, and $t = 10$ min.

PICTURE The counting rate r is proportional to the decay rate R, and the decay rate is given by $R = \left(\frac{1}{2}\right)^n R_0$ (Equation 40-12), where n is the time divided by 1.0 min.

SOLVE

1. Because the half-life is 1.0 min, the counting rate will be half as great at $t = 1.0$ min as at $t = 0$:

$$r_1 = \tfrac{1}{2}r_0 = \tfrac{1}{2}(2000\ \text{counts/s}) = \boxed{1.0 \times 10^3\ \text{counts/s at 1.0 min}}$$

2. At $t = 2.0$ min, the rate is half that at 1 min. It decreases by one-half each minute:

$$r_2 = \left(\tfrac{1}{2}\right)^2 r_0 = \tfrac{1}{4}(2000\ \text{counts/s}) = \boxed{5.0 \times 10^2\ \text{counts/s at 2.0 min}}$$

$$r_3 = \left(\tfrac{1}{2}\right)^3 r_0 = \tfrac{1}{8}(2000\ \text{counts/s}) = \boxed{2.5 \times 10^2\ \text{counts/s at 3.0 min}}$$

3. At $t = 10$ min, the rate will be $\left(\frac{1}{2}\right)^{10}$ multiplied by the initial rate:

$$r_{10} = \left(\tfrac{1}{2}\right)^{10} r_0 = \tfrac{1}{1024}(2000\ \text{counts/s}) = 1.95\ \text{counts/s} \approx \boxed{2.0\ \text{counts/s at 10 min}}$$

CHECK As expected, the counting rate decreases as the number of minutes increases.

CONCEPT CHECK 40-1

A radioactive isotope has a half-life of 10 s. You are observing a sample of this isotope. After approximately one minute of observation, there is only one atom of this isotope left in your sample. How many atoms of this isotope will be left in your sample 15 s later?

Example 40-3 Detection-Efficiency Considerations

If the detection efficiency in Example 40-2 is 20 percent, (*a*) how many radioactive nuclei are there at time $t = 0$ and (*b*) at time $t = 1.0$ min? (c) How many nuclei decay in the first minute?

PICTURE The detection efficiency depends on the probability that a radioactive decay particle will enter the detector and the probability that upon entering the detector it will produce a count. If the efficiency is 20 percent, the decay rate must be five times the counting rate.

SOLVE

(*a*) 1. The number of radioactive nuclei is related to the decay rate R and the decay constant λ:

$$R = \lambda N$$

2. The decay constant is related to the half-life:

$$\lambda = \frac{\ln 2.0}{t_{1/2}} = \frac{0.693}{1.0\text{ min}} = 0.693\text{ min}^{-1}$$

3. Because the detection efficiency is 20 percent, the decay rate is five times the counting rate. Calculate the initial decay rate:

$$R_0 = (5\text{ decays/count}) \times (2000\text{ counts/s})$$
$$= 1.0 \times 10^4\text{ decays/s}$$

4. Substitute to calculate the initial number of radioactive nuclei N_0 at $t = 0$:

$$N_0 = \frac{R_0}{\lambda} = \frac{1.0 \times 10^4\text{ s}^{-1}}{0.693\text{ min}^{-1}} \times \frac{60\text{ s}}{1\text{ min}}$$
$$= 8.66 \times 10^5 = \boxed{8.7 \times 10^5}$$

(*b*) At time $t = 1\text{ min} = t_{1/2}$, there are half as many radioactive nuclei as at $t = 0$:

$$N_1 = \tfrac{1}{2}(8.66 \times 10^5) = 4.33 \times 10^5$$
$$= \boxed{4.3 \times 10^5}$$

(*c*) The number of nuclei that decay in the first minute is $N_0 - N_1$:

$$\Delta N = N_0 - N_1$$
$$= 8.66 \times 10^5 - 4.33 \times 10^5$$
$$= \boxed{4.3 \times 10^5}$$

CHECK The results for Parts (*b*) and (*c*) are equal, as expected. At the end of one half-life, half of the nuclei have decayed and the other half remain.

The SI unit of radioactive decay is the **becquerel** (Bq), which is defined as one decay per second:

$$1\text{ Bq} = 1\text{ decay/s} \qquad 40\text{-}13$$

A historical unit that applies to all types of radioactivity is the **curie** (Ci), which is defined as

$$1\text{ Ci} = 3.7 \times 10^{10}\text{ decays/s} = 3.7 \times 10^{10}\text{ Bq} \qquad 40\text{-}14$$

The curie is the rate at which radiation is emitted by 1 g of radium. Because this is a very large unit, the millicurie (mCi) or microcurie (μCi) are often used.

BETA DECAY

Beta decay occurs in nuclei that have too many neutrons or too few neutrons for stability. During β decay, A remains the same while Z either increases by 1 (β^- decay) or decreases by 1 (β^+ decay).

An example of β decay is the decay of a free neutron into a proton and an electron. (The half-life of a free neutron is about 10.8 min.) The energy of β decay is 0.782 MeV, which is the difference between the rest energy of the neutron and the rest energy of the proton and an electron. More generally, during β^- decay, a nucleus of mass number A and atomic number Z decays into a nucleus, referred to as the **daughter nucleus,** of mass number A and atomic number $Z' = Z + 1$ and an electron is emitted. (The original nucleus is called the **parent.**) If the decay energy were shared by only the daughter nucleus and the emitted electron, the energy of the electron would be uniquely determined by the conservation of energy and momentum. Experiments show, however, the energies of the electrons emitted during the β^- decay of a nucleus are observed to vary from zero to the maximum energy available. A typical energy spectrum for the electrons is shown in Figure 40-5.

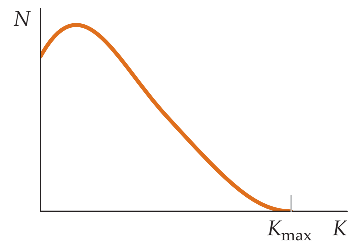

FIGURE 40-5 Number of electrons emitted during β^- decay versus kinetic energy. The fact that all the electrons do not have the same energy K_{max} suggests that another particle, one that shares the energy available for decay, is emitted.

To explain the fact that energy seemed not to be conserved during β decay, Wolfgang Pauli in 1930 suggested that a third particle, which he called the **neutrino,** is also emitted. Because the measured maximum energy of the emitted electrons is equal to the total available for the decay, the rest energy and therefore the mass of the neutrino was assumed to be zero. (It is now known that the mass of the neutrino is very small but not zero.) In 1948, measurements of the momenta of the emitted electron and the recoiling nucleus showed that the neutrino was also needed for the conservation of linear momentum during β decay. The neutrino was first observed experimentally in 1957. It is now known that there are at least three kinds of neutrinos, one (ν_e) associated with electrons, one (ν_μ) associated with muons, and one (ν_τ) associated with the tau particle, τ. Moreover, each neutrino has an antiparticle, written $\bar{\nu}_e$, $\bar{\nu}_\mu$, and $\bar{\nu}_\tau$. It is the electron antineutrino that is emitted during the decay of a neutron, which is written*

$$\mathrm{n} \rightarrow \mathrm{p} + \mathrm{e}^- + \bar{\nu}_e \qquad \text{40-15}$$

During β^+ decay, a proton changes into a neutron, and a positron (and a neutrino) is emitted. A free proton cannot decay by positron emission because of conservation of energy (the mass of the neutron and the positron is greater than the mass of the proton); however, because of binding-energy effects, a proton inside a nucleus can decay. A typical β^+ decay is

$$^{13}_{7}\mathrm{N} \rightarrow {}^{13}_{6}\mathrm{C} + \mathrm{e}^+ + \nu_e \qquad \text{40-16}$$

! Do not confuse the symbols e^- and e^+ with the symbol e. The symbols e^- and e^+ denote particles (the electron and the positron), whereas the symbol e denotes an amount of charge.

The electrons or the positrons emitted during β decay do not exist inside the nucleus. They are created during the process of decay, just as photons are created when an atom makes a transition from a higher energy state to a lower energy state.

An important example of β decay is that of ^{14}C, which is used in radioactive carbon dating:

$$^{14}\mathrm{C} \rightarrow {}^{14}\mathrm{N} + \mathrm{e}^- + \bar{\nu}_e \qquad \text{40-17}$$

The half-life for this decay is 5730 y. The radioactive isotope ^{14}C is produced in the upper atmosphere during nuclear reactions caused by cosmic rays. The chemical reactivity of a carbon atom that has a ^{14}C nucleus is the same as the chemical reactivity of a carbon atom that has a ^{12}C nucleus. For example, atoms that have these nuclei combine with oxygen to form CO_2 molecules. Because living organisms continually exchange CO_2 with the atmosphere, the ratio of ^{14}C to ^{12}C in a living organism is the same as the equilibrium ratio in the atmosphere, which is about 1.3×10^{-12}. After an organism dies, it no longer absorbs ^{14}C from the atmosphere, so the ratio of ^{14}C to ^{12}C continually decreases due to the radioactive decay of ^{14}C. The number of ^{14}C decays per minute per gram of carbon in a living organism can be calculated from the known half-life of ^{14}C and the number of ^{14}C nuclei in a gram of carbon. The result is that there are approximately 15.0 decays per minute per gram of carbon in a living organism. Using this result and the measured number of decays per minute per gram of carbon in a nonliving sample of bone, wood, or other object having carbon, we can determine the age of the sample. For example, if the measured rate were 7.5 decays per minute per gram, the age of the sample would be one half-life = 5730 years.

* This reaction is also written $\mathrm{n} \rightarrow \mathrm{p} + \beta^- + \bar{\nu}_e$.

Example 40-4 How Old Is the Artifact? *Context-Rich*

You have a summer job working in an archeological research lab. Your supervisor calls to tell you that they found a new bone at their current site and asks you to determine the age of the bone from a sample that she will send you. When the bone sample arrives, you take a section that contains 200 grams of carbon and you find a beta decay rate of 400 decays/min.

PICTURE There are approximately 15.0 decays per minute per gram of carbon in a living organism, and the half-life of carbon-14 is 5730 y. We need to determine the number of half-lives that have occurred since the death of the organism. We do this by using the equality $R_n = (1/2)^n R_0$ (Equation 40-12), where R_n is the current decay rate, R_0 is the initial decay rate, and n is the number of half-lives. We can determine the initial decay rate by multiplying the decay rate per gram by the mass of the carbon of the sample.

SOLVE

1. Write the decay rate after n half-lives in terms of the initial decay rate:
$$R_n = \left(\tfrac{1}{2}\right)^n R_0$$

2. Calculate the initial decay rate (the decay for 200 g of carbon when the organism died):
$$R_0 = [(15\ \text{decays/min})/\text{g}](200\ \text{g}) = 3000\ \text{decays/min}$$

3. Substitute the values for R_0 and R_n into the step-1 equation and solve for n:
$$R_n = \left(\tfrac{1}{2}\right)^n R_0$$
$$400\ \text{decays/min} = \left(\tfrac{1}{2}\right)^n 3000\ \text{decays/min}$$
$$\left(\tfrac{1}{2}\right)^n = \frac{400}{3000}$$
$$2^n = \frac{3000}{400} = 7.5$$

4. We solve for n by taking the logarithm of each side:
$$n \ln 2 = \ln 7.5 \quad \Rightarrow \quad n = \frac{\ln 7.5}{\ln 2} = 2.91$$

5. The age of the bone is $nt_{1/2}$:
$$t = nt_{1/2} = 2.91(5730\ \text{y}) = \boxed{1.67 \times 10^4\ \text{y}}$$

CHECK If the bone were from a recently living organism, we would expect the decay rate to be a steady $[(15\ \text{decays/min})/\text{g}](200\ \text{g}) = 3000$ decays/min. The current decay rate is given as 400 decays/min. Because 400/3000 is roughly 1/8 (actually 1/7.5), the sample must be approximately three half-lives old, which is about 3(5730 y). This is in agreement with the step-5 result of 2.91(5730 y).

PRACTICE PROBLEM 40-2 The Check of Example 40-4 states, "Because 400/3000 is roughly 1/8 (actually 1/7.5), the sample must be approximately three half-lives old . . . ." Explain why this ratio of 1/8 implies an age equal to three half-lives.

GAMMA DECAY

During γ decay, a nucleus in an excited state decays to a lower-energy state by the emission of a photon. This process is the nuclear counterpart of spontaneous emission of photons by atoms and molecules. Unlike β decay or α decay, neither the mass number A nor the atomic number Z change during γ decay. Because the spacing of the nuclear energy levels is of the order of 1 MeV (as compared with spacing of the order of 1 eV in atoms), the wavelengths of the emitted photons are of the order of 1 pm (1 pm $= 10^{-12}$ m):

$$\lambda = \frac{hc}{E} \approx \frac{1240\ \text{eV}\cdot\text{nm}}{1\ \text{MeV}} = 0.00124\ \text{nm} = 1.24\ \text{pm}$$

The mean lifetime for γ decay is often very short. It is usually observed only because it follows either α decay or β decay. For example, if a radioactive parent nucleus decays by β decay to an excited state of the daughter nucleus, the daughter nucleus then decays to its ground state by γ emission. Direct measurements of mean lifetimes as short as approximately 10^{-11} s are possible. Measurements of mean lifetimes shorter than 10^{-11} s are difficult, but they can sometimes be made by indirect methods.

A few γ emitters have very long lifetimes, of the order of hours. The energy states that do have such long lifetimes are called **metastable states.**

ALPHA DECAY

All very heavy nuclei ($Z > 83$) are potentially unstable via α decay because the mass of the original radioactive nucleus is greater than the sum of the masses of the decay products—an α particle and the daughter nucleus. Consider the decay of ^{232}Th ($Z = 90$) into ^{228}Ra ($Z = 88$) and an α particle. This process is written as

$$^{232}\mathrm{Th} \rightarrow {}^{228}\mathrm{Ra} + \alpha = {}^{228}\mathrm{Ra} + {}^{4}\mathrm{He} \qquad 40\text{-}18$$

The mass of the ^{232}Th atom is 232.038 050 u. The mass of the daughter atom ^{228}Ra is 228.031 064 u. Adding 4.002 603 u (the mass of ^{4}He) to the mass of ^{228}Ra, we get 232.033 667 u for the total mass of the decay products. This value is less than the mass of ^{232}Th by 0.004 383 u, which multiplied by 931.5 MeV/c^2 gives 4.08 MeV/c^2 for the excess mass of ^{232}Th when compared to the total mass of the decay products. The isotope ^{232}Th is therefore potentially unstable to α decay. This decay does in fact occur in nature with the emission of an α particle of kinetic energy 4.08 MeV. (The kinetic energy of the α particle is actually somewhat less than 4.08 MeV because some of the released energy is taken up by the recoiling ^{228}Ra nucleus.)

When a nucleus emits an α particle, both N and Z decrease by 2 and A decreases by 4. The daughter of a radioactive nucleus is often itself radioactive and decays by either α decay or β decay or both. If the original nucleus has a mass number A that is 4 times an integer, the daughter nucleus and all those in the decay chain will also have mass numbers equal to 4 multiplied by an integer. Similarly, if the mass number of the original nucleus is $4n + 1$, where n is an integer, all the nuclei in the decay chain will have mass numbers given by $4n + 1$, where n decreases by one at each α decay. We can see, therefore, that there are four possible α-decay chains, depending on whether A equals $4n$, $4n + 1$, $4n + 2$, or $4n + 3$, where n is an integer. All but one of these decay chains are found on Earth. The $4n + 1$ series is not found because its longest-lived member (other than the stable end product ^{209}Bi) is ^{237}Np, which has a half-life of only 2×10^{6} y. Because this period is much less than the age of Earth, this series has disappeared.

Figure 40-6 shows the thorium series, for which $A = 4n$. It begins with an α decay from ^{232}Th to ^{228}Ra. The daughter nuclide of an α decay is on the left or neutron-rich side of the stability curve (the dashed line in the figure), so it often decays by β^- decay. In the thorium series, ^{228}Ra decays by β^- decay to ^{228}Ac, which in turn decays by β^- decay to ^{228}Th. There are then four α decays to ^{212}Pb, which decays by β^- decay to ^{212}Bi. The series branches at ^{212}Bi, which decays either by α decay to ^{208}Tl or by β^- decay to ^{212}Po. The branches meet at the stable lead isotope ^{208}Pb.

The energies of α particles from natural radioactive sources range from approximately 4 MeV to 7 MeV, and the half-lives of the sources range from approximately 10^{-5} s to 10^{10} y. In general, the smaller the energy of the emitted α particle, the longer the half-life. As we discussed in Section 35-4, the enormous variation

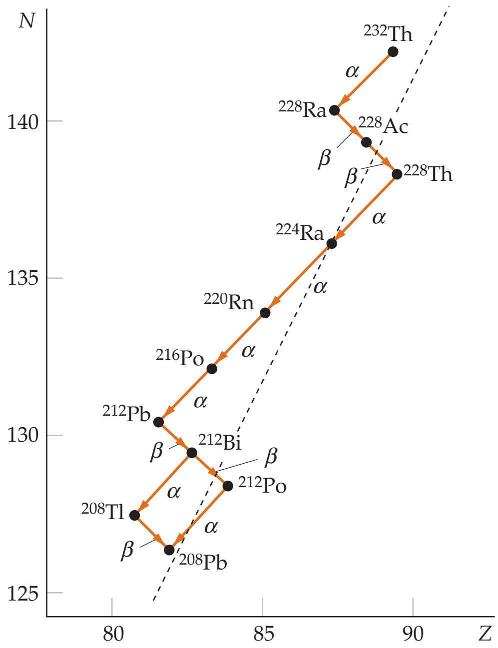

FIGURE 40-6 The thorium ($4n$) α decay series. The dashed line is the curve of stability.

in half-lives was explained by George Gamow in 1928. He considered α decay to be a process in which an α particle is first formed inside a nucleus and then tunnels through the Coulomb barrier (Figure 40-7). A slight increase in the energy of the α particle reduces the relative height $U_{max} - E$ of the barrier and also the thickness $r_1 - R$. Because the probability of penetration is so sensitive to the relative height and thickness of the barrier, a small increase in E leads to a large increase in the probability of barrier penetration and therefore to a significantly shorter lifetime. Gamow was able to derive an expression for the half-life as a function of E that is in excellent agreement with experimental results.

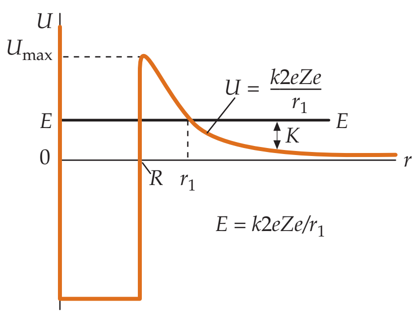

FIGURE 40-7 A model of the potential energy for an α particle and a nucleus. The strong attractive nuclear force that exists for values of r less than the nuclear radius R is indicated by the potential well. Outside the nucleus, the nuclear force is negligible, and the potential energy is given by the Coulomb potential energy function $U = +k2eZe/r$, where Ze is the nuclear charge and $2e$ is the charge of the α particle. The kinetic energy K of the α particle is equal to the energy E when the α particle is far away from the nucleus. A small increase in E reduces the relative height $U_{max} - E$ of the barrier and also reduces its thickness $r_1 - R$, leading to a much greater probability of penetration. An increase in the energy of the emitted α particles by a factor of 2 results in a reduction of the half-life by a factor of more than 10^{20}.

40-3 NUCLEAR REACTIONS

Information about nuclei is typically obtained by bombarding the nuclei with various particles and observing the results. Although the first experiments of this type were limited by the need to use naturally occurring radiation, they produced many important discoveries. In 1932, J. D. Cockcroft and E. T. S. Walton succeeded in producing the reaction

$$p + {}^{7}\text{Li} \rightarrow {}^{8}\text{Be} \rightarrow {}^{4}\text{He} + {}^{4}\text{He}$$

using artificially accelerated protons. At about the same time, the Van de Graaff electrostatic generator (by R. Van de Graaff in 1931) and the first cyclotron (by E. O. Lawrence and M. S. Livingston in 1932) were built. Since then, enormous advances in the technology for accelerating and detecting particles have been made, and many nuclear reactions have been studied.

When a particle is incident on a nucleus, several different things can happen. The incident particle may be scattered, either elastically or inelastically, or the incident particle may be absorbed by the nucleus, and another particle or particles may be emitted. In inelastic scattering, the nucleus is left in an excited state and subsequently decays by emitting photons (or other particles).

The amount of energy released or absorbed during a reaction (in the center of mass reference frame) is called the ***Q* value** of the reaction. The Q value equals c^2 multiplied by the mass difference. When energy is released during a reaction, the reaction is said to be an **exothermic reaction.** During an exothermic reaction, the total mass of the incoming particles is greater than the total mass of the outgoing particles, and the Q value is positive. If the total mass of the incoming particles is less than that of the outgoing particles, energy is required for the reaction to take place, and the reaction is said to be an **endothermic reaction.** The Q value of an endothermic reaction is negative. In general, if Δm is the change in mass, the Q value is

$$Q = -(\Delta m)c^2 \qquad \text{40-19}$$

Q VALUE

An endothermic reaction cannot take place below a specific threshold energy. In the laboratory reference frame in which stationary particles are bombarded by incoming particles, the threshold energy is somewhat greater than $|Q|$ because the outgoing particles must have some kinetic energy to conserve momentum.

A measure of the effective size of a nucleus for a particular nuclear reaction is the **cross section** σ. If I is the number of the incident particles per unit time per unit area (the incident intensity) and R is the number of reactions per unit time per nucleus, the cross section is

$$\sigma = \frac{R}{I} \qquad \text{40-20}$$

The cross section σ has the dimensions of area. Because nuclear cross sections are of the order of the square of the nuclear radius, a convenient unit for them is the **barn,** which is defined as

$$1\ \text{barn} = 10^{-28}\ \text{m}^2 \qquad \text{40-21}$$

The cross section for a particular reaction is a function of energy. For an endothermic reaction, it is zero for energies below the threshold energy.

Example 40-5 Exothermic or Endothermic?

Find the Q value of the reaction $p + {}^{7}\text{Li} \rightarrow {}^{4}\text{He} + {}^{4}\text{He}$ and state whether the reaction is exothermic or endothermic.

PICTURE We find the masses of the atoms from Table 40-1 and calculate the difference in the total mass of the outgoing particles and the incoming particles. The Q value is related to the change in mass Δm by $Q = -(\Delta m)c^2$. If we use the mass of protium rather than the mass of the proton, there will be four electrons on each side of the reaction, so the electron masses will cancel.

SOLVE

1. Find the mass of each atom from Table 40-1:
   ^{1}H 1.007 825 u
   ^{7}Li 7.016 004 u
   ^{4}He 4.002 603 u

2. Calculate the initial mass m_i of the incoming particles:
   $m_i = 1.007\,825\text{ u} + 7.016\,004\text{ u} = 8.023\,829\text{ u}$

3. Calculate the final mass m_f:
   $m_f = 2(4.002\,603\text{ u}) = 8.005\,206\text{ u}$

4. Calculate the change in mass:
   $\Delta m = m_f - m_i = 8.005\,206\text{ u} - 8.023\,829\text{ u}$
   $= -0.018\,623\text{ u}$

5. Calculate the Q value:
   $$Q = -(\Delta m)c^2 = (+0.018\,623\text{ u})c^2 \times \frac{931.5\text{ MeV}}{1\text{ u}}$$
   $$= \boxed{17.35\text{ MeV}}$$
   $\boxed{Q\text{ is positive, so the reaction is exothermic.}}$

CHECK Because the initial mass is greater than the final mass, the initial energy is greater than the final energy and the reaction is exothermic, yielding 17.35 MeV.

REACTIONS WITH NEUTRONS

Nuclear reactions that involve neutrons are important for understanding nuclear reactors. The most likely reaction between a nucleus and a neutron that has an energy of more than about 1 MeV is scattering. However, even if the scattering is elastic, the neutron loses some energy to the nucleus because the nucleus recoils. If a neutron is scattered many times in a material, its energy decreases until the neutron is of the order of the energy of thermal motion kT, where k is Boltzmann's constant and T is the absolute temperature. (At ordinary room temperatures, kT is approximately 0.025 eV.) The neutron is then equally likely to gain or lose energy from a nucleus when it is elastically scattered. A neutron that has an energy of the order of kT is called a **thermal neutron.**

At low energies, a neutron is likely to be captured, producing an excited nucleus. A γ ray is then emitted from the excited nucleus. Figure 40-8 shows the neutron-capture cross section for silver as a function of the energy of the neutron. The large

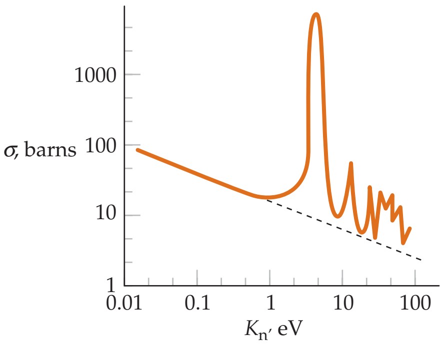

FIGURE 40-8 Neutron-capture cross section for silver as a function of the energy of the incident neutron. The straight line indicates the $1/v$ dependence of the cross section, which is proportional to the time spent by the neutron in the vicinity of the silver nucleus. Superimposed on this dependence are a large resonance and several smaller resonances.

peak in this curve is called a **resonance.** Except for the resonance, the cross section varies fairly smoothly with energy, decreasing with increasing energy roughly as $1/v$, where v is the speed of the neutron. We can understand this energy dependence as follows: Consider a neutron moving with speed v near a nucleus of diameter $2R$. The time it takes the neutron to pass the nucleus is $2R/v$. Thus, the neutron-capture cross section is proportional to the time spent by the neutron in the vicinity of the silver nucleus. The dashed line in Figure 40-8 indicates this $1/v$ dependence. At the maximum of the resonance, the value of the cross section is very large ($\sigma > 5000$ barns) compared with a value of only about 10 barns just past the resonance. Many elements show similar resonances in their neutron-capture cross sections. For example, the maximum cross section for ^{113}Cd is approximately 57 000 barns. This material is thus very useful for shielding against low-energy neutrons.

An important nuclear reaction that involves neutrons is fission, which is discussed in the next section.

40-4 FISSION AND FUSION

Figure 40-9 shows a plot of the nuclear mass difference per nucleon $(M - Zm_\mathrm{p} - Nm_\mathrm{n})/A$ in units of MeV/c^2 versus A. This curve is just the negative of the binding-energy curve shown in Figure 40-3. From Figure 40-9, we can see that the values for the mass difference per nucleon for both very heavy ($A \approx 200$) and very light ($A \leq 20$) nuclides are greater than the values for nuclides of intermediate mass. Thus, energy is released when a very heavy nucleus, such as ^{235}U, breaks up into two lighter nuclei—during a process called **fission**—or when two very light nuclei, such as ^{2}H and ^{3}H, fuse together to form a nucleus of greater mass—during a process called **fusion.**

The applications of both fission and fusion to the generation of electrical power and the development of nuclear weapons have had a profound effect on our lives since the early twentieth century. The application of these reactions to the development of energy resources may have an even greater effect in the future. We will look at some of the features of fission and fusion that are important for their application in reactors to generate power.

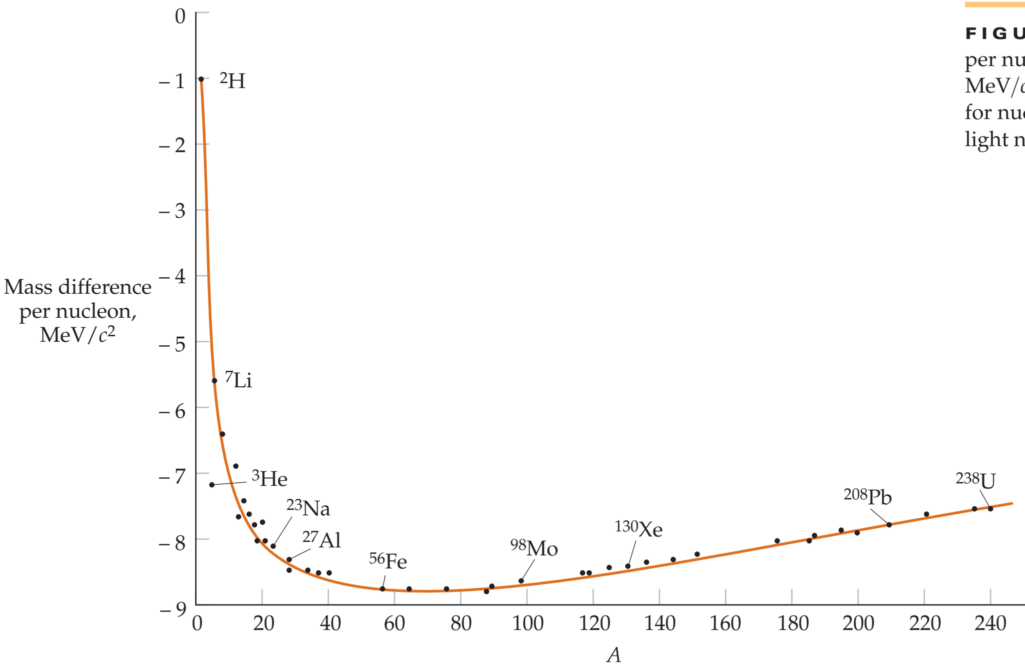

FIGURE 40-9 Plot of mass difference per nucleon $(M - Zm_\mathrm{p} - Nm_\mathrm{n})/A$ in units of MeV/c^2 versus A. The mass per nucleon is less for nuclei of intermediate mass than for very light nuclei or very heavy nuclei.

Hidden layers in paintings are analyzed by bombarding the painting with neutrons and observing the radiative emissions from nuclei that have captured a neutron. Different elements used in the painting have different half-lives. (*a*) Van Dyck's painting *Saint Rosalie Interceding for the Plague-Stricken of Palermo*. The black-and-white images in (*b*) and (*c*) were formed using a special film sensitive to electrons emitted by the radioactively decaying elements. Image (*b*), taken a few hours after the neutron irradiation, reveals the presence of manganese, found in umber, which is a dark earth pigment used for the painting's base layer. (Blank areas show where modern repairs, free of manganese, have been made.) The image in (*c*) was taken 4 days later, after the umber emissions had died away and when phosphorus, found in charcoal and boneblack, was the main radiating element. Upside down is revealed a sketch of Van Dyck himself. The self-portrait, executed in charcoal, had been overpainted by the artist. *((a) © 1991 by the Metropolitan Museum of Art. (b) and (c) Courtesy of Paintings Conservation Department, Metropolitan Museum of Art.)*

FISSION

Very heavy nuclei ($Z > 92$) are subject to spontaneous fission. They break apart into two nuclei even if the nuclei are not disturbed. We can understand this by considering the analogy of a charged liquid drop. If the drop is not too large, surface tension can overcome the repulsive forces of the charges and hold the drop together. There is, however, a certain maximum size beyond which the drop will be unstable and will spontaneously break apart. Because of spontaneous fission, an upper limit exists on the size of a nucleus and therefore on the number of elements that are possible.

Some heavy nuclei—uranium and plutonium, in particular—can be induced to fission by the capture of neutrons. During the fission of ^{235}U, for example, the uranium nucleus is excited by the capture of a neutron, causing it to split into two nuclei and emit several neutrons. The Coulomb force of repulsion drives the fission fragments apart, with the released energy eventually appearing as thermal energy. Consider, for example, the fission of a nucleus of mass number $A = 200$ into two nuclei of mass number $A = 100$. Because the rest energy for $A = 200$ is about 1 MeV per nucleon greater than that for $A = 100$, approximately 200 MeV per nucleus is released during such a fission. This is a large amount of energy. By contrast, during the chemical reaction of combustion, only about 4 eV of energy is released per molecule of oxygen consumed.

Example 40-6 Energy Released During the Fission of ^{235}U

Calculate the total energy (in kilowatt-hours) released during the fission of 1.00 g of ^{235}U, assuming that 200 MeV is released per fission.

PICTURE We need to find the number of uranium nuclei in one gram of ^{235}U, which we find using the fact that there are Avogadro's number ($N_A = 6.02 \times 10^{23}$) of nuclei in 235 grams.

SOLVE

1. The total energy is the number of nuclei multiplied by the energy per nucleus:

$$E = NE_{\text{nucleus}} = N(200\text{MeV/nucleus})$$

2. Calculate N:

$$N = \frac{6.02 \times 10^{23}\ \text{nuclei/mol}}{235\ \text{g/mol}} \times 1.00\ \text{g} = 2.56 \times 10^{21}\ \text{nuclei}$$

3. Calculate the energy per gram in eV and convert to kW·h:

$$E = \frac{200 \times 10^{6}\ \text{eV}}{1\ \text{nucleus}} \times 2.56 \times 10^{21}\ \text{nuclei}$$
$$= 5.12 \times 10^{29}\ \text{eV} = 8.19 \times 10^{10}\ \text{J}$$
$$= 8.19 \times 10^{7}\ \text{kW}\cdot\text{s} = \boxed{2.28 \times 10^{4}\ \text{kW}\cdot\text{h}}$$

The fission of uranium was discovered in 1938 by Otto Hahn and Fritz Strassmann, who found that medium-mass elements (for example, barium and lanthanum) were produced in the bombardment of uranium with neutrons. The discovery that several neutrons were emitted during the fission process led to speculation concerning the possibility of using those neutrons to cause further

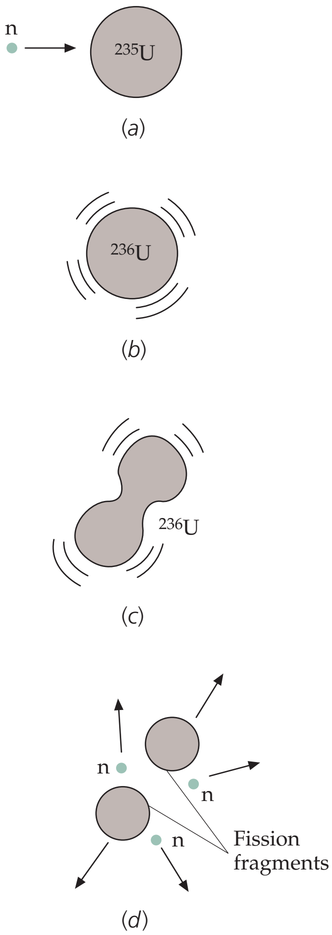

FIGURE 40-10 Schematic illustration of nuclear fission. (*a*) The absorption of a neutron by ^{235}U leads to (*b*) ^{236}U in an excited state. (*c*) The oscillation of ^{236}U has become unstable. (*d*) The nucleus splits apart into two nuclei that are less massive than the original nucleus and emits several neutrons that can produce fission in other nuclei.

fissions, thereby producing a chain reaction. When ^{235}U captures a neutron, the resulting ^{236}U nucleus emits γ rays as it de-excites to the ground state approximately 15 percent of the time and undergoes fission approximately 85 percent of the time. The fission process is somewhat analogous to the oscillation of a liquid drop, as shown in Figure 40-10. If the oscillations are violent enough, the drop splits in two. Using the liquid-drop model, Niels Bohr and John Wheeler calculated the critical energy E_c needed by the ^{236}U nucleus to undergo fission. (^{236}U is the nucleus formed momentarily by the capture of a neutron by ^{235}U.) For this nucleus, the critical energy is 5.3 MeV, which is less than the 6.4 MeV of excitation energy produced when ^{235}U captures a neutron. The capture of a neutron by ^{235}U therefore produces an excited state of the ^{236}U nucleus that has more than enough energy to break apart. On the other hand, the critical energy for fission of the ^{239}U nucleus is 5.9 MeV. The capture of a neutron by a ^{238}U nucleus produces an excitation energy of only 5.2 MeV. Therefore, when a neutron is captured by ^{238}U to form ^{239}U, the excitation energy is not great enough for fission to occur. In this case, the excited ^{239}U nucleus de-excites by γ emission and then decays to ^{239}Np by β decay, and then again to ^{239}Pu by β decay.

A fissioning nucleus can split into a pair of medium-mass nuclei, as shown in Figure 40-11. Depending on the particular reaction, 1, 2, or 3 neutrons may be emitted. The average number of neutrons emitted in the fission of ^{235}U is approximately 2.5. A typical fission reaction is

$$n + {}^{235}U \rightarrow {}^{141}Ba + {}^{92}Kr + 3n$$

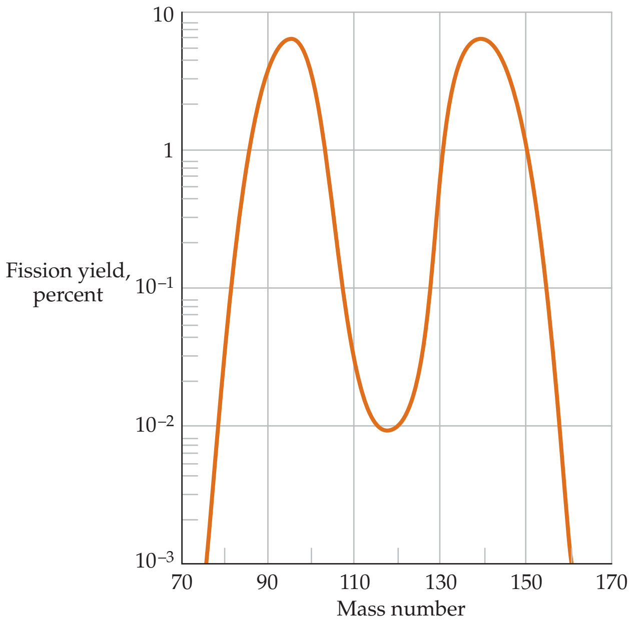

FIGURE 40-11 Distribution of the possible fission fragments of ^{235}U. The splitting of ^{235}U into two fragments of unequal mass is more likely than its splitting into fragments of equal mass.

NUCLEAR FISSION REACTORS

To sustain a chain reaction in a fission reactor, one of the neutrons (on average) that is emitted during and following* the fission of ^{235}U must be captured by another ^{235}U nucleus and cause it to fission. The **reproduction constant** k of a reactor is defined as the average number of neutrons from each fission that cause a subsequent fission. The maximum possible value of k for a uranium reactor is 2.5, but it is normally less than this for two important reasons: (1) Some of the neutrons may escape from the region containing fissionable nuclei and (2) some of the neutrons may be captured by nonfissioning nuclei in the reactor. If k is exactly 1, the reaction will be self-sustaining. If k is less than 1, the reaction will die out. If k is significantly greater than 1, the reaction rate will increase rapidly and become uncontrollable. In the design of nuclear bombs, such a runaway reaction is desired. In power reactors, the value of k must be kept very nearly equal to 1.

Because the neutrons emitted during and following fission have energies of the order of 1 MeV, whereas the chance for neutron capture leading to fission in ^{235}U is largest at small energies, the chain reaction can be sustained only if the neutrons are slowed down before they escape from the reactor. At high energies (1 MeV to 2 MeV), neutrons lose energy rapidly by inelastic scattering from ^{238}U, the principal constituent of natural uranium. (Natural uranium contains 99.3 percent ^{238}U and only 0.7 percent fissionable ^{235}U.) Once the neutron energy is below the excitation energies of the nuclei in the reactor (about 1 MeV), the main process of energy loss is by elastic scattering, in which a fast neutron collides with a nucleus at rest and transfers some of its kinetic energy to that nucleus. Such energy transfers are efficient only if the masses of the two bodies are comparable. A neutron will not transfer much energy in an elastic collision with a heavy uranium nucleus. Such a collision is like one between a marble and a billiard ball. The marble will be deflected by the much more massive billiard ball, and very little of its kinetic energy will be transferred to the billiard ball. A **moderator** consisting of material, such as water or carbon, that has light nuclei is therefore placed around the fissionable material in the core of the reactor to slow down the neutrons.

* Neutrons are sometimes emitted by the fission products. These neutrons are typically emitted a few seconds following the fission.

The inside of a nuclear power plant in Kent, England. A technician is standing on the reactor charge transfer plate, into which uranium fuel rods fit. *(© Jerry Mason/ Photo Researchers.)*

The neutrons are slowed down by elastic collisions with the nuclei of the moderator until they are in thermal equilibrium with the moderator. Because of the relatively large neutron-capture cross section of the hydrogen nucleus in water, reactors that use ordinary water as a moderator cannot easily achieve $k \approx 1$ unless they use enriched uranium, in which the ^{235}U content has been increased from 0.7 percent to between 1 percent and 4 percent. Natural uranium can be used if heavy water (D_2O) is used instead of ordinary (light) water (H_2O) as the moderator. Although heavy water is expensive, most Canadian reactors use heavy water for a moderator to avoid the cost of constructing uranium-enrichment facilities.

Figure 40-12 shows some of the features of a pressurized-water reactor commonly used in the United States to generate electricity. Fission in the core heats the water to a high temperature in the primary loop, which is closed. This water, which also serves as the moderator, is under high pressure to prevent the water from boiling.

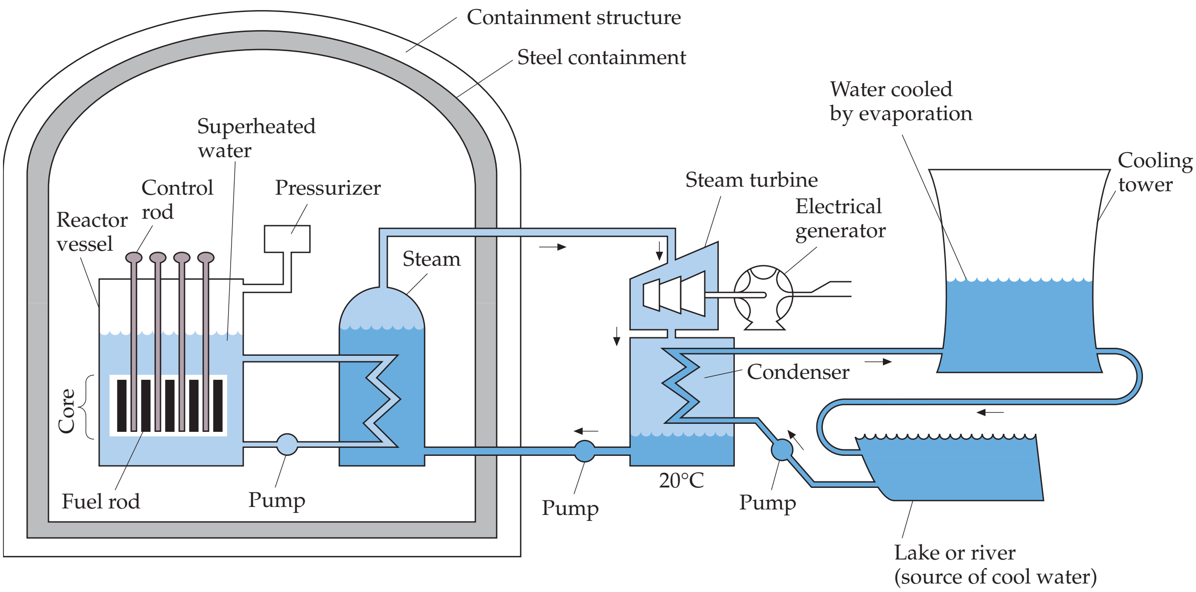

FIGURE 40-12 Simplified drawing of a pressurized-water reactor. The water in contact with the reactor core serves as both the moderator and the heat-transfer material. It is isolated from the water used to produce the steam that drives the turbines. Many features, such as the backup cooling mechanisms, are not shown here.

The hot water is pumped to a heat exchanger, where it heats the water in the secondary loop and converts the water to steam, which is then used to drive the turbines that produce electrical power. Note that the water in the secondary loop is isolated from the water in the primary loop to prevent its contamination by the radioactive nuclei in the reactor core.

The ability to control the reproduction factor k precisely is important if a power reactor is to be operated safely. Both natural negative-feedback mechanisms and mechanical methods of control are used. If k is greater than 1, the reaction rate increases and the temperature of the reactor increases. If water is used as a moderator, its density decreases with increasing temperature and the water becomes a less effective moderator. A second important control method is the use of control rods made of a material, such as cadmium, that has a very large neutron-capture cross section. To decrease the reaction rate, the control rods are inserted so that more neutrons are captured by the rods and k becomes less than 1. To increase the reaction rate, the rods are gradually withdrawn from the reactor; fewer neutrons are captured by the control rods and k becomes greater than 1.

Mechanical control of the reaction rate of a nuclear reactor using control rods is possible only because some of the neutrons emitted during the fission process are **delayed neutrons.** The time needed for a neutron to slow down from 1 MeV or 2 MeV to the thermal-energy level and then be captured is only of the order of a millisecond. If all the neutrons emitted during fission were prompt neutrons, that is, emitted immediately during the fission process, mechanical control would not be possible because the reactor would run away before the rods could be inserted farther. However, approximately 0.65 percent of the neutrons emitted are delayed by an average time of about 14 s. Those neutrons are emitted not during the fission process itself but during the decay of the fission fragments. The effect of the delayed neutrons can be seen in the following examples.

Example 40-7 Doubling Time

If the average time between fission generations (the time it takes for a neutron emitted during one fission to cause another) is $t_1 = 1\text{ ms} = 0.001\text{ s}$ and if the average number of neutrons from each fission that cause a subsequent fission is 1.001, how long will it take for the reaction rate to double?

PICTURE The reaction rate is the number of nuclei that fission per unit time. The time to double the reaction rate is the product of the number of generations N needed to double the reaction rate and the generation time. If $k = 1.001$, the reaction rate after N generations is 1.001^N. We find the number of generations by setting 1.001^N equal to 2 and solving for N.

SOLVE

1. Set 1.001^N equal to 2 and solve for N:

$$(1.001)^N = 2$$

$$N \ln 1.001 = \ln 2$$

$$N = \frac{\ln 2}{\ln 1.001} = 693$$

2. Multiply the number of generations by the generation time:

$$t = Nt_1 = 693(0.001\text{ s}) = \boxed{0.7\text{ s}}$$

CHECK The step-2 result of 0.7 s is approximately 700 times the average time between generations. This many generations is plausible because the reproduction factor k is so close to 1.

TAKING IT FURTHER The doubling time of about 0.7 s is not enough time for insertion of control rods.

Example 40-8 Delayed Neutrons and Control-Rod Insertion *Try-It-Yourself*

Assuming that 0.65 percent of the neutrons emitted are delayed by 14 s, find the average generation time and the doubling time if $k = 1.001$.

PICTURE The doubling time is Nt_{av}, where t_{av} is the average time between generations. Since 99.35 percent of the generation times are 0.001 s and 0.65 percent are 14 s, the average generation time is $0.9935(0.001\text{ s}) + 0.0065(14\text{ s})$.

SOLVE

Cover the column to the right and try these on your own before looking at the answers.

Steps	Answers
1. Compute the average generation time.	$t_{av} = 0.9935(0.001\text{ s}) + 0.0065(14\text{ s}) = 0.092\text{ s}$
2. Use your result to find the time for 693 generations.	$t = 63.8\text{ s} \approx \boxed{60\text{ s}}$

CHECK The number of delayed neutrons is approximately 0.7 percent of the total number of neutrons, but the generation time of 1 ms is approximately 0.007 percent of 14 s. Thus, an increase in the doubling time by a factor of about 100 is plausible.

TAKING IT FURTHER A doubling time of 60 s is plenty of time for mechanical insertion of control rods.

Because of the limited supply of natural uranium, the small fraction of ^{235}U in natural uranium, and the limited capacity of enrichment facilities, reactors based on the fission of ^{235}U cannot meet our energy needs for very long. A promising alternative is the **breeder reactor.** When the relatively plentiful but nonfissionable ^{238}U nucleus captures a neutron, it decays by β decay (with a half-life of 20 min) to ^{239}Np, which in turn decays by β decay (with a half-life of 2.35 days) to the fissionable nuclide ^{239}Pu. Because ^{239}Pu fissions with fast neutrons, no moderator is needed. A reactor initially fueled with a mixture of ^{238}U and ^{239}Pu will breed as much fuel as it uses or more if one or more of the neutrons emitted in the fission of ^{239}Pu is captured by ^{238}U. Practical studies indicate that a typical breeder reactor can be expected to double its fuel supply in 7 to 10 years.

There are two major safety problems inherent with breeder reactors. The fraction of delayed neutrons is only 0.3 percent for the fission of ^{239}Pu, so the time between generations is much less than that for ordinary reactors. Mechanical control is therefore much more difficult. Also, because the operating temperature of a breeder reactor is relatively high and a moderator is not desired, a heat-transfer material, such as liquid sodium metal, is used rather than water (which is the moderator as well as the heat-transfer material in an ordinary reactor). If the temperature of the reactor increases, the resulting decrease in the density of the heat-transfer material leads to positive feedback, because it will absorb fewer neutrons than before. Because of these safety considerations, breeder reactors are not yet in commercial use in the United States. There are, however, several in operation in France, Great Britain, and the former Soviet Union.

FUSION

During fusion, two light nuclei, such as deuterium (^{2}H) and tritium (^{3}H), fuse together to form a heavier nucleus. A typical fusion reaction is

$$^2\text{H} + {}^3\text{H} \rightarrow {}^4\text{He} + \text{n} + 17.6\text{ MeV}$$

The energy released in fusion depends on the particular reaction. For the $^2H + {}^3H$ reaction, the energy released is 17.6 MeV. Although this energy is less than the energy released during a fission reaction, it is a greater amount of energy per unit mass. The energy released during this fusion reaction is (17.6 MeV)/(5 nucleons) = 3.52 MeV per nucleon. This is approximately 3.5 times as great as the 1 MeV per nucleon released in fission.

The production of power from the fusion of light nuclei holds great promise because of the relative abundance of the fuel and the absence of some of the dangers inherent in fission reactors. Unfortunately, the technology necessary to make fusion a practical source of energy has not yet been developed. We will consider the $^2H + {}^3H$ reaction; other reactions present similar problems.

Because of the Coulomb repulsion between the ^2H and ^3H nuclei, very large kinetic energies, of the order of 1 MeV, are needed to get the nuclei close enough together for the attractive nuclear forces to become effective and to cause fusion. Such energies can be obtained in an accelerator, but because the scattering of one nucleus by the other is much more probable than fusion, the bombardment of one nucleus by another in an accelerator requires the input of more energy than is recovered. To obtain energy from fusion, the particles must be heated to a temperature great enough for the fusion reaction to occur as the result of random thermal collisions. Because a significant number of particles have kinetic energies greater than the mean kinetic energy, $\frac{3}{2}kT$, and because some particles can tunnel through the Coulomb barrier, a temperature T corresponding to $kT \approx 10$ keV is adequate to ensure that a reasonable number of fusion reactions will occur if the density of the particles is sufficiently high. The temperature corresponding to $kT = 10$ keV is of the order of 10^8 K. These temperatures occur in the interiors of stars, where such reactions are common. At these temperatures, a gas consists of positive ions and electrons and is called a **plasma.** One of the problems arising in attempts to produce controlled fusion reactions is the problem of confining the plasma long enough for the reactions to take place. In the interior of the Sun, the plasma is confined by the enormous gravitational field of the Sun. In a laboratory on Earth, confinement is a difficult problem.

The energy required to heat a plasma is proportional to the number density of its ions, n, whereas the collision rate is proportional to n^2 (the square of the number density). If τ is the confinement time, the output energy is proportional to $n^2\tau$. If the output energy is to exceed the input energy, we must have

$$C_1 n^2 \tau > C_2 n$$

where C_1 and C_2 are constants. In 1957, the British physicist J. D. Lawson evaluated these constants from estimates of the efficiencies of various hypothetical fusion reactors and derived the following relation between density and confinement time, known as **Lawson's criterion:**

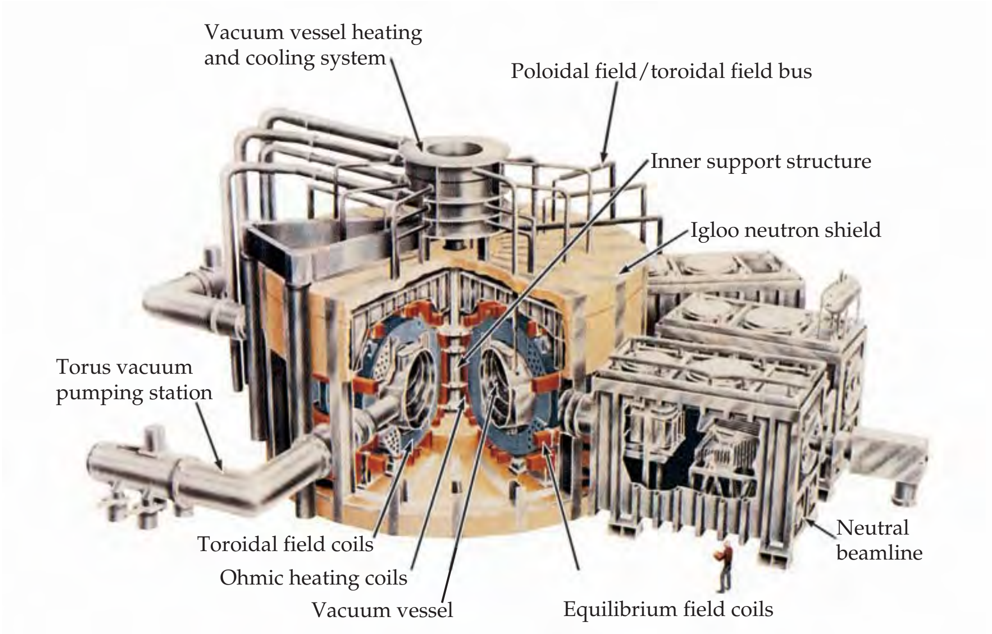
$$n\tau > 10^{20}\ \mathrm{s \cdot particles/m^3} \qquad \text{40-22}$$

LAWSON'S CRITERION

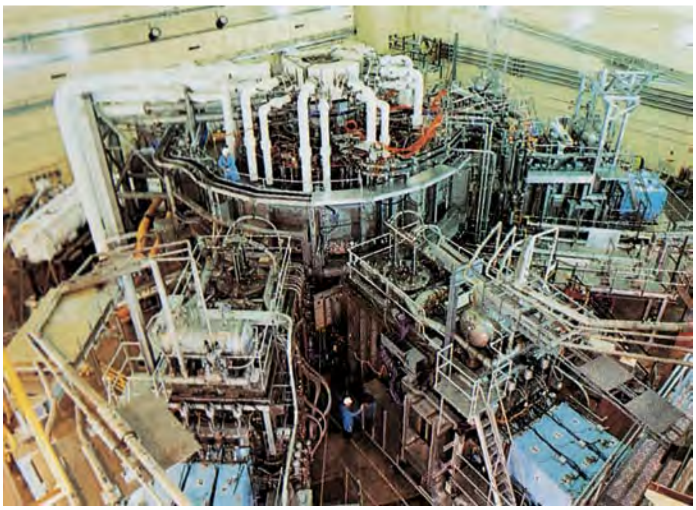
If Lawson's criterion is met and the thermal energy of the ions is great enough ($kT \approx 10$ keV), the energy released by a fusion reactor will just equal the energy input; that is, the reactor will just break even. For the reactor to be practical, much more energy must be released.

Two schemes for achieving Lawson's criterion are currently under investigation. In one scheme, **magnetic confinement,** a magnetic field is used to confine the plasma (see Section 26-2). In the most common arrangement, first developed in the former Soviet Union and called a *tokamak*, the plasma is confined in a large toroid.

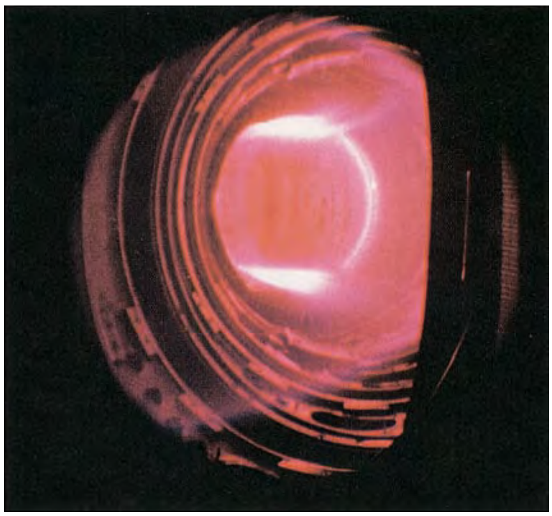
The magnetic field is a combination of the doughnut-shaped magnetic field due to the windings of the toroid and the self-field due to the current of the circulating plasma. The break-even point has almost been achieved using magnetic confinement, but we are still a long way from building a practical fusion reactor.



(*a*)



(*b*)



(*c*)

(*a*) Schematic of the Tokamak Fusion Test Reactor (TFTR). The toroidal coils, surrounding the doughnut-shaped vacuum vessel, are designed to conduct current for 3-s pulses, separated by waiting times of 5 min. Pulses peak at 73 000 A, producing a magnetic field of 5.2 T. This magnetic field is the principal means of confining the deuterium–tritium plasma that circulates within the vacuum vessel. Current for the pulses is delivered by converting the rotational energy of two 600-ton flywheels. Sets of poloidal coils, perpendicular to the toroidal coils, carry an oscillating current that generates a current through the confined plasma itself, heating it ohmically. Additional poloidal fields help stabilize the confined plasma. Between four and six neutral-beam injection systems (only one of which is shown in the schematic) are used to inject high-energy deuterium atoms into the deuterium–tritium plasma, heating beyond what could be obtained ohmically, ultimately to the point of fusion. (*b*) The TFTR itself. The diameter of the vacuum vessel is 7.7 m. (*c*) An 800-kA plasma, lasting 1.6 s, as it discharges within the vacuum vessel. *((All) Courtesy of the Princeton Plasma Physics Laboratory.)*

In a second scheme, called **inertial confinement,** a pellet of solid deuterium and tritium is bombarded from all sides by intense pulsed laser beams of energies of the order of 10^4 J lasting about 10^{-8} s. (Intense beams of ions are also used.) Computer simulation studies indicate that the pellet should be compressed to approximately 10^4 times its normal density and heated to a temperature greater than 10^8 K. This should produce approximately 10^6 J of fusion energy in 10^{-11} s, which is so brief that confinement is achieved by inertia alone.

Because the break-even point is just barely being achieved in magnetic-confinement fusion, and because the building of a fusion reactor involves many practical problems that have not yet been solved, the availability of fusion to meet our energy needs is not expected for at least several decades. However, fusion holds great promise as an energy source for the future.

(b)

(*a*) The Nova target chamber, an aluminum sphere approximately 5 m in diameter, inside which 10 beams from the world's most powerful laser converge onto a hydrogen-containing pellet 0.5 mm in diameter. (*b*) The resulting fusion reaction is visible as a tiny star, lasting 10^{-10} s, releasing 10^{13} neutrons. *((All) Courtesy of the Lawrence Livermore National Laboratory/U.S. Department of Energy.)*

Summary

TOPIC	RELEVANT EQUATIONS AND REMARKS	
1. Properties of Nuclei	A nucleus has N neutrons, Z protons, and a mass number $A = N + Z$. For light nuclei, N and Z are approximately equal, whereas for heavy nuclei, N is greater than Z.	
Isotopes	Isotopes are two or more nuclei that have the same atomic number Z but have different values of N and A.	
Size and shape	Most nuclei are approximately spherical in shape and have a volume that is proportional to A. Because the mass is proportional to A, nuclear density is independent of A.	
Radius	$R = R_0 A^{1/3} \approx (1.2\text{ fm})A^{1/3}$	40-1
Mass and binding energy	The mass of a stable nucleus is less than the sum of the masses of its nucleons. The mass difference Δm multiplied by c^2 equals the binding energy E_b of the nucleus. The binding energy is approximately proportional to the mass number A.	
2. Radioactivity	Unstable nuclei are radioactive and decay by emitting α particles (^{4}He nuclei), β particles (electrons or positrons), or γ rays (photons). All radioactivity is statistical in nature and follows an exponential decay law: $N = N_0 e^{-\lambda t}$	40-6
Decay rate	$R = \lambda N = R_0 e^{-\lambda t}$	40-7
Mean lifetime	$\tau = \dfrac{1}{\lambda}$	40-9
Half-life	$t_{1/2} = \tau \ln 2 = 0.693\tau$ The half-lives of α decay range from a fraction of a second to millions of years. For β decay, the half-lives range up to hours or days. For γ decay, the half-lives are usually less than a microsecond.	40-11
Decay-rate units	The number of decays per second of 1 g of radium is the curie (Ci). $1\text{ Ci} = 3.7 \times 10^{10}\text{ decays/s} = 3.7 \times 10^{10}\text{ Bq}$ $(1\text{ Bq} = 1\text{ decay/s})$	
3. Nuclear Reactions		
Q value	The Q value equals c^2 multiplied by the total mass of the incoming particles less the total mass of the outgoing particles in the center of mass reference frame. If the net mass change is Δm, the Q value is $Q = -(\Delta m)c^2$	40-19
Exothermic reaction	If total mass decreases during a reaction, Q is positive and measures the energy released.	
Endothermic reaction	If total mass increases during a reaction, Q is negative. Then $\|Q\|$ is the threshold energy for the reaction in the center of mass reference frame.	
4. Fission	Fission occurs when some heavy elements, such as ^{235}U or ^{239}Pu, capture a neutron and split apart into two nuclei. The two nuclei then fly apart because of electrostatic repulsion. A chain reaction is possible because several neutrons are emitted by a nucleus when it undergoes fission. A chain reaction can be sustained in a reactor if, on the average, one of the emitted neutrons is slowed down by scattering in the reactor and is then captured by another fissionable nucleus. Very heavy nuclei ($Z > 92$) are subject to spontaneous fission.	

TOPIC	RELEVANT EQUATIONS AND REMARKS
5. Fusion	A large amount of energy is released when two light nuclei, such as ^{2}H and ^{3}H, fuse together. Fusion takes place spontaneously inside the Sun and other stars, where the temperature is great enough (about 10^8 K) for thermal motion to bring the charged hydrogen ions close enough together to fuse. Although controlled fusion holds great promise as a future energy source, practical difficulties have thus far hindered its development.
Lawson criterion	The minimum product of particle density n and confinement time τ to get more energy out of a fusion reactor than is put in is $n\tau > 10^{20}$ s · particles/m^3.

Answer to Concept Check

41-1 The number left can be either one or zero, where zero left is more probable than one left.

Answers to Practice Problems

40-1 (*a*) $60E_1$ (*b*) $20E_1$

40-2 It is because $\frac{1}{8} = \left(\frac{1}{2}\right)^3$, so $n = 3$.

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • Isotopes of nitrogen, iron and tin have stable isotopes ^{14}N, ^{56}Fe and ^{118}Sn. Give the symbols for two other isotopes of (*a*) nitrogen, (*b*) iron, and (*c*) tin.

2 • Why is the decay chain $A = 4n + 1$ not found in nature?

3 • A decay by α emission is often followed by β decay. When this occurs, it is by β^- and not β^+ decay. Why?

4 • The half-life of ^{14}C is much less than the age of the universe, yet ^{14}C is found in nature. Why?

5 • What effect would a long-term variation in cosmic-ray activity have on the accuracy of ^{14}C dating?

6 • Why does an element that has $Z = 130$ not exist?

7 • Why is a moderator needed in an ordinary nuclear fission reactor?

8 • Explain why water is more effective than lead in slowing down fast neutrons.

9 • The stable isotope of sodium is ^{23}Na. What kind of beta decay would you expect of (*a*) ^{22}Na and (*b*) ^{24}Na?

10 • What is the advantage of a breeder reactor over an ordinary reactor? What are the disadvantages of a breeder reactor?

11 • True or false:

(*a*) In a breeder reactor, fuel can be produced as fast as it is consumed.
(*b*) The atomic nucleus is composed of protons, neutrons, and electrons.
(*c*) The mass of a ^{2}H nucleus is less than the mass of a ^{1}H nucleus plus the mass of a neutron.
(*d*) After two half-lives, all the radioactive nuclei in a given sample have decayed.

12 • Why is it that extreme changes in the temperature or the pressure of a radioactive sample have little or no effect on the radioactivity?

ESTIMATION AND APPROXIMATION

13 • We found in Chapter 25 that the ratio of the resistivity of the most insulating material to the resistivity of the least resistive material (excluding superconductors) is approximately 10^{22}. Few properties of materials show such a wide range of values. Using information in the textbook or other resources, find the ratio of largest to smallest for some nuclear properties of matter. Some examples might be the range of mass densities found in an atom, the half-life of radioactive nuclei, or the range of nuclear masses.

14 •• According to the United States Department of Energy, the U.S. population consumes approximately 10^{20} joules of energy each year. Estimate the mass (in kilograms) of (*a*) uranium that would be needed to produce this much energy using nuclear fission and (*b*) deuterium and tritium that would be needed to produce this much energy using nuclear fusion.

PROPERTIES OF NUCLEI

15 • Calculate the binding energy and the binding energy per nucleon from the masses given in Table 40-1 for (*a*) ^{12}C, (*b*) ^{56}Fe, and (*c*) ^{238}U. SSM

16 • Calculate the binding energy and the binding energy per nucleon from the masses given in Table 40-1 for (*a*) ^{6}Li, (*b*) ^{39}K, and (*c*) ^{208}Pb.

17 • Use the radius formula $R = R_0A^{1/3}$ (Equation 40-1), where $R_0 = 1.2$ fm, to compute the radii of the following nuclei: (*a*) ^{16}O, (*b*) ^{56}Fe, and (*c*) ^{197}Au.

18 • During a fission process, a ^{239}Pu nucleus splits into two nuclei whose mass number ratio is 3 to 1. Calculate the radii of the nuclei formed during the process.

19 •• The neutron, when isolated from an atomic nucleus, decays into a proton, an electron, and an antineutrino as follows: $n \rightarrow {}^1H + e^- + \bar{\nu}$. The thermal energy of a neutron is of the order of kT, where k is the Boltzmann constant. (*a*) In both joules and electron volts, calculate the energy of a thermal neutron at 25°C. (*b*) What is the speed of that thermal neutron? (*c*) A beam of monoenergetic thermal neutrons is produced at 25°C and has an intensity I. After traveling 1350 km, the beam has an intensity of $\frac{1}{2}I$. Using this information, estimate the half-life of the neutron. Express your answer in minutes. SSM

20 • Use $R = R_0A^{1/3}$ (Equation 40-1), where $R_0 = 1.2$ fm, for the radius of a spherical nucleus to calculate the density of nuclear matter. Express your answer in grams per cubic centimeter.

21 •• In 1920, 12 years before the discovery of the neutron, Ernest Rutherford argued that proton–electron pairs might exist in the confines of the nucleus in order to explain the mass number, A, being greater than the nuclear charge, Z. He also used this argument to account for the source of beta particles in radioactive decay. Rutherford's scattering experiments in 1910 showed that the nucleus had a diameter of approximately 10 fm. Using this nuclear diameter, the uncertainty principle, and that beta particles have an energy range of 0.02 MeV to 3.40 MeV, show why the hypothetical electrons cannot be confined to a region occupied by the nucleus. SSM

22 •• Consider the following fission process: ${}^{235}_{92}U + n \rightarrow {}^{95}_{37}Rb + {}^{137}_{55}Cs + 4n$. Determine the electrostatic potential energy, in MeV, of the reaction products when the surfaces of the ^{95}Rb nucleus and the ^{137}Cs nucleus are just touching immediately after being formed during the fission process.

RADIOACTIVITY

23 • Homer enters the visitors' chambers, and his Geiger beeper sounds. He shuts off the beeper, removes the device from his shoulder patch, and holds it near the only new object in the room—an orb that is to be presented as a gift from the visiting Cartesians. Pushing a button marked "monitor," Homer reads that the device is reading a counting rate of 4000 counts/s above the background counting rate. After 10 min, the counting rate has dropped to 1000 counts/s above the background rate. (*a*) What is the half-life of the source? (*b*) How high will the counting rate be (above the background counting rate) 20 min after the monitoring device was switched on?

24 • A certain source gives 2000 counts/s at time $t = 0$. Its half-life is 2.0 min. How many counts per second will it give after (*a*) 4.0 min, (*b*) 6.0 min, and (*c*) 8.0 min?

25 • The counting rate from a radioactive source is 8000 counts/s at time $t = 0$, and 10 min later the rate is 1000 counts/s. (*a*) What is the half-life? (*b*) What is the decay constant? (*c*) What is the counting rate after 20 min?

26 • The half-life of radium is 1620 y. Calculate the number of disintegrations per second of 1.00 g of radium and show that the disintegration rate is approximately 1.0 Ci.

27 • A radioactive piece of silver foil ($t_{1/2} = 2.4$ min) is placed near a Geiger counter and 1000 counts/s are observed at time $t = 0$. (*a*) What is the counting rate at $t = 2.4$ min and at $t = 4.8$ min? (*b*) If the counting efficiency is 20 percent, how many radioactive silver nuclei are there at time $t = 0$? At time $t = 2.4$ min? (*c*) At what time will the counting rate be about 30 counts/s?

28 • Use Table 40-1 to calculate the energy release, in MeV, for the α decay of (*a*) ^{226}Ra and (*b*) ^{242}Pu.

29 •• Plutonium is very toxic to the human body. Once it enters the body it collects primarily in the bones, although it also can be found in other organs. Red blood cells are synthesized within the marrow of the bones. The isotope ^{239}Pu is an alpha emitter that has a half-life of 24 360 years. Because alpha particles are an ionizing radiation, the blood-making ability of the marrow is, in time, destroyed by the presence of ^{239}Pu. In addition, many kinds of cancers will also develop in the surrounding tissues because of the ionizing effects of the alpha particles. (*a*) If a person accidentally ingested 2.0 μg of ^{239}Pu and all of it is absorbed by the bones of the person, how many alpha particles are produced per second within the body of the person? (*b*) When, in years, will the activity be 1000 alpha particles per second? SSM

30 •• Consider an alpha-emitting parent nucleus ${}^{A}_{Z}X$ initially at rest. The nucleus decays into a daughter nucleus Y and an alpha particle as follows: ${}^{A}_{Z}X \rightarrow {}^{A-4}_{Z-2}Y + {}^{4}_{2}\alpha + Q$. (*a*) Show that the alpha particle has a kinetic energy of $(A - 4)Q/A$. (*b*) Show that the kinetic energy of the recoiling daughter nucleus is given by $K_Y = 4Q/A$.

31 • The fissile material ^{239}Pu is an alpha emitter. Write the reaction that describes ^{239}Pu undergoing alpha decay. Given that ^{239}Pu, ^{235}U, and an alpha particle have respective masses of 239.052 156 u, 235.043 923 u, and 4.002 603 u, use the relations appearing in Problem 30 to calculate the kinetic energies of the alpha particle and the recoiling daughter nucleus. SSM

32 • Through a friend in the security department at the museum, Angela obtains a sample of a wooden tool handle that contains 175 g of carbon. The decay rate of the ^{14}C in the sample is 8.1 Bq. How long ago was the wood in the handle last alive?

33 • A sample of a radioactive isotope is found to have an activity of 115.0 Bq immediately after it is pulled from the reactor that formed the isotope. Its activity 2 h 15 min later is measured to be 85.2 Bq. (*a*) Calculate the decay constant and the half-life of the sample. (*b*) How many radioactive nuclei were there in the sample initially?

34 •• A 1.00-mg sample of substance that has an atomic mass of 59.934 u and emits β particles has an activity of 1.131 Ci. Find the decay constant for the substance in reciprocal seconds and find the half-life in years.

35 •• Radiation has been used for a long time in medical therapy to control the development and growth of cancer cells. Cobalt-60, a gamma emitter that emits photons that have energies of 1.17 MeV and 1.33 MeV, is used to irradiate and destroy deep-rooted cancers. Small needles made of ^{60}Co of a specified activity are encased in gold and used as body implants in tumors for time periods that are related to tumor size, tumor cell reproductive rate, and the activity of the needle. (*a*) A 1.00-μg sample of ^{60}Co, that has a half-life of

5.27 y and that is used to irradiate a small internal tumor with gamma rays, is prepared in the cyclotron of a medical center. Determine the activity of the sample in curies. (*b*) What will the activity of the sample be 1.75 y from now? SSM

36 •• (*a*) Show that if the decay rate is R_0 at time $t = 0$ and R_1 at some later time $t = t_1$, the decay constant is given by $\lambda = t_1^{-1}\ln(R_0/R_1)$ and the half-life is given by $t_{1/2} = t_1 \ln(2)/\ln(R_0/R_1)$. (*b*) Use these results to find the decay constant and the half-life if the decay rate is 1200 Bq at $t = 0$ and 800 Bq at $t_1 = 60.0$ s.

37 •• A wooden casket is thought to be 18 000 years old. How much carbon would have to be recovered from the object to yield a ^{14}C counting rate of no less than 5 counts/min with a detection efficiency of 20 percent?

38 •• A sample of radioactive material is initially found to have an activity of 115.0 decays/min. After 4 d 5 h, its activity is measured to be 73.5 decays/min. (*a*) Calculate the half-life of the material. (*b*) How long (from the initial time) will it take for the sample to reach an activity of 10.0 decays/min?

39 •• The rubidium isotope ^{87}Rb is a β^- emitter that has a half-life of 4.9×10^{10} y. It decays into ^{87}Sr. This nuclear decay is used to determine the age of rocks and fossils. Rocks containing the fossils of early animals have a ratio of ^{87}Sr to ^{87}Rb of 0.0100. Assuming that there was no ^{87}Sr present when the rocks were formed, calculate the age of the fossils.

40 ••• Consider a single nucleus of a radioactive isotope that has a decay rate equal to λ. The nucleus has not decayed at $t = 0$. The probability that the nucleus will decay between time t and time $t + dt$ is equal to $\lambda e^{-\lambda t}dt$. (*a*) Show that this statement is consistent with the fact that the probability is 1 that the nucleus will decay between $t = 0$ and $t = \infty$. (*b*) Show that the expected lifetime of the nucleus is equal to $1/\lambda$. *Hint: The expected lifetime is equal to* $\int_0^\infty t\lambda e^{-\lambda t}dt$ *divided by* $\int_0^\infty \lambda e^{-\lambda t}dt$. (*c*) A sample of material contains a number of these radioactive nuclei at time $t = 0$. What is the mean lifetime of the radioactive nuclei in the sample?

NUCLEAR REACTIONS

41 • Using Table 40-1, find the Q values for the following reactions: (*a*) $^1H + {}^3H \rightarrow {}^3He + n + Q$ and (*b*) $^2H + {}^2H \rightarrow {}^3He + n + Q$.

42 • Using Table 40-1, find the Q values for the following reactions: (*a*) $^2H + {}^2H \rightarrow {}^3H + {}^1H + Q$, (*b*) $^2H + {}^3He \rightarrow {}^4He + {}^1H + Q$, and (*c*) $^6Li + n \rightarrow {}^3H + {}^4He + Q$.

43 •• (*a*) Use the values 14.003 242 u and 14.003 074 u for the atomic masses of ^{14}C and ^{14}N, respectively, to calculate the Q value (in MeV) for the β-decay reaction ${}^{14}_{6}C \rightarrow {}^{14}_{7}N + e^- + \bar{v}_e$. (*b*) Explain why you should not add the mass of the electron to that of atomic ^{14}N for the calculation in Part (*a*). SSM

44 •• (*a*) Use the values 13.005 738 u and 13.003 354 u for the atomic masses of ${}^{13}_{7}N$ and ${}^{13}_{6}C$, respectively, to calculate the Q value (in MeV) for the β-decay reaction

$$^{13}_{7}N \rightarrow {}^{13}_{6}C + e^+ + v_e$$

(*b*) Explain why you need to add twice the mass of an electron to the mass of ${}^{13}_{6}C$ during the calculation of the Q value for the reaction in Part (*a*).

FISSION AND FUSION

45 • Assuming an average energy of 200 MeV per fission, calculate the number of fissions per second needed for a 500-MW reactor. SSM

46 • If the reproduction factor in a reactor is 1.1, find the number of generations needed for the power level to (*a*) double, (*b*) increase by a factor of 10, and (*c*) increase by a factor of 100. Find the time needed in each case if (*d*) there are no delayed neutrons, so that the time between generations is 1.0 ms, and (*e*) there are delayed neutrons that make the average time between generations 100 ms.

47 •• Consider the following fission reaction: ${}^{235}_{92}U + n \rightarrow {}^{95}_{42}Mo + {}^{139}_{57}La + 2n + Q$. The masses of the neutron, ^{235}U, ^{95}Mo, and ^{139}La are 1.008 665 u, 235.043 923 u, 94.905 842 u, and 138.906 348 u, respectively. Calculate the Q value, in MeV, for the fission reaction. SSM

48 •• In 1989, researchers claimed to have achieved fusion in an electrochemical cell at room temperature. Their now thoroughly discredited claim was that a power output of 4.00 W was produced by deuterium fusion reactions in the palladium electrode of their apparatus. The two most likely reactions are

$$^2H + {}^2H \rightarrow {}^3He + n + 3.27\text{ MeV}$$

and

$$^2H + {}^2H \rightarrow {}^3H + {}^1H + 4.03\text{ MeV}$$

Of the deuterium nuclei that participated in these reactions, assume half of the deuterium nuclei participated in the first reaction and the other half participated in the second reaction. How many neutrons per second would we expect to be emitted in the generation of 4.00 W of power?

49 •• A fusion reactor that uses only deuterium for fuel would have the two reactions in Problem 48 taking place in the reactor. The ^3H produced in the second reaction reacts immediately with another ^2H in the reaction

$$^3H + {}^2H \rightarrow {}^4He + n + 17.6\text{ MeV}$$

The ratio of ^2H to ^1H atoms in naturally occurring hydrogen is 1.5×10^{-4}. How much energy would be produced from 4.0 L of water if all of the ^2H nuclei undergo fusion?

50 ••• The fusion reaction between ^2H and ^3H is

$$^3H + {}^2H \rightarrow {}^4He + n + 17.6\text{ MeV}$$

Using the conservation of momentum and the given Q value, find the final energies of both the ^4He nucleus and the neutron, assuming the initial kinetic energy of the system is 1.00 MeV and the initial momentum of the system is zero.

51 ••• Energy is generated in the Sun and other stars by fusion. One of the fusion cycles, the proton–proton cycle, consists of the following reactions:

$$^1H + {}^1H \rightarrow {}^2H + e^+ + \nu_e$$

$$^1H + {}^2H \rightarrow {}^3He + \gamma$$

followed by

$$^1H + {}^3He \rightarrow {}^4He + e^+ + \nu_e$$

(*a*) Show that the net effect of these reactions is

$$4\,{}^1H \rightarrow {}^4He + 2e^+ + 2\nu_e + \gamma$$

(*b*) Show that 24.7 MeV is released during this cycle (not counting the additional energy of 1.02 MeV that is released when each positron meets an electron and the two annihilate). (*c*) The Sun radiates energy at the rate of approximately 4.0×10^{26} W. Assuming that this is due to the conversion of four protons into helium, γ rays, and neutrinos, which releases 26.7 MeV, what is the rate of proton consumption in the Sun? How long will the Sun last if it continues to radiate at its present level? (Assume that protons constitute about half of the total mass, 2.0×10^{30} kg, of the Sun.)

GENERAL PROBLEMS

52 • (*a*) Show that $ke^2 = 1.44\ \text{MeV}\cdot\text{fm}$, where k is the Coulomb constant and e is the magnitude of the electron charge. (*b*) Show that $hc = 1240\ \text{MeV}\cdot\text{fm}$.

53 • The counting rate from a radioactive source is 6400 counts/s. The half-life of the source is 10 s. Make a plot of the counting rate as a function of time for times up to 1 min. What is the decay constant for the source? SSM

54 • Find the energy needed to remove a neutron from (*a*) ^{4}He and (*b*) ^{7}Li.

55 • The isotope ^{14}C decays according to $^{14}\text{C} \rightarrow {}^{14}\text{N} + \text{e}^- + \bar{v}_\text{e}$. The atomic mass of ^{14}N is 14.003 074 u. Determine the maximum kinetic energy of the electron. (Neglect recoil of the nitrogen atom.)

56 • The density of a neutron star is the same as the density of a nucleus. If our Sun were to collapse to a neutron star, what would be the radius of that object?

57 •• Show that the ^{109}Ag nucleus is stable and does not undergo alpha decay, $^{109}_{47}\text{Ag} \rightarrow {}^4_2\text{He} + {}^{105}_{45}\text{Rh} + Q$. The mass of the ^{109}Ag nucleus is 108.904 756 u, and the products of the decay are 4.002 603 u and 104.905 250 u, respectively. SSM

58 •• Gamma rays can be used to induce photofission (fission triggered by the absorption of a photon) in nuclei. Calculate the threshold photon wavelength for the following nuclear reaction: $^2\text{H} + \gamma \rightarrow {}^1\text{H} + \text{n}$. Use Table 40-1 for the masses of the interacting particles.

59 • The relative abundance of ^{40}K (potassium 40) is 1.2×10^{-4}. The isotope ^{40}K has a molar mass of 40.0 g/mol, is radioactive, and has a half-life of 1.3×10^9 y. Potassium is an essential element of every living cell. In the human body the mass of potassium constitutes approximately 0.36 percent of the total mass. Determine the activity of this radioactive source in a student whose mass is 60 kg.

60 •• When a positron makes contact with an electron, the electron–positron pair annihilate by way of the reaction $\beta^+ + \beta^- \rightarrow 2\gamma$. Calculate the minimum total energy, in MeV, of the two photons created when a positron–electron pair annihilate.

61 •• The isotope ^{24}Na is a β emitter and has a half-life of 15 h. A saline solution containing the radioactive isotope has an activity of 600 kBq and is injected into the bloodstream of a patient. Ten hours later, the activity of 1 mL of blood from the individual yields a counting rate of 12 counts/s at a counting efficiency of 20 percent. Determine the volume of blood in the patient.

62 •• (*a*) Determine the distance of closest approach of an 8.0-MeV α particle in a head-on collision with a stationary nucleus of ^{197}Au and with a stationary nucleus of ^{10}B, neglecting the recoil of the struck nuclei. (*b*) Repeat the calculation taking into account the recoil of the struck nuclei.

63 •• Twelve nucleons are in a one-dimensional infinite square well of length $L = 3.0$ fm. (*a*) Using the approximation that the mass of a nucleon is 1.0 u, find the lowest energy of a nucleon in the well. Express your answer in MeV. What is the ground-state energy of the system of 12 nucleons in the well if (*b*) all the nucleons are neutrons so that there can be no more than 2 in each spatial state and (*c*) 6 of the nucleons are neutrons and 6 are protons so that there can be as many as 4 nucleons in each spatial state? (Neglect the energy of Coulomb repulsion of the protons.)

64 •• The helium nucleus or α particle is a very tightly bound system. Nuclei with $N = Z = 2n$, where n is an integer (for example, ^{12}C, ^{16}O, ^{20}Ne, and ^{24}Mg), can be modeled as agglomerates of α particles. (*a*) Use this model to estimate the binding energy of a pair of α particles from the atomic masses of ^{4}He and ^{16}O. Assume that the four α particles in ^{16}O form a regular tetrahedron that has one α particle at each vertex. (*b*) From the result obtained in Part (*a*) determine, on the basis of the model, the binding energy of ^{12}C and compare your result with the result obtained from the atomic mass of ^{12}C.

65 •• Nuclei of a radioactive isotope that has a decay constant of λ are produced in an accelerator at a constant rate R_p. The number of radioactive nuclei N then obeys the equation $dN/dt = R_\text{p} - \lambda N$. (*a*) If N is zero at $t = 0$, sketch N versus t for the situation. (*b*) The isotope ^{62}Cu is produced at a rate of 100 per second by placing ordinary copper (^{63}Cu) in a beam of high-energy photons. The reaction is

$$\gamma + {}^{63}\text{Cu} \rightarrow {}^{62}\text{Cu} + \text{n}$$

The isotope ^{62}Cu decays by β decay and has a half-life of 10 min. After a time long enough so that $dN/dt \approx 0$, how many ^{62}Cu nuclei are there?

66 •• The total energy consumed in the United States in 1 y is approximately 7.0×10^{19} J. How many kilograms of ^{235}U would be needed to provide this amount of energy if we assume that 200 MeV of energy is released by each fissioning uranium nucleus, that all of the uranium atoms undergo fission, and that all of the energy-conversion mechanisms used are 100 percent efficient?

67 •• (*a*) Find the wavelength of a particle in the ground state of a one-dimensional infinite square well of length $L = 2.00$ fm. (*b*) Find the momentum in units of MeV/c for a particle that has this wavelength. (*c*) Show that the total energy of an electron that has this wavelength is approximately $E \approx pc$. (*d*) What is the kinetic energy of an electron in the ground state of the well? This calculation shows that if an electron were confined in a region of space as small as a nucleus, it would have a very large kinetic energy.

68 •• If ^{12}C, ^{11}B, and ^{1}H have respective masses of 12.000 000 u, 11.009 306 u, and 1.007 825 u, determine the minimum energy, Q, in MeV, required to remove a proton from a ^{12}C nucleus.

69 ••• Assume that a neutron decays into a proton and an electron without the emission of a neutrino. The kinetic energy shared by the proton and the electron is then 0.782 MeV. In the rest frame of the neutron, the total momentum is zero, so the momentum of the proton must be equal and opposite the momentum of the electron. This determines the ratio of the kinetic energies of the two particles, but because the electron is relativistic, the exact calculation of these relative kinetic energies is somewhat challenging. (*a*) Assume that the kinetic energy of the electron is 0.782 MeV and calculate the momentum p of the electron in units of MeV/c. *Hint: Use* $E^2 = p^2c^2 + (mc^2)^2$ (*Equation 39-27*). (*b*) Using your result from Part (*a*), calculate the kinetic energy $p^2/2m_\text{p}$ of the proton. (*c*) Because the total kinetic energy of the electron and the proton is 0.782 MeV, the calculation in Part (*b*) gives a correction to the assumption that the kinetic energy of the electron is 0.782 MeV. What percentage of 0.782 MeV is this correction? SSM

70 ••• In the laboratory reference frame, a neutron of mass m moving with speed v_L makes an elastic head-on collision with a nucleus of mass M that is at rest. (*a*) Show that the speed of the center of mass in the lab frame is $V = mv_\text{L}/(m + M)$. (*b*) What is the speed of the nucleus in the center-of-mass frame before the collision and after the collision? (*c*) What is the speed of the nucleus in the laboratory frame after the collision? (*d*) Show that the energy of the nucleus after the collision in the laboratory frame is

$$\frac{1}{2}M(2V)^2 = \frac{4mM}{(m + M)^2}\left(\frac{1}{2}mv_\text{L}^2\right)$$

(*e*) Show that the fraction of the energy lost by the neutron in the elastic collision is

$$\frac{-\Delta E}{E} = \frac{4mM}{(m + M)^2} = \frac{4(m/M)}{[1 + (m/M)]^2}$$

71 ••• (*a*) Use the result from Part (*e*) of Problem 70 to show that after N head-on collisions of a neutron with carbon nuclei at rest, the energy of the neutron is approximately $(0.714)^N E_0$, where E_0 is its original energy. (*b*) How many head-on collisions are required to reduce the energy of the neutron from 2.0 MeV to 0.020 eV, assuming stationary carbon nuclei?

72 ••• On the average, a neutron loses 63 percent of its energy in a collision with a hydrogen atom and 11 percent of its energy in a collision with a carbon atom. Calculate the number of collisions needed to reduce the energy of a neutron from 2.0 MeV to 0.020 eV if the neutron collides with (*a*) hydrogen atoms and (*b*) carbon atoms.

73 ••• Frequently, the daughter nucleus of a radioactive parent nucleus is itself radioactive. Suppose the parent nucleus, designated by P, has a decay constant λ_P, while the daughter nucleus, designated by D, has a decay constant λ_D. The number of daughter nuclei N_D are then given by the solution to the differential equation

$$dN_D/dt = \lambda_P N_P - \lambda_D N_D$$

where N_P is the number of parent nuclei. (*a*) Justify this differential equation. (*b*) Show that the solution for the equation is

$$N_D(t) = \frac{N_{P0}\lambda_P}{\lambda_D - \lambda_P}(e^{-\lambda_P t} - e^{-\lambda_D t})$$

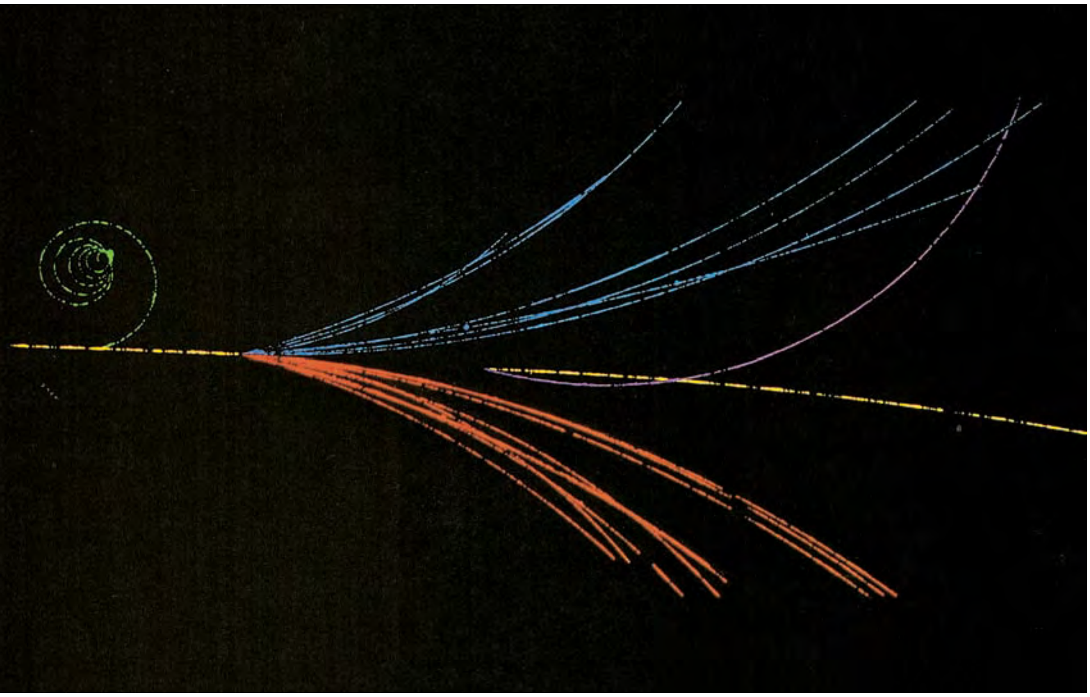
where N_{P0} is the number of parent nuclei present at $t = 0$ when there are no daughter nuclei. (*c*) Show that the expression for N_D in Part (*b*) gives $N_D(t) > 0$ whether $\lambda_P > \lambda_D$ or $\lambda_D > \lambda_P$. (*d*) Make a plot of $N_P(t)$ and $N_D(t)$ as a function of time when $\tau_D = 3\tau_P$, where τ_D and τ_P are the mean lifetimes of the daughter and parent nuclei, respectively. SSM

74 ••• Suppose isotope A decays to isotope B and has a decay constant λ_A, and isotope B in turn decays and has a decay constant λ_B. Suppose a sample contains, at $t = 0$, only isotope A nuclei. Derive an expression for the time at which the number of isotope B nuclei will be a maximum. (See Problem 73.)

75 ••• An example of the situation discussed in Problem 73 is the radioactive isotope ^{229}Th, an α emitter that has a half-life of 7300 y. Its daughter, ^{225}Ra, is a β emitter that has a half-life of 14.8 d. In this instance, as in many instances, the half-life of the parent is much longer than the half-life of the daughter. Using the expression given in Problem 73, Part (*b*), starting with a sample of pure ^{229}Th containing N_{P0} nuclei, show that the number, N_D, of ^{225}Ra nuclei will, after several years, be given by

$$N_D = \frac{\lambda_P}{\lambda_D} N_P$$

where N_P is the number of ^{229}Th nuclei. The number of daughter nuclei are said to be in *secular equilibrium*.



CHAPTER 41

TRACKS IN A BUBBLE CHAMBER PRODUCED BY AN INCOMING HIGH-ENERGY PROTON (YELLOW), INCIDENT FROM THE LEFT, COLLIDING WITH A PROTON AT REST. THE SMALL GREEN SPIRAL IS AN ELECTRON KNOCKED OUT OF AN ATOM. IT CURVES TO THE LEFT BECAUSE OF AN EXTERNAL MAGNETIC FIELD IN THE CHAMBER. THE COLLISION PRODUCES SEVEN NEGATIVE PARTICLES (BLUE), ALL π^-; A NEUTRAL PARTICLE Λ^0 THAT LEAVES NO TRACK; AND NINE POSITIVE PARTICLES (RED) INCLUDING SEVEN π^+, A K^+, AND A PROTON. THE Λ^0 TRAVELS IN THE ORIGINAL DIRECTION OF THE INCOMING PROTON BEFORE DECAYING INTO A PROTON (YELLOW) AND A π^- (PURPLE). *(© Lawrence Livermore Laboratory/Science Photo Library/Photo Researchers.)*

Elementary Particles and the Beginning of the Universe

? How do you determine the energy of particle interactions? (See Example 41-1.)

Items that we encounter in everyday life are made of atoms. In some sense, atoms are the building blocks of nature. However, we know that atoms are not the most fundamental constituents of matter. With the discovery of the electron by J. J. Thomson (1897), the Bohr theory of the nuclear atom (1913), and the discovery of the neutron (1932), it became clear that atoms and even nuclei have considerable structure. Indeed the once simple picture of particle physics in which there were just four "elementary" particles—the proton, neutron, electron, and photon—has become much more complex.

Since the 1950s, enormous sums of money have been spent constructing particle accelerators of greater and greater energies in hopes of finding particles predicted by various theories. At present, we know of several hundred particles that at one time or another have been considered to be elementary, and research teams at the giant accelerator laboratories around the world are searching for and finding new particles. Some of these particles have such short lifetimes (of the order of 10^{-23} s) that they can be detected only indirectly. Many particles are observed only during nuclear reactions using high-energy accelerators. In addition to the usual particle properties of mass, charge, and spin, new properties have been found and given whimsical names such as strangeness, charm, color, topness, and bottomness.

In this chapter, we will first look at the various ways of classifying the multitude of particles that have been found. We will then describe the current theory of elementary particles, called the standard model, *in which all matter in nature—from the exotic particles produced in the giant accelerator laboratories to ordinary grains of sand—is considered to be constructed from just two families of elementary particles, leptons and quarks. In the final section, we will use our knowledge of elementary particles to discuss the big bang theory which describes the origin of the universe.*

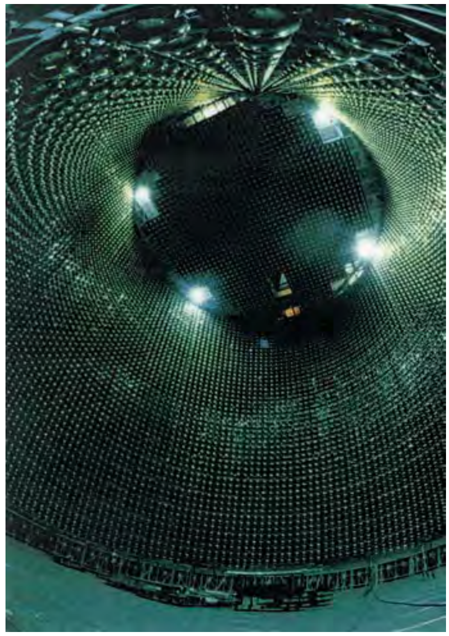
41-1 HADRONS AND LEPTONS

All the different forces observed in nature, from ordinary friction to the tremendous forces involved during supernova explosions, can be understood in terms of the four basic interactions: (1) the strong nuclear interaction (also called the hadronic interaction), (2) the electromagnetic interaction, (3) the weak (nuclear) interaction, and (4) the gravitational interaction. The four basic interactions provide a convenient structure for the classification of particles. Some particles participate in all four interactions, whereas other particles participate in only some of the interactions. For example, all particles participate in gravitational interaction, the weakest of the interactions. All particles that have electric charge participate in the electromagnetic interaction.

Particles that interact by the strong interaction are called **hadrons.** There are two kinds of hadrons: **baryons,** which have spin $\frac{1}{2}$ or $\frac{3}{2}$ or $\frac{5}{2}$, etc., and **mesons,** which have spin 0 or 1 or 2, etc. Baryons, which include nucleons, are the most massive of the elementary particles. Mesons have intermediate masses, between the mass of the electron and the mass of the proton. Particles that decay by the strong interaction have very short lifetimes, of the order of 10^{-23} s, which is about the time it takes light to travel a distance equal to the diameter of a nucleus. On the other hand, particles that decay by the weak interaction have much longer lifetimes, of the order of 10^{-10} s. Table 41-1 lists some of the properties of those hadrons that are stable against decay by the strong interaction.

Hadrons are rather complicated entities and have complex structures. If we use the term *elementary particle* to mean a point particle that has no structure and is not constructed from some more elementary entities, then hadrons are not elementary particles. It is now believed that all hadrons are composed of more fundamental entities called *quarks,* which, as far as we know, are truly elementary particles.

Particles that participate in the weak interaction but not in the strong interaction are called **leptons.** These include electrons, muons, and neutrinos, which are all less massive than the lightest hadron. The word *lepton,* meaning "light particle," was chosen to reflect the relatively small mass of the particles. However, the most recently discovered lepton, the *tau,* found by Martin Lewis Perl in 1975, has a mass of 1784 MeV/c^2, nearly twice the mass of the proton (938 MeV/c^2), so we now have a "heavy lepton." In addition, the word *muon,* short for mu-meson, is something of a misnomer. The muon is not now categorized as a meson, so it is best to refer to it



The Super-Kamiokande detector, built in Japan in 1996 as a joint Japanese–American experiment, is essentially a water tank the size of a large cathedral installed in a deep zinc mine 1 mile inside a mountain. When neutrinos pass through the tank, one of the neutrinos occasionally collides with an atom, sending blue light through the water to an array of detectors. This photograph shows the detector wall and top that have approximately 9000 photomultiplier tubes that help detect the neutrinos. Experimental results reported in June 1998 were evidence that the mass of the neutrino cannot be zero. (*ICCR (Institute for Cosmic Ray Research), The University of Tokyo.*)

Table 41-1 Hadrons That Are Stable Against Decay via the Strong Nuclear Interaction

Name	Symbol	Mass MeV/c^2	Spin, $\hbar$	Charge, e	Antiparticle	Mean Lifetime, s	Typical Decay Products*

* Other decay modes also occur for most particles.

† The Σ^0 is included here for completeness even though it does decay via the strong interaction.

‡ The K^0 has two distinct lifetimes, sometimes referred to as $\mathrm{K}^0_{\text{short}}$ and $\mathrm{K}^0_{\text{long}}$. All other particles have a unique lifetime.

as a muon and not as a mu-meson. As far as we know, leptons are point particles that have no structure and can be considered to be truly elementary in the sense that they are not composed of other particles.

There are six leptons. They are the electron and the electron neutrino, the muon and the muon neutrino, and the tau and the tau neutrino. (Each of the leptons has an antiparticle.) The masses of the electron, the muon, and the tau are quite different. The mass of the electron is 0.511 MeV/c^2, the mass of the muon is 106 MeV/c^2, and the mass of the tau is 1784 MeV/c^2. The standard model predicts that neutrinos, like photons, do not have mass. However, there is now strong evidence that their mass, though very small, is greater than zero. During the late 1990s, experiments using a detector in Japan called the Super-Kamiokande (Super-K) found that neutrinos emitted from the Sun arrived on Earth in much smaller numbers than the numbers that are predicted from the fusion processes in the Sun. This result can be explained if the mass of the neutrino is not zero.* In addition, a neutrino mass as small as a few eV/c^2 would have great cosmological significance. The answer to the question of whether the universe will continue to expand indefinitely or will reach a maximum size and begin to contract depends on the total mass in the universe. Thus, the answer could depend on whether the mass of the neutrino is actually zero or is merely small, because the cosmic density of each species of neutrino is ~100 per cm^3.

* The connection between the shortfall of solar-neutrino detections and the mass of the neutrino is elucidated in "On Morphing Neutrinos and Why They Must Have Mass" by Eugene Hecht, *The Physics Teacher* 41 (2003): 164–168.

(*b*)

(*a*) A computer display of the production and decay of a τ_1 and τ_2 pair. An electron and a positron annihilate at the center marked by the yellow cross, producing a τ^+ and τ^- pair, which travel in opposite directions, but quickly decay while still inside the beam pipe (yellow circle). The τ^+ decays into two invisible neutrinos and a μ^+, which travels toward the bottom left. Its track in the drift chamber is calculated by a computer and indicated in red. It penetrates the lead–argon counters outlined in purple and is detected at the blue dot near the bottom blue line that marks the end of a muon detector. The τ^- decays into three charged pions (red tracks moving upward) plus invisible neutrinos. (*b*) The Mark I detector, built by a team from the Stanford Linear Accelerator Center (SLAC) and the Lawrence Berkeley Laboratory, became famous for many discoveries, including the J/ψ meson and the τ lepton. Tracks of particles are recorded by wire spark chambers wrapped in concentric cylinders around the beam pipe extending out to the ring where physicist Carl Friedberg has his right foot. Beyond this are two rings of protruding tubes, housing photomultipliers that view various scintillation counters. The rectangular magnets at the left guide the counterrotating beams that collide in the center of the detector. *((a) Science Photo Library/Photo Researchers. (b) © Lawrence Berkeley Laboratory/Science Photo Library/Photo Researchers.)*

The observation of electron neutrinos from the supernova 1987A puts an upper limit on the masses of the neutrinos. Because the velocity of a particle that has mass depends on its energy, the arrival time of a burst of neutrinos that have mass from a supernova would be spread out in time. The fact that the electron neutrinos from the 1987 supernova all arrived at Earth within 13 s of one another results in an upper limit of about 16 eV/c^2 for their mass. Note that an upper limit does not imply that the mass is not zero. Measurements of the relative number of muon neutrinos and electron neutrinos entering the huge, underground Super-K detector suggest that at least one type of neutrino can oscillate between types (for example, between a mu neutrino and a tau neutrino). Further measurements of antineutrinos from nuclear reactors strongly show that all three types of neutrinos oscillate between types and thus have mass. Measurements made in Japan, using the *Kam*ioka *L*iquid Scintillator *A*nti-*N*eutrino *D*etector (KamLAND), show that oscillations from one species of neutrino to another species of neutrino can be observed over path lengths as short as 180 km (Figure 41-1).

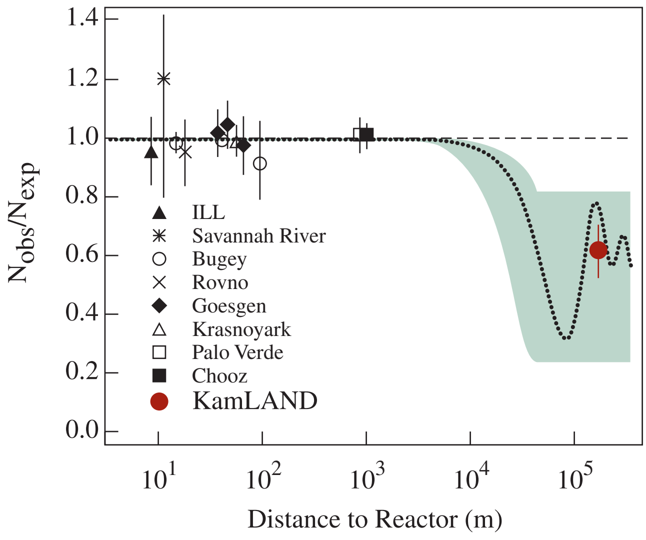

FIGURE 41-1 First evidence for antineutrino disappearance. The ratio of the number of antineutrinos observed N_{obs} to the number that one would expect to observe N_{exp} (assuming no neutrino oscillations) is plotted versus distance to the nearest antineutrino sources. The KamLAND site is 180 km from nearby antineutrino sources (nuclear reactors), while the other eight detector sites are less than 1.0 km from nearby nuclear reactors. For those eight sites, $N_{obs}/N_{exp} = 1.0$, which is what is expected assuming no neutrino oscillations. However, the KamLAND detector found $N_{obs}/N_{exp} = 0.6$. This result is strong evidence that while neutrinos do not oscillate in significant numbers while traveling over path lengths of less than 1.0 km, they do oscillate in significant numbers while traveling over path lengths only a few orders of magnitude longer than 1 km. *(© Lawrence Berkeley Laboratory/Science Photo Library/Photo Researchers.)*

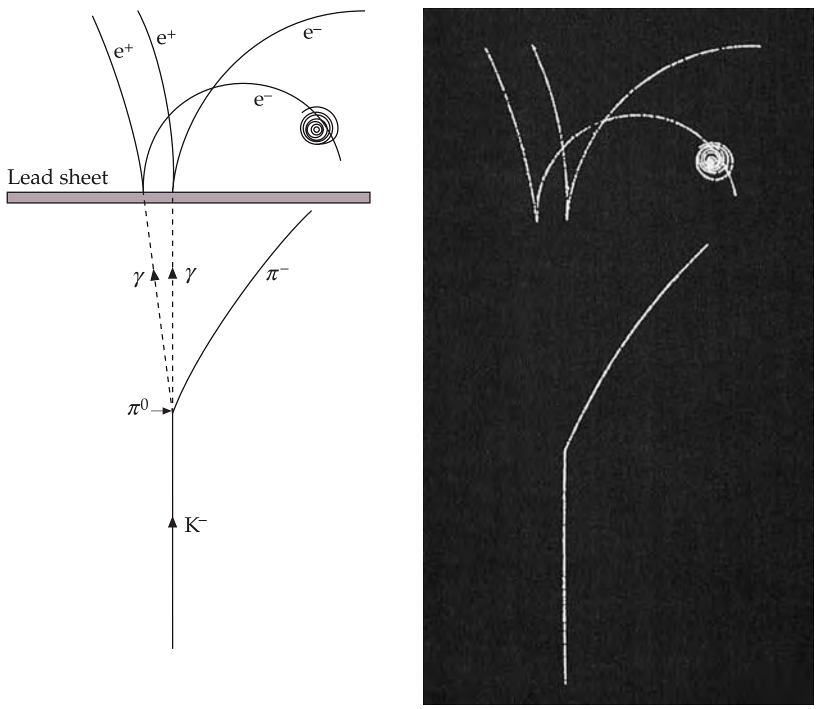
41-2 SPIN AND ANTIPARTICLES

One important characteristic of a particle is its intrinsic spin angular momentum. We have already discussed the fact that the electron has a quantum number m_s that corresponds to the z component of its intrinsic spin characterized by the quantum number $s = \frac{1}{2}$. Protons, neutrons, neutrinos, and the various other particles that also have an intrinsic spin characterized by the quantum number $s = \frac{1}{2}$ are called **spin-$\frac{1}{2}$ particles.** Particles that have spin $\frac{1}{2}$ (or $\frac{3}{2}, \frac{5}{2}$, etc.) are called fermions and obey the exclusion principle. Particles such as pions and other mesons have zero spin or integral spin ($s = 0, 1, 2$, etc.). Those particles are called bosons and do not obey the exclusion principle. That is, any number of those particles can be in the same quantum state.

Spin-$\frac{1}{2}$ particles are described by the Dirac equation, which is an extension of the Schrödinger equation that includes special relativity. One feature of Paul Dirac's theory, proposed in 1927, is the prediction of the existence of antiparticles. In special relativity, the energy of a particle is related to the mass and the momentum of the particle by $E = \pm\sqrt{p^2c^2 + m^2c^4}$ (Equation 39-27). We usually choose the positive solution and dismiss the negative-energy solution with a physical argument. However, the Dirac equation requires the existence of wave functions that correspond to the negative-energy states. Dirac got around this difficulty by postulating that all the negative-energy states were



A negative kaon (K^-) enters a bubble chamber from the bottom and decays into a π^-, which moves off to the right, and a π^0, which immediately decays into two photons whose paths are indicated by the dashed lines in the drawing. Each photon interacts in the lead sheet, producing an electron–positron pair. The spiral at the right is another electron that has been knocked out of an atom in the chamber. (Other extraneous tracks have been removed from the photograph.) *(Figure 4 from "First Results from KamLAND: Evidence for Reactor Antineutrino Disappearance" by the KamLAND Collaboration,* Physical Review Letters, *Vol. 90, No. 2, December 17, 2003. Copyright © 2003 The American Physical Society. Reprinted with permission.)*

filled and would therefore not be observable. Only holes in the "infinite sea" of negative-energy states would be observed. For example, a hole in the negative sea of electron energy states would appear as a particle identical to the electron except having positive charge. When such a particle came in the vicinity of an electron the two particles would annihilate, releasing two photons having a minimum total energy of $2m_ec^2$, where m_e is the mass of the electron. This interpretation received little attention until a particle with just those properties, called the positron, was discovered in 1932 by Carl Anderson.

Antiparticles are never created alone but always in particle–antiparticle pairs. In the creation of an electron–positron pair by a photon, the energy of the photon must be at least as great as the rest energy of the electron plus the rest energy of the positron, which is $2m_ec^2 \approx 1.02$ MeV. Although the positron is stable, it has only a short-term existence in our universe because of the large supply of electrons in matter. The fate of a positron is annihilation according to the reaction

$$\mathrm{e}^+ + \mathrm{e}^- \rightarrow \gamma + \gamma \qquad 41\text{-}1$$

The probability of this reaction is large only if the positron and electron are moving slowly relative to one another. In the center-of-mass reference frame, the momentum of the two particles prior to annihilation is zero, so two photons moving in opposite directions are needed to conserve linear momentum.

The fact that we call electrons *particles* and positrons *antiparticles* does not imply that positrons are less fundamental than electrons. It merely reflects the nature of our universe. If our matter were made up of negative protons and positive electrons, then positive protons and negative electrons would suffer quick annihilation and would be called antiparticles.

An aerial view of the European Laboratory for Particle Physics (CERN) just outside of Geneva, Switzerland. The large circle shows the Large Electron–Positron collider (LEP) tunnel, which is 27 km in circumference. The irregular dashed line is the border between France and Switzerland. *(Richard Ehrlich.)*

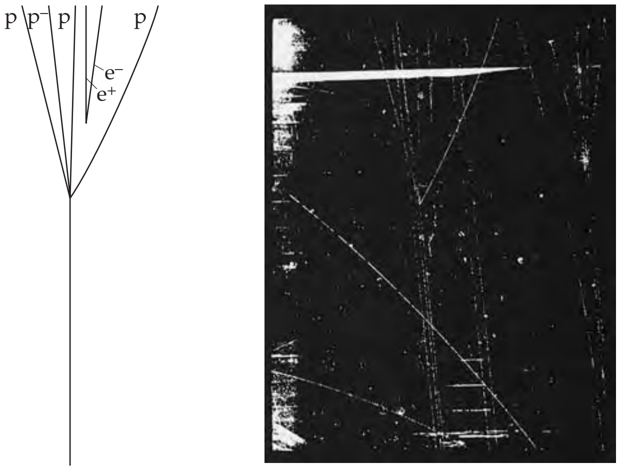


FIGURE 41-2 Bubble-chamber tracks that show the creation of a proton–antiproton pair in the collision of an incident 25-GeV proton with a stationary proton in liquid hydrogen. *(CERN.)*

The antiproton (p^-) was discovered in 1955 by Emilio Segrè and Owen Chamberlain using a beam of protons in the Bevatron at Berkeley to produce the reaction*

$$p^+ + p^+ \rightarrow p^+ + p^+ + p^+ + p^- \qquad 41\text{-}2$$

The creation of a proton–antiproton pair (Figure 41-2) requires kinetic energy of at least $2m_pc^2 = 1877\text{ MeV} = 1.877\text{ GeV}$ in the zero-momentum reference frame in which the two protons approach each other with equal and opposite momenta. In the laboratory frame in which one of the protons is initially at rest, the kinetic energy of the incoming proton must be at least $6m_pc^2 = 5.63\text{ GeV}$ (see Problem 38 of Chapter 39). This energy was not available in laboratories before the development of high-energy accelerators in the 1950s. Antiprotons annihilate with protons to produce two gamma rays in a reaction similar to the reaction in Equation 41-1.

The tunnel of the proton–antiproton collider at CERN. The same bending magnets and focusing magnets can be used for protons or antiprotons moving in opposite directions. The rectangular box in the foreground is a focusing magnet, and the next four boxes are the bending magnets. *(CERN.)*

* The antiproton is sometimes denoted by $\bar{p}$ rather than p^-. For neutral particles, such as the neutron, the bar must be used to denote the antiparticle. Thus, the antineutron is denoted by $\bar{n}$. The electron and proton are often denoted by e and p without the minus sign or plus sign superscripts.

Example 41-1 Proton–Antiproton Annihilation *Context-Rich*

You have been reading about nuclear physics and particle interactions. In particular, you have been looking at the reaction $p^+ + p^- \longrightarrow \gamma + \gamma$ (proton–antiproton annihilation). You wonder if the photons produced are visible to the human eye if the two protons are initially at rest. Are the photons visible to the human eye?

PICTURE If the photons are visible, they should have wavelengths in the visible range (400 nm to 800 nm.) Because the proton and the antiproton are at rest, conservation of momentum requires that the two photons created during their annihilation have equal and opposite momenta and therefore equal energies, frequencies, and wavelengths. Conservation of energy implies that the photons have a combined energy equal to the rest energy of the proton plus the rest energy of the antiproton (approximately 938 MeV each).

SOLVE

1. Set the total energy of the two photons, $2E_\gamma$, equal to the rest energy of the proton plus antiproton and solve for E_γ:

$$2E_\gamma = 2m_\text{p}c^2$$

so

$$E_\gamma = m_\text{p}c^2 = 938\text{ MeV}$$

2. Set the energy of the photon equal to $hf = hc/\lambda$ and solve for the wavelength λ:

$$E_\gamma = hf = \frac{hc}{\lambda}$$

$$\lambda = \frac{hc}{E_\gamma} = \frac{1240\text{ eV}\cdot\text{nm}}{938\text{ MeV}}$$

$$= 1.32 \times 10^{-6}\text{ nm} = 1.32\text{ fm}$$

3. Compare this wavelength with the wavelengths of visible light:

$\boxed{\text{The photons are } \textit{not} \text{ in the visible spectrum.}}$

CHECK In Chapter 36, we found that the energies of photons in the visible spectrum are equal to only a few electron volts. It is not a surprise to find that photons that have energies on the order of 10^9 electron volts are not in the visible spectrum.

TAKING IT FURTHER The wavelength of the photons produced by proton–antiproton annihilation is more than eight orders of magnitude less than 400 nm—the shortest wavelength in the visible spectrum.

41-3 THE CONSERVATION LAWS

One adage is "anything that can happen does." If a conceivable decay or reaction does not occur, there must be a reason. The reason is usually expressed in terms of a conservation law. The conservation of energy rules out the decay of any particle for which the total mass of the decay products would be greater than the initial mass of the particle before decay. The conservation of linear momentum requires that when an electron and a positron at rest annihilate, two photons must be emitted. Angular momentum must also be conserved during a reaction or a decay. A fourth conservation law that restricts the possible particle decays and reactions is the conservation of electric charge. The net electric charge before a decay or a reaction must equal the net charge after the decay or the reaction.

There are two additional conservation laws that are important in the reactions and the decays of elementary particles: the conservation of baryon number and the conservation of lepton number. Consider the proposed decay

$$p \rightarrow \pi^0 + e^+$$

where π is the symbol for the pion (pi-meson). This decay would conserve charge, energy, angular momentum, and linear momentum, but it does not occur. It does not conserve either lepton number or baryon number. (The proton p is a baryon, the positron e^+ is a lepton, and the π^0 is a meson.) The conservation of lepton number and baryon number implies that whenever a lepton or a baryon is created, an antiparticle of the same type is also created. We assign the **lepton number** $L = +1$ to all leptons, $L = -1$ to all antileptons, and $L = 0$ to all other particles. Similarly, the **baryon number** $B = +1$ is assigned to all baryons, $B = -1$ to all antibaryons, and $B = 0$ to all other particles. The sum of the baryon numbers and the sum of the lepton numbers cannot change during a reaction or a decay. The conservation of baryon number along with the conservation of energy implies that the least massive baryon, the proton, must be stable.

The conservation of lepton number implies that the neutrino emitted during the β decay of the free neutron is an antineutrino:

$$\mathrm{n} \rightarrow \mathrm{p}^+ + \mathrm{e}^- + \bar{\nu}_\mathrm{e} \qquad 41\text{-}3$$

The fact that neutrinos and antineutrinos are different is illustrated by an experiment in which ^{37}Cl is bombarded with an intense antineutrino beam from the decay of reactor neutrons (reactor neutrons are fission products that are produced in nuclear reactors). If neutrinos and antineutrinos were the same, we would expect the following reaction:

$$^{37}_{17}\mathrm{Cl} + \bar{\nu}_\mathrm{e} \rightarrow {}^{37}_{18}\mathrm{Ar} + \mathrm{e}^- \qquad 41\text{-}4$$

This reaction is not observed. However, if protons are bombarded with antineutrinos, the reaction

$$\mathrm{p} + \bar{\nu}_\mathrm{e} \rightarrow \mathrm{n} + \mathrm{e}^+ \qquad 41\text{-}5$$

is observed. Note that the sum of the lepton numbers is -1 on the left side of the reaction equation in Equation 41-4 and is $+1$ on the right side of the reaction equation. But the sum of the lepton numbers is -1 on both sides of the reaction equation in Equation 41-5.

Not only are neutrinos and antineutrinos distinct particles, but the neutrinos associated with electrons are distinct from the neutrinos associated with muons. Electron-like leptons (e and ν_e), muon-like leptons (μ and ν_μ), and tau-like leptons (τ and ν_τ) are each separately conserved, so we assign separate lepton numbers L_e, L_μ, and L_τ to the particles. The leptons and their lepton numbers are listed in Table 41-2.

Table 41-2 Lepton Numbers

	L_e	L_μ	L_τ
e^-	+1	0	0
ν_e	+1	0	0
e^+	−1	0	0
$\bar{\nu}_e$	−1	0	0
μ^-	0	+1	0
ν_μ	0	+1	0
μ^+	0	−1	0
$\bar{\nu}_\mu$	0	−1	0
τ^-	0	0	+1
ν_τ	0	0	+1
τ^+	0	0	−1
$\bar{\nu}_\tau$	0	0	−1

CONCEPT CHECK 41-1

Why is it that the conservation of baryon number along with the conservation of energy implies that the proton, which is the least massive baryon, must be stable?

Example 41-2 What Laws Are Being Violated? *Conceptual*

What conservation laws (if any) are violated by the following proposed decays: (*a*) $n \rightarrow p + \pi^-$, (*b*) $\Lambda^0 \rightarrow p^- + \pi^+$, and (*c*) $\mu^- \rightarrow e^- + \gamma$? ($\Lambda^0$ is the symbol for the lambda-zero particle.)

PICTURE All reactions must separately conserve energy, electric charge, baryon number, electron lepton number, muon lepton number, and tau lepton number.

SOLVE

(*a*) There are no leptons in this decay, so there is no problem with the conservation of lepton number. The net charge is zero before the decay and after the decay, so charge is conserved. Also, the baryon number is +1 both before and after the decay. However, rest energy of the proton (938.3 MeV) plus the rest energy of the pion (139.6 MeV) is greater than the rest energy of the neutron (939.6 MeV). In the rest frame of the neutron, the energy prior to the reaction (the rest energy of the neutron) is less than the total rest energy following the reaction.

This decay does not conserve energy.

(*b*) Again, there are no leptons involved, and the net charge is zero before the decay and after the decay. Also, the rest energy of the lambda-zero (1116 MeV) is greater than the rest energy of the antiproton (938.3 MeV) plus the rest energy of the pion (139.6 MeV), so in the rest frame of the lambda-zero the energy prior to the reaction (the rest energy of the lambda-zero) is greater than the total rest energy following the reaction. Energy could be conserved, with the loss in rest energy equal to the gain in kinetic energy of the decay products. There are no leptons in the reaction, so all three lepton numbers are conserved. The baryon number is +1 for the lambda particle and −1 for the antiproton and zero for the pi-meson.

This decay does not conserve baryon number.

(*c*) The μ^- has a muon lepton number (L_μ) equal to +1 and an electron lepton number (L_e) equal to 0, the e^- has $L_\mu = 0$ and $L_e = +1$, and the γ has $L_\mu = L_e = 0$.

This reaction does not conserve either muon lepton number or electron lepton number.

TAKING IT FURTHER The muon does decay by $\mu^- \rightarrow e^- + \bar{\nu}_e + \nu_\mu$, which does conserve both muon lepton numbers and electron lepton numbers.

There are some conservation laws that are not universal but apply only to certain kinds of interactions. In particular, there are quantities that are conserved during decays and reactions that occur by the strong interaction but not during decays or reactions that occur by the weak interaction. One of these quantities that is particularly important is **strangeness,** introduced by M. Gell-Mann and K. Nishijima in 1952 to explain the strange behavior of some of the heavy baryons and mesons. Consider the reaction

$$p + \pi^- \rightarrow \Lambda^0 + K^0 \qquad 41\text{-}6$$

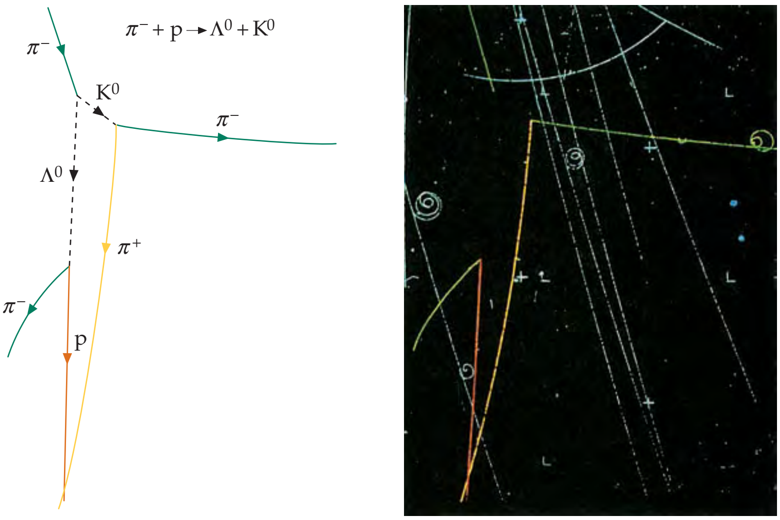
where K is the symbol for the kaon (K-meson). The proton and the pion interact by the strong interaction. Both the Λ^0 and K^0 decay into hadrons

$$\Lambda^0 \rightarrow p + \pi^- \qquad 41\text{-}7$$

and

$$K^0 \rightarrow \pi^+ + \pi^- \qquad 41\text{-}8$$

However, the decay times for both the Λ^0 and K^0 are of the order of 10^{-10} s, which is characteristic of the weak interaction, rather than 10^{-23} s, which would be expected for the strong interaction. Other particles showing similar behavior were called **strange particles.** These particles are always produced in pairs, even when



An early photograph of bubble-chamber tracks at the Lawrence Berkeley Laboratory, showing the production and the decay of two particles that have nonzero strangeness, the K^0 and the Λ^0. These neutral particles are identified by the tracks of their electrically charged decay particles. The lambda particle was named because of the similarity of the tracks of its decay particles to the uppercase Greek letter lambda (Λ). (The blue tracks are particles not involved in the reaction of Equation 41-6.) *(© Lawrence Berkeley Laboratory/Science Photo Library/Photo Researchers.)*

all other conservation laws are met. This behavior is described by assigning a new property called strangeness to the particles. During reactions and decays that occur by the strong interaction, strangeness is conserved. During reactions and decays that occur by the weak interaction, the strangeness can only change by ± 1. The strangeness of the ordinary hadrons—the nucleons and pions—was arbitrarily taken to be zero. The strangeness of the K^0 was arbitrarily chosen to be $+1$. The strangeness of the Λ^0 particle must then be -1 so that strangeness is conserved during the reaction described by Equation 41-6. The strangeness of other particles could then be assigned by looking at their various reactions and decays. During reactions and decays that occur by the weak interaction, the strangeness can change by ± 1.

Figure 41-3 shows the masses of the baryons and the mesons that are stable against decay by the strong interaction versus strangeness. We can see from this figure that the particles cluster in multiplets of one, two, or three particles of approximately equal mass, and that the strangeness of a multiplet of particles is related to the *center of charge* of the multiplet.

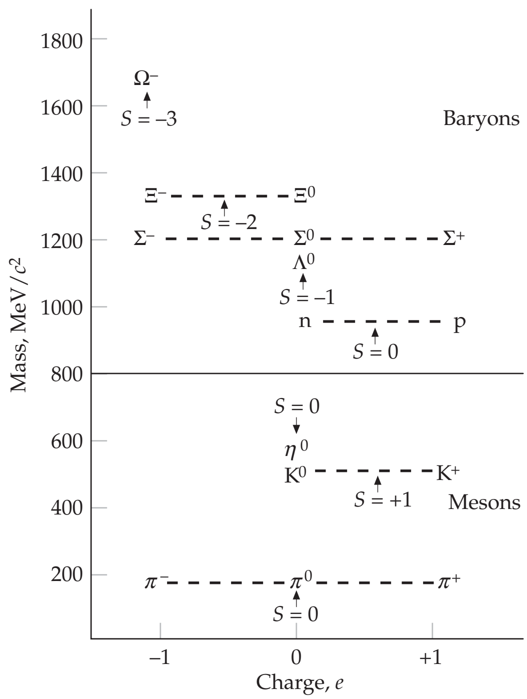


FIGURE 41-3 The strangeness of hadrons shown on a plot of mass versus charge. The strangeness of a baryon–charge multiplet is related to the number of places on the plot that the center of charge of the multiplet is displaced from that of the nucleon doublet. For each "displacement" of e, the strangeness changes by ± 1. For mesons, the strangeness is related to the number of places the center of charge is displaced from that of the pion triplet. Because of the unfortunate original assignment of $+1$ for the strangeness of K-mesons (kaons), all of the baryons that are stable against decay by the strong interaction have negative or zero strangeness.

Example 41-3 Strong Interaction, Weak Interaction, or No Interaction — *Conceptual*

State whether the following decays can occur by the strong interaction, by the weak interaction, or not at all: (*a*) $\Sigma^+ \rightarrow \mathrm{p} + \pi^0$, (*b*) $\Sigma^0 \rightarrow \Lambda^0 + \gamma$, and (*c*) $\Xi^0 \rightarrow \mathrm{n} + \pi^0$, where Σ, Λ and Ξ are the symbols for the sigma, lambda and xi particles respectively.

PICTURE We first note that the mass of each decaying particle is greater than the mass of the decay products, so none of the three reactions are in conflict with the principle of conservation of energy. In addition, no leptons are involved in any of the three decays, and charge and baryon number are both conserved during all three reactions. The decay will occur by the strong interaction if strangeness is conserved (if $\Delta S = 0$). If $\Delta S = \pm 1$, the decay will occur via the weak interaction. If $|\Delta S| > 1$, the decay will not occur.

SOLVE

(*a*) From Figure 41-3, we can see that the strangeness of the Σ^+ is -1, whereas the strangeness of both the proton and the pion is zero.

This decay is possible by the weak interaction but not by the strong interaction. It is, in fact, one of the decay modes of the Σ^+ particle which has a lifetime of the order of 10^{-10} s.

(*b*) The strangeness of both the Σ^0 and Λ^0 is -1, whereas the strangeness of the photon is zero.

This decay can proceed by the strong interaction. It is, in fact, the dominant mode of decay of the Σ^0 particle which has a lifetime of approximately 10^{-20} s.

(*c*) The strangeness of the Ξ^0 is -2, whereas the strangeness of both the neutron and the pion is zero.

Because strangeness cannot change by 2 during a decay or a reaction, this decay does not occur.

41-4 QUARKS

Leptons appear to be truly elementary particles in that they do not break down into smaller entities and they seem to have no measurable size or structure. Hadrons, on the other hand, are complex particles that have size and structure, and they decay into other hadrons. Furthermore, at the present time, there are only six known leptons, whereas there are many more hadrons. Except for the Σ^0 particle, Table 41-1 includes only hadrons that are stable against decay by the strong interaction. Hundreds of other hadrons have been discovered; their properties, such as charge, spin, mass, strangeness, and decay schemes, have been measured.

The most important advance in our understanding of elementary particles was the quark model proposed by M. Gell-Mann and G. Zweig in 1963 in which all hadrons consist of combinations of two or three truly elementary particles called **quarks.*** In the original model, quarks came in three types, called **flavors,** labeled u, d, and s (for *u*p, *d*own, and *s*trange). An unusual property of quarks is that they carry fractional electron charges. The charge of the u quark is $+\frac{2}{3}e$ and the charge of the d and s quarks is $\frac{1}{3}e$. Each quark has spin $\frac{1}{2}$ and a baryon number of $\frac{1}{3}$. The strangeness of the u and d quark is 0, and the strangeness of the s quark is -1. Each quark has an antiquark that has the opposite electric charge, baryon number, and strangeness. Baryons consist of three quarks (or three antiquarks for baryons that are antiparticles), whereas mesons consist of a quark and an antiquark, giving mesons baryon numbers $B = 0$, as required. The proton consists of the combination uud and the neutron consists of the combination udd. Baryons that have a strangeness $S = -1$ have one s quark. All the particles listed in Table 41-1 can be

* The name *quark* was chosen by M. Gell-Mann from a quotation from *Finnegan's Wake* by James Joyce.

constructed from these three quarks and three antiquarks.† The great strength of the quark model is that all the allowed combinations of three quarks or quark–antiquark pairs result in known hadrons. Strong evidence for the existence of quarks inside a nucleon is provided by high-energy scattering experiments called *deep inelastic scattering*. During these experiments, a nucleon is bombarded with electrons, muons, or neutrinos of energies from 15 GeV to 200 GeV. Analyses of particles scattered at large angles indicate that inside the nucleon are three spin-$\frac{1}{2}$ particles of sizes much smaller than that of the nucleon. These experiments are analogous to Rutherford's scattering of α particles by atoms in which the presence of a tiny nucleus in the atom was inferred from the large-angle scattering of the α particles.

In 1967, a fourth quark was proposed to explain some discrepancies between experimental determinations of certain decay rates and calculations based on the quark model. The fourth quark is labeled c for a new property called **charm.** Like strangeness, charm is conserved during strong interactions but changes by ± 1 in weak interactions. In 1975, a new heavy meson called the ψ meson was discovered that has the properties expected of a $c\bar{c}$ combination. Since then, other mesons that have combinations such as $c\bar{d}$ and $\bar{c}d$, as well as baryons having the charmed quark, have been discovered. Two more quarks labeled t and b (for *t*op and *b*ottom) were proposed in the 1970s. In 1977, a massive new meson called the Υ (upsilon) meson or **bottomonium,** which is considered to have the quark combination $b\bar{b}$, was discovered. The top quark was observed in 1995. The properties of the six quarks are listed in Table 41-3.

The six quarks and six leptons (and their antiparticles) are thought to be the fundamental elementary particles of which all matter is composed. Table 41-4 lists the masses of the fundamental particles. In this table, the masses given for neutrinos are upper limits. The masses given for quarks are educated guesses. There is strong experimental evidence for the existence of each of these particles.

Table 41-3 Properties of Quarks and Antiquarks

Flavor	Spin	Charge	Baryon Number	Strangeness	Charm	Topness	Bottomness
Quarks							
u (up)	$\frac{1}{2}\hbar$	$+\frac{2}{3}e$	$+\frac{1}{3}$	0	0	0	0
d (down)	$\frac{1}{2}\hbar$	$-\frac{1}{3}e$	$+\frac{1}{3}$	0	0	0	0
s (strange)	$\frac{1}{2}\hbar$	$-\frac{1}{3}e$	$+\frac{1}{3}$	−1	0	0	0
c (charmed)	$\frac{1}{2}\hbar$	$+\frac{2}{3}e$	$+\frac{1}{3}$	0	+1	0	0
t (top)	$\frac{1}{2}\hbar$	$+\frac{2}{3}e$	$+\frac{1}{3}$	0	0	+1	0
b (bottom)	$\frac{1}{2}\hbar$	$-\frac{1}{3}e$	$+\frac{1}{3}$	0	0	0	+1
Antiquarks							
$\bar{u}$	$\frac{1}{2}\hbar$	$-\frac{2}{3}e$	$-\frac{1}{3}$	0	0	0	0
$\bar{d}$	$\frac{1}{2}\hbar$	$+\frac{1}{3}e$	$-\frac{1}{3}$	0	0	0	0
$\bar{s}$	$\frac{1}{2}\hbar$	$+\frac{1}{3}e$	$-\frac{1}{3}$	+1	0	0	0
$\bar{c}$	$\frac{1}{2}\hbar$	$-\frac{2}{3}e$	$-\frac{1}{3}$	0	−1	0	0
$\bar{t}$	$\frac{1}{2}\hbar$	$-\frac{2}{3}e$	$-\frac{1}{3}$	0	0	−1	0
$\bar{b}$	$\frac{1}{2}\hbar$	$+\frac{1}{3}e$	$-\frac{1}{3}$	0	0	0	−1

† The correct quark combinations of hadrons are not always obvious, because of the symmetry requirements on the total wave function. For example, the π^0 meson is represented by a linear combination of $u\bar{u}$ and $d\bar{d}$.

Table 41-4 Masses of Fundamental Particles

Particle	Mass
Quarks	
u (up)	336 MeV/c^2
d (down)	338 MeV/c^2
s (strange)	540 MeV/c^2
c (charmed)	1500 MeV/c^2
t (top)	174 000 MeV/c^2
b (bottom)	4500 MeV/c^2
Leptons	
e^- (electron)	0.511 MeV/c^2
ν_e (electron neutrino)	$<$ 2.2 eV/c^2
μ^- (muon)	105.659 MeV/c^2
ν_μ (muon neutrino)	$<$ 0.17 MeV/c^2
τ^- (tau)	1784 MeV/c^2
ν_τ (tau neutrino)	$<$ 28 MeV/c^2

Example 41-4 Given the Constituent Quark Species, Identify the Particle *Conceptual*

What are the properties of the particles made up of the following quarks: (*a*) $u\bar{u}$, (*b*) $\bar{u}d$, (*c*) dds, and (*d*) uss?

PICTURE Baryons are made up of three quarks, whereas mesons consist of a quark and an antiquark. We add the electric charges of the quarks to find the total charge of the hadron. We also find the strangeness of the hadron by adding the strangeness of the quarks.

SOLVE

(*a*) Because $u\bar{d}$ is a quark-antiquark combination, it has baryon number 0 and is therefore a meson. There is no strange quark here (that is, $S = 0$), so the strangeness of the meson is zero. The charge of the up quark is $+\frac{2}{3}e$ and the charge of the antidown quark is $+\frac{1}{3}e$, so the charge of the meson is $+1e$.

The quark combination $u\bar{d}$ is the π^+ meson.

(*b*) The particle $\bar{u}d$ is also a meson that has zero strangeness. Its electric charge is $-\frac{2}{3}e + \left(-\frac{1}{3}e\right) = -1e$.

The quark combination $\bar{u}d$ is the π^- meson.

(*c*) The particle dds is a baryon that has strangeness -1 because it has one strange quark. Its electric charge is $-\frac{1}{3}e - \frac{1}{3}e - \frac{1}{3}e = -1e$.

The quark combination dds is the Σ^- particle.

(*d*) The particle uss is a baryon that has strangeness -2. Its electric charge is $+\frac{2}{3}e - \frac{1}{3}e - \frac{1}{3}e = 0$.

The quark combination uss is the Ξ^0 particle.

QUARK CONFINEMENT

Despite considerable experimental effort, no isolated quark has ever been observed. It is now believed that it is impossible to obtain an isolated quark. Although the force between quarks is not known, it is believed that the potential energy of two quarks increases with increasing separation distance so that an infinite amount of energy would be needed to separate the quarks completely.

This would be true, for example, if the force of attraction between two quarks remains constant or increases with separation distance, rather than decreasing with increasing separation distance as is the case for other fundamental forces, such as the electric force between two charges, the gravitational force between two masses, and the strong nuclear force between two hadrons.

When a large amount of energy is added to a quark system, such as a nucleon, a quark–antiquark pair is created and the original quarks remain confined within the original system. Because quarks cannot be isolated, but are always bound together to form a baryon or a meson, the mass of a quark cannot be accurately known, which is why the masses listed in Table 41-4 are merely educated guesses.

41-5 FIELD PARTICLES

In addition to the six fundamental leptons and six fundamental quarks, there are other particles, called *field particles,* or *field quanta,* that are associated with the forces exerted by one elementary particle on another. In **quantum electrodynamics,** the electromagnetic field of a single charged particle is described by **virtual photons** that are continuously being emitted and reabsorbed by the particle. If we put energy into the system by accelerating the charge, some of these virtual photons are shaken off and become real, observable photons. The photon is said to mediate the electromagnetic interaction. Each of the four basic interactions can be described via mediating field particles.

The field quantum associated with the gravitational interaction, called the **graviton,** has not yet been observed. The gravitational *charge* analogous to electric charge is mass.

The weak interaction is thought to be mediated by three field quanta called **vector bosons:** W^+, W^-, and Z^0. These particles were predicted by Sheldon Glashow, Abdus Salam, and Steven Weinberg in a theory called the *electroweak theory,* which we discuss in the next section. The W and Z particles were first observed in 1983 by a group of over a hundred scientists led by Carlo Rubbia using the high-energy accelerator at CERN in Geneva, Switzerland. The masses of the $W^\pm$ particles (about 80 GeV/c^2) and the Z particle (about 91 GeV/c^2) measured during this experiment were in excellent agreement with those predicted by the electroweak theory. (The W^- particle is the antiparticle of the W^+ particle, so they must have identical masses.)

The field quanta associated with the strong force between quarks are called **gluons.** Isolated gluons have not been observed experimentally. The *charge* responsible for the strong interactions comes in three varieties, labeled *red, green,* and *blue* (analogous with the three primary colors), and the strong charge is called the **color charge.** The field theory for strong interactions, analogous to quantum electrodynamics for electromagnetic interactions, is called **quantum chromodynamics (QCD).**

Table 41-5 lists the bosons responsible for mediating the basic interactions.

Table 41-5 Bosons That Mediate the Basic Interactions

Interaction	Boson	Spin	Mass	Electric Charge
Strong	g (gluon)	1	0	0
Weak	$W^\pm$	1	80.22 GeV/c^2	$\pm 1e$
	Z^0	1	91.19 GeV/c^2	0
Electromagnetic	γ (photon)	1	0	0
Gravitational	Graviton†	2	0	0

† Not yet observed.

41-6 THE ELECTROWEAK THEORY

In the **electroweak theory,** the electromagnetic and weak interactions are considered to be two different manifestations of a more fundamental electroweak interaction. At very high energies ($\gg$ 100 GeV), the electroweak interaction would be mediated by four bosons. From symmetry considerations, these would be a triplet consisting of W^+, W^0, and W^-, all of equal mass, and a singlet B^0 of some other mass. Neither the W^0 nor the B^0 would be observed directly, but one linear combination of the W^0 and the B^0 would be the Z^0 and another would be the photon. At ordinary energies, the symmetry is broken. This leads to the separation of the electromagnetic interaction mediated by the massless photon and the weak interaction mediated by the W^+, W^-, and Z^0 particles. The fact that the photon is massless and that the W and Z particles have masses of the order of 100 GeV/c^2 shows that the symmetry assumed in the electroweak theory does not exist at lower energies.

The symmetry-breaking mechanism is called a **Higgs field,** which requires a new boson, the **Higgs boson,** whose rest energy is expected to be of the order of 1 TeV (1 TeV $= 10^{12}$ eV). The Higgs boson has not yet been observed. Calculations show that Higgs bosons (if they exist) should be produced in head-on collisions between protons of energies of the order of a few TeV. Such energies are not presently available, but the Large Hadron Collider, a particle accelerator under construction near Geneva, Switzerland, is scheduled to come on line late in 2007. The LHC is designed to produce head-on proton–proton collisions for which each proton has an energy of 7 TeV.

41-7 THE STANDARD MODEL

The combination of the quark model, electroweak theory, and quantum chromodynamics is called the **standard model.** In this model, the fundamental particles are the leptons and quarks, each of which comes in six flavors, as shown in Table 41-4; the force carriers are the photon, the $W^\pm$ and Z particles, and the gluons (of which there are eight types). The leptons and quarks are all spin-$\frac{1}{2}$ fermions, which obey the exclusion principle, and the force carriers are integral-spin bosons, which do not obey the exclusion principle. Every interaction in nature is due to one of the four basic interactions: strong, electromagnetic, weak, and gravitational. A particle experiences one of the basic interactions if it carries a charge associated with that interaction. Electric charge is the familiar charge that we have studied previously. Weak charge, also called flavor charge, is carried by leptons and quarks. The charge associated with the strong interaction is called color charge and is carried by quarks and gluons but not by leptons. The charge associated with the gravitational force is mass. It is important to note that the photon, which mediates the electromagnetic interaction, does not carry electric charge. Similarly, the $W^\pm$ and Z particles, which mediate the weak interaction, do not carry weak charge. However, the gluons, which mediate the strong interaction, do carry color charge. This fact is related to the confinement of quarks as discussed in Section 41-4.

All matter is made up of leptons or quarks. There are no known composite particles consisting of leptons bound together by the weak force. Leptons exist only as isolated particles. Hadrons (baryons and mesons) are composite particles consisting of quarks bound together by the color charge. A result of QCD theory is that only color-neutral combinations of quarks are allowed. Three quarks of

Table 41-6 Properties of the Basic Interactions

	Gravitational	Weak	Electromagnetic	Strong	
				Fundamental	Residual
Acts on	Mass	Flavor	Electric charge	Color charge	
Particles experiencing	All	Quarks, leptons	Electrically charged	Quarks, gluons	Hadrons
Particles mediating	Graviton	$W^{\pm}, Z$	γ	Gluons	Mesons
Strength for two quarks at 10^{-18} m†	10^{-41}	0.8	1	25	(not applicable)
Strength for two protons in nucleus†	10^{-36}	10^{-7}	1	(not applicable)	20

† Strengths are relative to electromagnetic strength.

different colors can combine to form color-neutral baryons, such as the neutron and the proton. Mesons each have a quark and an antiquark and are also color-neutral. Excited states of hadrons are considered to be different particles. For example, the Δ^+ particle is an excited state of the proton. Both are made up of the *uud* quarks, but the proton is in the ground state and has spin $\frac{1}{2}$ and a rest energy of 938 MeV, whereas the Δ^+ particle is in the first excited state and has spin $\frac{3}{2}$ and a rest energy of 1232 MeV. The two *u* quarks can be in the same spin state in the Δ^+ without violating the exclusion principle, because they have different color. All baryons eventually decay to the lightest baryon, the proton. That the proton does not decay is consistent with the conservation of energy and conservation of baryon number.

The strong interaction has two parts, the fundamental interaction or color interaction and what is called the *residual strong interaction.* The fundamental interaction is responsible for the force exerted by one quark on another quark and is mediated by gluons. The residual strong interaction is responsible for the force between color-neutral nucleons, such as the neutron and the proton. This force is due to the residual strong interactions between the color-charged quarks that make up the nucleons and can be viewed as being mediated by the exchange of mesons. The residual strong interaction between color-neutral nucleons can be thought of as analogous to the residual electromagnetic interaction between neutral atoms that bind them together to form molecules. Table 41-6 lists some of the properties of the basic interactions.

For each particle, there is an antiparticle. A particle and its antiparticle have identical mass and spin but opposite electric charge. For leptons, the lepton numbers L_e, L_μ, and L_τ of the antiparticles are the negatives of the corresponding lepton numbers for the particles. For example, the lepton number for the electron is $L_e = +1$, and the lepton number for the positron is $L_e = -1$. For hadrons, the baryon number, strangeness, charm, topness, and bottomness are the sums of those quantities for the quarks that make up the hadron. The number of each antiparticle is the negative of the number for the corresponding particle. For example, the lambda particle Λ^0, which is made up of the *uds* quarks, has $B = 1$ and $S = -1$, whereas its antiparticle $\overline{\Lambda}^0$, which is made up of the $\overline{u}\overline{d}\overline{s}$ quarks, has $B = -1$ and $S = +1$. A particle such as the photon γ or the Z^0 particle that has zero electric charge; $B = 0$, $L = 0$, $S = 0$; and zero charm, topness, and bottomness is its own antiparticle. Note that the K^0 meson ($d\bar{s}$) has a zero value for all of these quantities except strangeness, which is $+1$. Its antiparticle, the $\overline{K}^0$ meson ($\bar{d}s$), has strangeness -1, which makes it distinct from the K^0. The π^+ ($u\bar{d}$) and π^- ($\bar{u}d$) are somewhat special in that they have electric charge but zero values for L, B, and S. They are antiparticles of each other, but because there is no conservation law for mesons, it is impossible to say which is the particle and which is the antiparticle. Similarly, the W^+ and W^- are antiparticles of each other.

GRAND UNIFICATION THEORIES

With the success of the electroweak theory, attempts have been made to combine the strong, electromagnetic, and weak interactions in various **grand unification theories (GUTs).** In one of these theories, leptons and quarks are considered to be two aspects of a single class of particles. Under certain conditions, a quark could change into a lepton and vice versa, even though this would appear to violate the conservation of lepton number and baryon number. One of the exciting predictions of this theory is that the proton is not stable but merely has a very long lifetime of the order of 10^{32} y. Such a long lifetime makes proton decay difficult to observe. However, projects are ongoing in which detectors monitor very large numbers of protons in search of an event indicating the decay of a proton.

41-8 THE EVOLUTION OF THE UNIVERSE

In the presently accepted model, the universe began with a singular cataclysmic event called the **big bang** and is expanding. The first evidence that the universe is expanding was the astronomer Edwin Powell Hubble's discovery of the relation between the redshifts in the spectra of galaxies and their distances from us. This relation is illustrated in Figure 41-4 for a group of spiral galaxies used by astronomers for calibrating distances. Provided that the redshift is due to the Doppler effect, the recession velocity v of a galaxy is related to its distance r from us by Hubble's law,

$$v = Hr \tag{41-9}$$

where H is the **Hubble constant.** In principle, the value of H is easy to obtain because it relies on the direct calculation of v from redshift measurements. However, astronomical distances are very challenging to measure, and they have been determined for only a fraction of the 10^{10} or so galaxies in the observable universe.

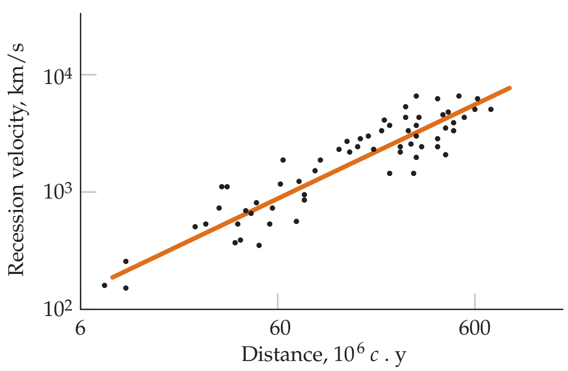

FIGURE 41-4 A plot of the recession velocities of individual galaxies versus distance.

Thus, the value of H changes as distance calibration data are refined. The currently accepted value of the Hubble constant is about

$$H = \frac{23 \text{ km/s}}{10^6 c \cdot \text{y}} \qquad 41\text{-}10$$

Hubble's law tells us that the galaxies are all rushing away from us, and those galaxies that are the farthest away are moving the fastest. However, there is no reason why our location should be special. An observer in any galaxy would make the same observations and compute the same Hubble constant. Thus, Hubble's law suggests that all of the galaxies are receding from each other at an average speed of 23 km/s per $10^6 c \cdot \text{y}$ of separation. In other words, the universe is expanding. Notice that the basic dimension of H is reciprocal time. The quantity $1/H$ is called the **Hubble age** and equals about 1.3×10^{10} y. This would correspond to the age of the universe if the gravitational pull on the receding galaxies were ignored.

Example 41-5 Using Hubble's Law

Redshift measurements of a galaxy in the constellation Virgo yield a recession velocity of 1200 km/s. How far is it to that galaxy?

PICTURE We calculate the distance from Hubble's law.

SOLVE

Use Hubble's law to find r:

$$r = \frac{v}{H} = (1200 \text{ km/s})\frac{10^6 c \cdot \text{y}}{23 \text{ km/s}} = \boxed{52 \times 10^6 c \cdot \text{y}}$$

PRACTICE PROBLEM 41-1 Show that $1/H = 1.3 \times 10^{10}$ y.

THE 2.7-*K* BACKGROUND RADIATION

In investigating ways of accounting for the cosmic abundance of atoms that are heavier than hydrogen atoms, cosmologists recognized that nucleosynthesis in stars could explain the abundance of atoms heavier than helium atoms but could not by itself explain the abundance of helium atoms. Helium must therefore have been formed during the big bang. To synthesize an amount of helium sufficient to account for its present abundance, the big bang would have to have occurred at an extremely high initial temperature to provide the necessary reaction rate before fusion was shut down by the decreasing density of the very rapid initial expansion. The high temperature implies a corresponding thermal (blackbody) radiation field that would cool as the expansion progressed. Theoretical analysis predicted that from the estimated time of the big bang to the present, the remnants of the radiation field should have cooled to a temperature of about 3 K, corresponding to a blackbody spectrum with peak wavelength λ_{max} in the microwave region. In 1965, the predicted cosmic background radiation was discovered by Arno Penzias and Robert Wilson at the Bell Labs. Since this landmark discovery, careful analysis has established that the temperature of the background field is 2.7281 K and has shown that it has an isotropic distribution in space.

THE BIG BANG

The singular event that initiated the expansion of the universe is thought to have been a huge explosion. The four interactions of nature (strong, electromagnetic, weak, and gravitational) initially were unified into a single interaction. Physicists have been successful in developing theoretical descriptions that unify the first three interactions, but a theory of quantum gravity, needed for the extreme densities of the single-interaction period, does not yet exist. Consequently, until the cooling universe "froze" or "condensed out" the gravitational interaction at approximately 10^{-43} s after the big bang, when the temperature was still 10^{32} K, we have no means of describing what was occurring. At this point, the average energy of the particles created would have been about 10^{19} GeV. As the universe continued to cool below 10^{32} K, the three interactions other than gravity remained unified and are described by the grand unification theories (GUTs). Quarks and leptons were indistinguishable and particle quantum numbers were not conserved. It was during this period that a slight excess of quarks over antiquarks occurred, roughly 1 part in 10^9, that ultimately resulted in the predominance of matter over antimatter that we now observe in the universe.

At 10^{-35} s, the universe had expanded sufficiently to cool to approximately 10^{27} K, at which point another phase transition occurred as the strong interaction condensed out of the GUTs group, leaving only the electromagnetic and weak interactions still unified as the **electroweak interaction.** During this period, the previously free quarks in the dense mixture of roughly equal numbers of quarks, leptons, their antiparticles, and photons began to combine into hadrons and their antiparticles, including the nucleons. By the time the universe had cooled to approximately 10^{13} K, at about $t = 10^{-6}$ s, the hadrons had mostly disappeared. This is because 10^{13} K corresponds to $kT \sim 1$ GeV, which is the minimum energy needed to create nucleons and antinucleons from the photons present by the reactions

$$\gamma \rightarrow p^{+} + p^{-} \qquad 41\text{-}11a$$

and

$$\gamma \rightarrow n^{+} + \overline{n} \qquad 41\text{-}11b$$

The particle–antiparticle pairs annihilated and there was no new production to replace them. Only the slight earlier excess of quarks over antiquarks led to a slight excess of protons and neutrons over their antiparticles. The annihilations resulted in photons and leptons, and after about $t = 10^{-4}$ s, those particles in roughly equal numbers dominated the universe. This was the **lepton era.** At about $t = 10$ s, the temperature had fallen to 10^{10} K ($kT \sim 1$ MeV). Further expansion and cooling dropped the average photon energy below the energy needed to form an electron–positron pair. Annihilation then removed all of the positrons as it had the antiprotons and antineutrons earlier, leaving only the small excess of electrons arising from charge conservation, and the **radiation era** began. The particles present were primarily photons and neutrinos.

Within a few more minutes, the temperature dropped sufficiently to enable fusing protons and neutrons to form nuclei that were not immediately photodisintegrated. The nuclei of deuterium, helium, and lithium were produced during this **nucleosynthesis period,** but the rapid expansion soon dropped the temperature too low for the fusion to continue and the formation of heavier elements had to await the birth of stars.

A long time later, when the temperature had dropped to about 3000 K as the universe grew to about 1/1000 of its present size, kT dropped below typical atomic ionization energies and atoms were formed. By then, the expansion had redshifted the radiation field so that the total radiation energy was about equal to the energy represented by the remaining mass. As expansion and cooling continued, the energy of the steadily redshifting radiation declined at a steady rate until, at $t = 10^{10}$ y (now), matter came to dominate the universe, with its energy density exceeding that of the 2.7-K radiation remaining from the big bang by a factor of about 1000.

Summary

TOPIC	RELEVANT EQUATIONS AND REMARKS
1. Basic Interactions	There are four basic interactions: strong, electromagnetic, weak, and gravitational.
Strong	The *charge* associated with the strong interaction is called color. Quarks and gluons have color and experience the strong interaction. Hadrons (baryons and mesons) experience a residual strong interaction resulting from the fundamental strong interaction between the quarks that make up the hadrons. Decay times by the strong interaction are typically 10^{-23} s.
Electromagnetic	All particles that have electric charge experience the force due to the electromagnetic interaction.
Weak	The *charge* associated with the weak interaction is called flavor. Quarks and leptons have flavor and experience the weak interaction. Decay times by the weak interaction are typically 10^{-10} s.
Gravitational	The *charge* associated with the gravitational interaction is called mass.
2. Fundamental Particles	There are two families of fundamental particles, leptons and quarks, each having six members. It is thought that these particles have no size and no internal structure.
Leptons	Leptons are spin-$\frac{1}{2}$ fermions: the electron e and its neutrino ν_e, the muon μ and its neutrino ν_μ, and the tau τ and its neutrino ν_τ. The electron, muon, and tau have mass, electric charge, and flavor, but not color; so they participate in the gravitational, electromagnetic, and weak interactions, but not the strong interaction. The neutrinos have flavor but no electric charge and no color. They have a very small mass.
Quarks	There are six quarks, called up u, down d, strange s, charmed c, top t, and bottom b. Each is a spin-$\frac{1}{2}$ fermion. The quarks participate in all of the basic interactions. Because they are always confined in mesons or baryons, their masses can only be estimated.
3. Hadrons	Hadrons are composite particles that are made up of quarks. There are two types of hadrons, baryons and mesons. Baryons, which include the neutron and proton, are fermions of half-integral spin consisting of three quarks. Mesons, which include pions and kaons, have zero or integral spin. Hadrons interact with each other by the residual strong interaction.
4. Field Particles	In addition to the six fundamental leptons and six fundamental quarks, there are field particles that are associated with the basic interactions. *Interaction* — *Field Particle* Gravitational — Graviton (not yet observed) Electromagnetic — Photon Weak — W^+, W^-, Z^0 Strong — Gluons
5. The Conservation Laws	Some quantities, such as energy, linear momentum, electric charge, angular momentum, baryon number, and each of the three lepton numbers, are strictly conserved during all reactions and decays. Others, such as strangeness and charm, are conserved during reactions and decays that proceed by the strong interaction but not in those that proceed by the weak interaction.
6. Particles and Antiparticles	Particles and their antiparticles have identical masses but opposite values for their other properties, such as charge, lepton number, baryon number, and strangeness. Particle–antiparticle pairs can be produced during various nuclear reactions if the energy available is greater than $2mc^2$, where m is the mass of the particle.
7. Hubble's Law	Hubble's law relates the recession velocity of a galaxy, determined from the redshift of its spectrum, to the distance of the galaxy from us: $v = Hr$ (41-9) where the Hubble constant $H = 23$ km/s per million light-years. From Hubble's law, we conclude that the universe is expanding and that the expansion began approximately $1/H$ years ago.

TOPIC	RELEVANT EQUATIONS AND REMARKS
8. The Big Bang	According to the model currently used to describe the evolution of the universe, the universe began with a big bang approximately 10^{10} years ago. The big bang model is supported by substantial experimental observations, including the isotropic, 2.7-K background blackbody radiation spectrum.

Answer to Concept Check

41-1 A proton is a baryon that has a baryon number (B) equal to 1, and all particles that are not baryons have $B = 0$. If a proton decays, conservation of baryon number implies that the decay products must contain a minimum of one baryon. In addition, conservation of energy implies that the rest mass of the decay products cannot be greater than the rest mass of the proton. Because there are no baryons that have a rest mass less than the rest mass of the proton, the proton cannot decay without either violating conservation of baryon number, conservation of energy, or both.

Problems

In a few problems, you are given more data than you actually need; in a few other problems, you are required to supply data from your general knowledge, outside sources, or informed estimate.

Interpret as significant all digits in numerical values that have trailing zeros and no decimal points.

- • Single-concept, single-step, relatively easy
- •• Intermediate-level, may require synthesis of concepts
- ••• Challenging
- SSM Solution is in the *Student Solutions Manual*
- Consecutive problems that are shaded are paired problems.

CONCEPTUAL PROBLEMS

1 • How are baryons and mesons similar? How are they different?

2 • The muon and the pion have nearly the same masses. How do the particles differ?

3 • How can you tell whether a decay proceeds by the strong interaction or the weak interaction? SSM

4 • True or false:

(*a*) All baryons are hadrons.
(*b*) All hadrons are baryons.

5 • True or false: All mesons are spin-$\frac{1}{2}$ particles.

6 • A particle that is made of exactly two quarks is (*a*) a meson, (*b*) a baryon, (*c*) a lepton, (*d*) either a meson or a baryon, but definitely not a lepton.

7 • Have any quark–antiquark combinations whose electric charge is not an integer multiplied by the fundamental charge e been observed?

8 • True or false:

(*a*) A lepton is a combination of three quarks.
(*b*) The typical times for decays by the weak interaction are orders of magnitude longer than the typical times for decays by the strong interaction.
(*c*) The muon and the pion are both mesons.

9 • True or false:

(*a*) Electrons interact with protons by the strong interaction.
(*b*) Strangeness is not conserved in reactions involving the weak interactions.
(*c*) Neutrons have zero charm.

ESTIMATION AND APPROXIMATION

10 •• Grand unification theories predict that the proton has a long but finite lifetime. Current experiments based on detecting the decay of protons in water infer that this lifetime is at least 10^{32} years. Assume 10^{32} years is, in fact, the mean lifetime of the proton. Estimate the expected time between proton decays that occur in the water of a filled Olympic-size swimming pool. An Olympic-size swimming pool is 100 m × 25 m × 2.0 m. Give your answer in days.

11 •• Table 41-6 lists some properties of the four fundamental interactions. To better understand the significance of this table, confirm the ratio of the numerical entries in the second and fourth column of the last row of the table by estimating the ratio of the electromagnetic force to the gravitational force between two protons of a nucleus.

SPIN AND ANTIPARTICLES

12 • Two pions at rest annihilate according to the reaction $\pi^+ + \pi^- \rightarrow \gamma + \gamma$. (*a*) Why must the energies of the two γ rays be equal? (*b*) Find the energy of each γ ray. (*c*) Find the wavelength of each γ ray.

13 • Find the minimum energy of the photon needed for the following pair-production reactions: (*a*) $\gamma \rightarrow \pi^+ + \pi^-$, (*b*) $\gamma \rightarrow \mathrm{p} + \mathrm{p}^-$, and (*c*) $\gamma \rightarrow \mu^- + \mu^+$.

THE CONSERVATION LAWS

14 • State which of the following decays or reactions violate one or more of the conservation laws, and give the law or laws violated in each case: (*a*) $p^+ \rightarrow n + e^+ + \bar{\nu}_e$, (*b*) $n \rightarrow p^+ + \pi^-$, (*c*) $e^+ + e^- \rightarrow \gamma$, (*d*) $p^+ + p^- \rightarrow \gamma + \gamma$, and (*e*) $\bar{\nu}_e + p^+ \rightarrow n + e^+$.

15 • Determine the change in strangeness in each reaction that follows, and state whether the each decay can proceed by the strong interaction, by the weak interaction, or not at all: (*a*) $\Omega^- \rightarrow \Xi^0 + \pi^-$, (*b*) $\Xi^0 \rightarrow p + \pi^- + \pi^0$, and (*c*) $\Lambda^0 \rightarrow p + \pi^-$.

16 • Determine the change in strangeness for each decay, and state whether each decay can proceed by the strong interaction, by the weak interaction, or not at all: (*a*) $\Omega^- \rightarrow \Lambda^0 + K^-$ and (*b*) $\Xi^0 \rightarrow p + \pi^-$.

17 • Determine the change in strangeness for each decay, and state whether each decay can proceed by the strong interaction, by the weak interaction, or not at all: (*a*) $\Omega^- \rightarrow \Lambda^0 + \bar{\nu}_e + e^-$ and (*b*) $\Sigma^+ \rightarrow p + \pi^0$.

18 • (*a*) Which of the following decays of the τ particle is possible?

$$\tau \rightarrow \mu^- + \bar{\nu}_\mu + \nu_\tau$$
$$\tau \rightarrow \mu^- + \nu_\mu + \bar{\nu}_\tau$$

(*b*) Explain why the other decay is not possible. (*c*) Calculate the kinetic energy of the decay products for the decay that is possible.

19 •• Using Table 41-2 and the laws of conservation of charge number, baryon number, strangeness, and spin, identify the unknown particle, symbolized by (?), in each of the following reactions: (*a*) $p + \pi^- \rightarrow \Sigma^0 + (?)$, (*b*) $p + p \rightarrow \pi^+ + n + K^+ + (?)$, and (*c*) $p + K^- \rightarrow \Xi^- + (?)$ SSM

20 •• Test the following decays for violation of the conservation of energy, electric charge, baryon number, and lepton number: (*a*) $n \rightarrow \pi^+ + \pi^- + \mu^+ + \mu^-$ and (*b*) $\pi^0 \rightarrow e^+ + e^- + \gamma$. Assume that linear momentum and angular momentum are conserved. State which conservation laws (if any) are violated in each decay.

QUARKS

21 • Find the baryon number, charge, and strangeness for the following quark combinations and identify the hadron: (*a*) *uud*, (*b*) *udd*, (*c*) *uus*, (*d*) *dds*, (*e*) *uss*, and (*f*) *dss*.

22 • Find the baryon number, charge, and strangeness for the following quark combinations: (*a*) $u\bar{d}$, (*b*) $\bar{u}d$, (*c*) $u\bar{s}$, and (*d*) $\bar{u}s$.

23 • The Δ^{++} particle is a baryon that decays by the strong interaction. Its strangeness, charm, topness, and bottomness are all zero. What combination of quarks gives a particle that has those properties?

24 • Find a possible combination of quarks that gives the correct values for electric charge, baryon number, and strangeness for (*a*) K^+ and (*b*) K^0.

25 • The D^+ meson has zero strangeness, but it has charm of +1. (*a*) What is a possible quark combination that will give the correct properties for the particle? (*b*) Repeat Part (*a*) for the D^- meson, which is the antiparticle of the D^+ meson.

26 • Find a possible combination of quarks that gives the correct values for electric charge, baryon number, and strangeness for (*a*) K^- (the K^- is the antiparticle of the K^+) and (*b*) $\bar{K}^0$.

27 •• Find a possible quark combination for the following particles: (*a*) Λ^0, (*b*) p^-, and (*c*) Σ^-. SSM

28 •• Find a possible quark combination for the following particles: (*a*) $\bar{n}$, (*b*) Ξ^0, and (*c*) Σ^+.

29 •• Find a possible quark combination for the following particles: (*a*) Ω^- and (*b*) Ξ^-.

30 •• State the properties of the particles made up of the following quarks: (*a*) *ddd*, (*b*) $u\bar{c}$, (*c*) $u\bar{b}$, and (*d*) $\bar{s}\bar{s}\bar{s}$.

THE EVOLUTION OF THE UNIVERSE

31 • A galaxy is receding from Earth at 2.5 percent the speed of light. Estimate the distance from Earth to the galaxy. SSM

32 • Estimate the speed of a galaxy that is $12 \times 10^9\ c \cdot y$ away from us.

33 •• The Doppler frequency shift for a light from a source that is receding from a stationary receiver is given by $f' = f_0\sqrt{(1 - \beta)/(1 + \beta)}$, where $\beta = v/c$ (Equation 39-16*b*). Show that the Doppler wavelength shift for light is $\lambda' = \lambda_0\sqrt{(1 + \beta)/(1 - \beta)}$.

34 •• The red line in the spectrum of atomic hydrogen is frequently referred to as the Hα line, and it has a wavelength of 656.3 nm. Using Hubble's law and the Doppler equation for light from Problem 33, determine the wavelength of the Hα line in the spectrum emitted from galaxies at distances of (*a*) $5.00 \times 10^6\ c \cdot y$, (*b*) $5.00 \times 10^8\ c \cdot y$, and (*c*) $5.00 \times 10^9\ c \cdot y$ from Earth.

GENERAL PROBLEMS

35 • (*a*) What conditions are necessary for a particle and its antiparticle to be identical? (*b*) Find the quark combination of both the particle and the antiparticle of both the π^0 and the Ξ^0 particles. (*c*) Of the π^0 and the Ξ^0 particles, which, if any, is its own antiparticle?

36 •• The red line in the spectrum of atomic hydrogen is frequently referred to as the *Hα* line, and it has a wavelength of 656.3 nm. Light from a distant galaxy shows a redshift of the *Hα* line of hydrogen to a wavelength of 1458 nm. (*a*) What is the recessional velocity of the galaxy? (*b*) Estimate the distance to the galaxy.

37 •• (*a*) In terms of the quark model, show that the reaction $\pi^0 \rightarrow \gamma + \gamma$ does not violate any conservation laws. (*b*) Which conservation law is violated by the reaction $\pi^0 \rightarrow \gamma$? SSM

38 •• Test the following decays for violation of the conservation of energy, electric charge, baryon number, and lepton number: (*a*) $\Lambda^0 \rightarrow p + \pi^-$, (*b*) $\Sigma^- \rightarrow n + p^-$, and (*c*) $\mu^- \rightarrow e^- + \bar{\nu}_e + \nu_\mu$. Assume that linear momentum and angular momentum are conserved. State which conservation laws (if any) are violated in each decay.

39 •• Consider the following high-energy particle reaction: $p + p \rightarrow \Lambda^0 + K^0 + p + (?)$, where (?) represents an unknown particle. During this reaction, stationary protons are bombarded with a beam of high-energy protons. (*a*) Use the laws of conservation of charge number, baryon number, strangeness (Table 41-2), and spin to determine the unknown particle. (*b*) Calculate the *Q* value for the reaction. (*c*) The threshold kinetic energy K_{th} for this reaction is given by $K_{th} = -\frac{1}{2}Q(m_p + m_p + M_1 + M_2 + M_3 + M_4)/m_p$, where M_1, M_2, M_3, and M_4 are the masses of the reaction products. Find K_{th}.

40 ••• In this problem, you will calculate the difference in the time of arrival of two neutrinos of different energy from a supernova that is 170 000 light-years away. Let the energies of the neutrinos be $E_1 = 20$ MeV and $E_2 = 5$ MeV, and assume that the mass of a neutrino is 2.0 eV/c^2. Because the total energies of the neutrinos is so much greater than their rest energies, the neutrinos have speeds that are very nearly equal to c and energies that are approximately $E \approx pc$. (*a*) If t_1 and t_2 are the times that the neutrinos with speeds u_1 and u_2 take to travel a distance x, show that $\Delta t = t_2 - t_1 = x(u_1 - u_2)/u_1u_2 \approx (x\,\Delta u)/c^2$. (*b*) The speed of a neutrino of mass m and total energy E can be found from $E = mc^2/[1 - (u^2/c^2)]^{1/2}$ (Equation 39-24). Show that when $E \gg mc^2$, the speed ratio u/c is given approximately by $u/c \approx 1 - \frac{1}{2}(mc^2/E)^2$. (*c*) Use the results from Part (*a*) and Part (*b*) to calculate $u_1 - u_2$ for the energies and mass given, and calculate Δt from the result from Part (*a*) for $x = 170\,000\ c \cdot \mathrm{y}$. (*d*) Repeat the calculation in Part (*c*) using 20 eV/c^2 for the neutrino mass.

41 ••• A Λ^0 at rest decays by the reaction $\Lambda^0 \rightarrow \mathrm{p} + \pi^-$. (*a*) Calculate the total kinetic energy of the decay products. (*b*) Find the ratio of the kinetic energy of the pion to the kinetic energy of the proton. (*c*) Find the kinetic energies of the proton and the pion for the decay.

42 ••• A Σ^0 particle at rest decays by the reaction $\Sigma^0 \rightarrow \Lambda^0 + \gamma$. (*a*) What is the total energy (total energy includes rest energy) of the decay products? (*b*) Assuming that the kinetic energy of the Λ^0 is negligible compared with the energy of the photon, calculate the approximate momentum of the photon. (*c*) Use your result from Part (*b*) to calculate the kinetic energy of the Λ^0. (*d*) Use your result from Part (*c*) to obtain a better estimate of the momentum and the energy of the photon.

Appendix A

SI Units and Conversion Factors

Base Units*

Length	The *meter* (m) is the distance traveled by light in a vacuum in 1/299,792,458 s.
Time	The *second* (s) is the duration of 9,192,631,770 periods of the radiation corresponding to the transition between the two hyperfine levels of the ground state of the ^{133}Cs atom.
Mass	The *kilogram* (kg) is the mass of the international standard body preserved at Sèvres, France.
Mole	The *mole* (mol) is the amount of substance of a system which contains as many elementary entities as there are atoms in 0.012 kilogram of carbon 12.
Current	The *ampere* (A) is that constant current which, if maintained in two straight parallel conductors of infinite length, of negligible circular cross section, and placed 1 m apart in vacuum would produce between these conductors a force equal to 2×10^{-7} N/m of length.
Temperature	The *kelvin* (K) is 1/273.16 of the thermodynamic temperature of the triple point of water.
Luminous intensity	The *candela* (cd) is the luminous intensity in a given direction, of a source that emits monochromatic radiation of frequency 540×10^{12} hertz and that has a radiant intensity in that direction of 1/683 watt/steradian.

* These definitions are found on the Internet at http://physics.nist.gov/cuu/Units/current.html

Derived Units

Force	newton (N)	$1\ \mathrm{N} = 1\ \mathrm{kg \cdot m/s^2}$
Work, energy	joule (J)	$1\ \mathrm{J} = 1\ \mathrm{N \cdot m}$
Power	watt (W)	$1\ \mathrm{W} = 1\ \mathrm{J/s}$
Frequency	hertz (Hz)	$1\ \mathrm{Hz} = \mathrm{cy/s}$
Charge	coulomb (C)	$1\ \mathrm{C} = 1\ \mathrm{A \cdot s}$
Potential	volt (V)	$1\ \mathrm{V} = 1\ \mathrm{J/C}$
Resistance	ohm (Ω)	$1\ \Omega = 1\ \mathrm{V/A}$
Capacitance	farad (F)	$1\ \mathrm{F} = 1\ \mathrm{C/V}$
Magnetic field	tesla (T)	$1\ \mathrm{T} = 1\ \mathrm{N/(A \cdot m)}$
Magnetic flux	weber (Wb)	$1\ \mathrm{Wb} = 1\ \mathrm{T \cdot m^2}$
Inductance	henry (H)	$1\ \mathrm{H} = 1\ \mathrm{J/A^2}$

Conversion Factors

Conversion factors are written as equations for simplicity; relations marked with an asterisk are exact.

Length

1 km = 0.6215 mi
1 mi = 1.609 km
1 m = 1.0936 yd = 3.281 ft = 39.37 in
*1 in = 2.54 cm
*1 ft = 12 in = 30.48 cm

Compton wavelength	$\lambda_C = h/m_e c$	$2.426\,310\,238(16) \times 10^{-12}$ m

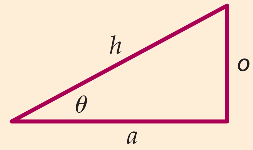
* The values for these and other constants may be found on the Internet at http://physics.nist.gov/cuu/Constants/index.html. The numbers in parentheses represent the uncertainties in the last two digits. (For example, 2.044 43(13) stands for 2.044 43 ± 0.000 13.) Values without uncertainties are exact, including those values with ellipses (such as the value of pi is exactly 3.1415. . .).

For additional data, see the following tables in the text.

Geometry and Trigonometry

$C = \pi d = 2\pi r$	definition of π
$A = \pi r^2$	area of circle
$V = \frac{4}{3}\pi r^3$	spherical volume
$A = \partial V/\partial r = 4\pi r^2$	spherical surface area
$V = A_{\text{base}} L = \pi r^2 L$	cylindrical volume
$A = \partial V/\partial r = 2\pi r L$	cylindrical surface area

$o = h \sin\theta$
$a = h \cos\theta$



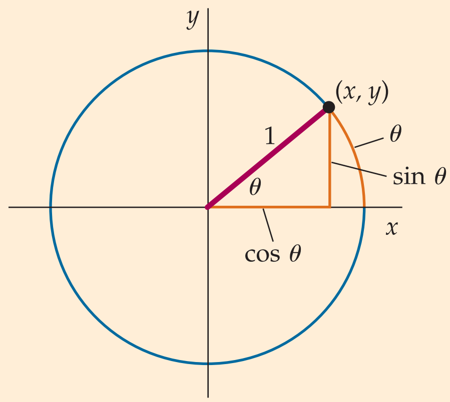
$\sin^2\theta + \cos^2\theta = 1$

$\sin(A \pm B) = \sin A \cos B \pm \cos A \sin B$

$\cos(A \pm B) = \cos A \cos B \mp \sin A \sin B$

$\sin A \pm \sin B = 2 \sin[\frac{1}{2}(A \pm B)] \cos[\frac{1}{2}(A \mp B)]$

$\sin\theta \equiv y$
$\cos\theta \equiv x$
$\tan\theta \equiv \dfrac{y}{x}$



If $|\theta| << 1$, then
$\cos\theta \approx 1$ and $\tan\theta \approx \sin\theta \approx \theta$ (θ in radians)

Quadratic Formula

If $ax^2 + bx + c = 0$, then $x = \dfrac{-b \pm \sqrt{b^2 - 4ac}}{2a}$

Binomial Expansion

If $|x| < 1$, then $(1 + x)^n =$

$$1 + nx + \frac{n(n-1)}{2!}x^2 + \frac{n(n-1)(n-2)}{3!}x^3 + \ldots$$

If $|x| << 1$, then $(1 + x)^n \approx 1 + nx$

Differential Approximation

If $\Delta F = F(x + \Delta x) - F(x)$ and if $|\Delta x|$ is small,

then $\Delta F \approx \dfrac{dF}{dx}\Delta x$.

Math Tutorial

In this tutorial, we review some of the basic results of algebra, geometry, trigonometry, and calculus. In many cases, we merely state results without proof. Table M-1 lists some mathematical symbols.

M-1 SIGNIFICANT DIGITS

Many numbers we work with in science are the result of measurement and are therefore known only within a degree of uncertainty. This uncertainty should be reflected in the number of digits used. For example, if you have a 1-meter-long rule with scale spacing of 1 cm, you know that you can measure the height of a box to within a fifth of a centimeter or so. Using this rule, you might find that the box height is 27.0 cm. If there is a scale with a spacing of 1 mm on your rule, you might perhaps measure the box height to be 27.03 cm. However, if there is a scale with a spacing of 1 mm on your rule, you might not be able to measure the height more accurately than 27.03 cm because the height might vary by 0.01 cm or so, depending on which part of the box you measure the height at. When you write down that the height of the box is 27.03 cm, you are stating that your best estimate of the height is 27.03 cm, but you are not claiming that it is exactly 27.030000 . . . cm high. The four digits in 27.03 cm are called **significant digits.** Your measured length, 2.703 m, has four significant digits. Significant digits are also called significant figures.

The number of significant digits in an answer to a calculation will depend on the number of significant digits in the given data. When you work with numbers that have uncertainties, you should be careful not to include more digits than the certainty of measurement warrants. *Approximate* calculations (order-of-magnitude estimates) always result in answers that have only one significant digit or none. When you multiply, divide, add, or subtract numbers, you must consider the accuracy of the results. Listed below are some rules that will help you determine the number of significant digits of your results.

Table M-1 Mathematical Symbols

$=$	is equal to
$\neq$	is not equal to
$\approx$	is approximately equal to
$\sim$	is of the order of
$\propto$	is proportional to
$>$	is greater than
$\geq$	is greater than or equal to
$\gg$	is much greater than
$<$	is less than
$\leq$	is less than or equal to
$\ll$	is much less than
Δx	change in x
$\lvert x \rvert$	absolute value of x
$n!$	$n(n-1)(n-2)\ldots 1$
$\sum$	sum
lim	limit
$\Delta t \to 0$	Δt approaches zero
$\frac{dx}{dt}$	derivative of x with respect to t
$\frac{\partial x}{\partial t}$	partial derivative of x with respect to t
$\int$	integral

1. When multiplying or dividing quantities, the number of significant digits in the final answer is no greater than that in the quantity with the fewest significant digits.
2. When adding or subtracting quantities, the number of decimal places in the answer should match that of the term with the smallest number of decimal places.
3. Exact values have an unlimited number of significant digits. For example, a value determined by counting, such as 2 tables, has no uncertainty and is an exact value. In addition, the conversion factor 0.0254000 . . . m/in is an exact value because 1.000 . . . inches is exactly equal to 0.0254000 . . . meters. (The yard is, by definition, equal to exactly 0.9144 meters, and 0.9144 divided by 36 is exactly equal to 0.0254.)
4. Sometimes zeros are significant and sometimes they are not. If a zero is before a leading nonzero digit, then the zero is not significant. For example, the number 0.00890 has three significant digits. The first three zeroes are not significant digits but are merely markers to locate the decimal point. Note that the zero after the nine is significant.
5. Zeros that are between nonzero digits are significant. For example, 5603 has four significant digits.
6. The number of significant digits in numbers with trailing zeros and no decimal point is ambiguous. For example 31000 could have as many as five significant digits or as few as two significant digits. To prevent ambiguity, you should report numbers by using scientific notation or by using a decimal point.

Example M-1 Finding the Average of Three Numbers

Find the average of 19.90, −7.524, and −11.8179.

PICTURE You will be adding 3 numbers and then dividing the result by 3. The first number has three significant digits, the second number has four, and the third number has five.

SOLVE

1. Sum the three numbers.

$$19.90 + (-7.524) + (-11.8179) = 0.55\mathit{81}$$

2. If the problem only asked for the sum of the three numbers, we would round the answer to the least number of decimal places among all the numbers being added. However, we must divide this intermediate result by 3, so we use the intermediate answer with the two extra digits (italicized and red).

$$\frac{0.55\mathit{81}}{3} = 0.18\mathit{60333}\ldots$$

3. Only two of the digits in the intermediate answer, $0.18\mathit{60333}\ldots$, are significant digits, so we must round this number to get our final answer. The number 3 in the denominator is a whole number and has an unlimited number of significant digits. Thus, the final answer has the same number of significant digits as the numerator, which is 2.

The final answer is $\boxed{0.19}$.

CHECK The sum in step 1 has two significant digits following the decimal point, the same as the number being summed with the least number of significant digits after the decimal point.

PRACTICE PROBLEMS

1. $\dfrac{5.3\text{ mol}}{22.4\text{ mol/L}}$
2. $57.8\text{ m/s} - 26.24\text{ m/s}$

M-2 EQUATIONS

An **equation** is a statement written using numbers and symbols to indicate that two quantities, written on either side of an equals sign (=), are equal. The quantity on either side of the equal sign may consist of a single term, or of a sum or difference of two or more **terms.** For example, the equation $x = 1 - (ay + b)/(cx - d)$ contains three terms, x, 1 and $(ay + b)/(cx - d)$.

You can perform the following operations on equations:

1. The same quantity can be added to or subtracted from each side of an equation.
2. Each side of an equation can be multiplied or divided by the same quantity.
3. Each side of an equation can be raised to the same power.

These operations are meant to be applied to each *side* of the equation rather than each term in the equation. (Because multiplication is distributive over addition, operation 2—and only operation 2—of the preceding operations also applies term by term.)

Caution: *Division by zero is forbidden at* any *stage in solving an equation; results (if any) would be invalid.*

Adding or Subtracting Equal Amounts

To find x when $x - 3 = 7$, add 3 to both sides of the equation: $(x - 3) + 3 = 7 + 3$; thus, $x = 10$.

Multiplying or Dividing by Equal Amounts

If $3x = 17$, solve for x by dividing both sides of the equation by 3; thus, $x = \frac{17}{3}$, or 5.7.

Example M-2 Simplifying Reciprocals in an Equation

Solve the following equation for x:

$$\frac{1}{x} + \frac{1}{4} = \frac{1}{3}$$

Equations containing reciprocals of unknowns occur in geometric optics and in electric circuit analysis—for example, in finding the net resistance of parallel resistors.

PICTURE In this equation, the term containing x is on the same side of the equation as a term not containing x. Furthermore, x is found in the denominator of a fraction.

SOLVE

1. Subtract $\frac{1}{4}$ from each side:

$$\frac{1}{x} = \frac{1}{3} - \frac{1}{4}$$

2. Simplify the right side of the equation by using the lowest common denominator:

$$\frac{1}{x} = \frac{1}{3} - \frac{1}{4} = \frac{4}{12} - \frac{3}{12} = \frac{4-3}{12} = \frac{1}{12} \quad \text{so} \quad \frac{1}{x} = \frac{1}{12}$$

3. Multiply both sides of the equation by $12x$ to determine the value of x:

$$12\cancel{x}\frac{1}{\cancel{x}} = \cancel{12}x\frac{1}{\cancel{12}}$$

$$\boxed{12} = x$$

CHECK Substitute 12 for x in the left side of original equation.

$$\frac{1}{x} + \frac{1}{4} = \frac{1}{12} + \frac{3}{12} = \frac{4}{12} = \frac{1}{3}$$

PRACTICE PROBLEMS Solve each of the following for x:

3. $(7.0\ \text{cm}^3)x = 18\ \text{kg} + (4.0\ \text{cm}^3)x$
4. $\frac{4}{x} + \frac{1}{3} = \frac{3}{x}$

M-3 DIRECT AND INVERSE PROPORTIONS

When we say variable quantities x and y are **directly proportional,** we mean that as x and y change, the ratio x/y is constant. To say that two quantities are proportional is to say that they are directly proportional. When we say variable quantities x and y are **inversely proportional,** we mean that as x and y change, the ratio xy is constant.

Relationships of direct and inverse proportion are common in physics. Objects moving at the same velocity have momenta directly proportional to their masses. The ideal-gas law ($PV = nRT$) states that pressure P is directly proportional to (absolute) temperature T, when volume V remains constant and is inversely proportional to volume, when temperature remains constant. Ohm's law ($V = IR$) states that the voltage V across a resistor is directly proportional to the electric current in the resistor when the resistance R remains constant.

CONSTANT OF PROPORTIONALITY

When two quantities are directly proportional, the two quantities are related by a *constant of proportionality*. If you are paid for working at a regular rate R in dollars per day, for example, the money m you earn is directly proportional to the time t you work; the rate R is the constant of proportionality that relates the money earned in dollars to the time worked t in days:

$$\frac{m}{t} = R \qquad \text{or} \qquad m = Rt$$

If you earn \$400 in 5 days, the value of R is \$400/(5 days) = \$80/day. To find the amount you earn in 8 days, you could perform the calculation

$$m = (\$80/\text{day})(8 \text{ days}) = \$640$$

Sometimes the constant of proportionality can be ignored in proportion problems. Because the amount you earn in 8 days is $\frac{8}{5}$ times what you earn in 5 days, this amount is

$$m = \frac{8}{5}(\$400) = \$640$$

Example M-3 Painting Cubes

You need 15.4 mL of paint to cover one side of a cube. The area of one side of the cube is 426 cm^2. What is the relation between the volume of paint needed and the area to be covered? How much paint do you need to paint one side of a cube in which the one side has an area of 503 cm^2?

PICTURE To determine the amount of paint for the side whose area is 503 cm^2, you will need to set up a proportion.

SOLVE

1. The volume V of paint needed increases in proportion to the area A to be covered.

   $\boxed{V \text{ and } A \text{ are directly proportional.}}$

   That is, $\dfrac{V}{A} = k$ or $V = kA$

   where k is the proportionality constant

2. Determine the value of the proportionality constant using the given values $V_1 = 15.4$ mL and $A_1 = 426$ cm^2:

   $$k = \frac{V_1}{A_1} = \frac{15.4 \text{ mL}}{426 \text{ cm}^2} = 0.0361 \text{ mL/cm}^2$$

3. Determine the volume of paint needed to paint a side of a cube whose area is 503 cm^2 using the proportionality constant in step 1:

   $$V_2 = kA_2 = (0.0361 \text{ mL/cm}^2)(503 \text{ cm}^2) = \boxed{18.2 \text{ mL}}$$

CHECK Our value for V_2 is greater than the value for V_1, as expected. The amount of paint needed to cover an area equal to 503 cm^2 should be greater than the amount of paint needed to cover an area of 426 cm^2 because 503 cm^2 is larger than 426 cm^2.

PRACTICE PROBLEMS

5. A cylindrical container holds 0.384 L of water when full. How much water would the container hold if its radius were doubled and its height remained unchanged?
Hint: The volume of a right circular cylinder is given by $V = \pi r^2 h$, *where* r *is its radius and* h *is its height. Thus,* V *is directly proportional to* r^2 *when* h *remains constant.*
6. For the container in Practice Problem 5, how much water would the container hold if both its height and its radius were doubled? How much water would the container hold if its radius were doubled and its height remained unchanged?
Hint: The volume V *of a right circular cylinder is given by* $V = \pi r^2 h$, *where* r *is its radius and* h *is its height.*

M-4 LINEAR EQUATIONS

A **linear equation** is an equation of the form $x + 2y - 4z = 3$. That is, an equation is linear if each term either is constant or is the product of a constant and a variable raised to the first power. Such equations are said to be linear because the plots of these equations form straight lines or planes. The equations of direct proportion between two variables are linear equations.

GRAPH OF A STRAIGHT LINE

A linear equation relating y and x can always be put into the standard form

$$y = mx + b \qquad \text{M-1}$$

where m and b are constants that may be either positive or negative. Figure M-1 shows a graph of the values of x and y that satisfy Equation M-1. The constant b, called the ***y* intercept,** is the value of y at $x = 0$. The constant m is the **slope** of the line, which equals the ratio of the change in y to the corresponding change in x. In the figure, we have indicated two points on the line, (x_1, y_1) and (x_2, y_2), and the changes $\Delta x = x_2 - x_1$ and $\Delta y = y_2 - y_1$. The slope m is then

$$m = \frac{y_2 - y_1}{x_2 - x_1} = \frac{\Delta y}{\Delta x}$$

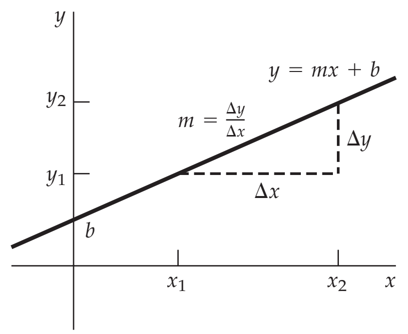

FIGURE M-1 Graph of the linear equation $y = mx + b$, where b is the y intercept and $m = \Delta y/\Delta x$ is the slope.

If x and y are both unknown in the equation $y = mx + b$, there are no unique values of x and y that are solutions to the equation. Any pair of values (x_1, y_1) on the line in Figure M-1 will satisfy the equation. If we have two equations, each with the same two unknowns x and y, the equations can be solved simultaneously for the unknowns. Example M-4 shows how simultaneous linear equations can be solved.

Example M-4 Using Two Equations to Solve for Two Unknowns

Find any and all values of x and y that simultaneously satisfy

$$3x - 2y = 8 \qquad \text{M-2}$$

and

$$y - x = 2 \qquad \text{M-3}$$

PICTURE Figure M-2 shows a graph of the two equations. At the point where the lines intersect, the values of x and y satisfy both equations. We can solve two simultaneous equations by first solving either equation for one variable in terms of the other variable and then substituting the result into the other equation.

SOLVE

1. Solve Equation M-3 for y: $y = x + 2$
2. Substitute this value for y into Equation M-2: $3x - 2(x + 2) = 8$
3. Simplify the equation and solve for x:
$$3x - 2x - 4 = 8$$
$$x - 4 = 8$$
$$x = \boxed{12}$$
4. Use your solution for x and one of the given equations to find the value of y:
$$y - x = 2, \text{ where } x = 12$$
$$y - 12 = 2$$
$$y = 2 + 12 = \boxed{14}$$

CHECK An alternative method is to multiply one equation by a constant such that one of the unknown terms is eliminated when the equations are added or subtracted. We can multiply through Equation M-3 by 2

$$2(y - x) = 2(2)$$
$$2y - 2x = 4$$

and add the result to Equation M-2 and solve for x:

$$\cancel{2y} - 2x = 4$$
$$3x - \cancel{2y} = 8$$
$$3x - 2x = 12 \Rightarrow x = 12$$

Substitute into Equation M-3 and solve for y:

$$y - 12 = 2 \Rightarrow y = 14$$

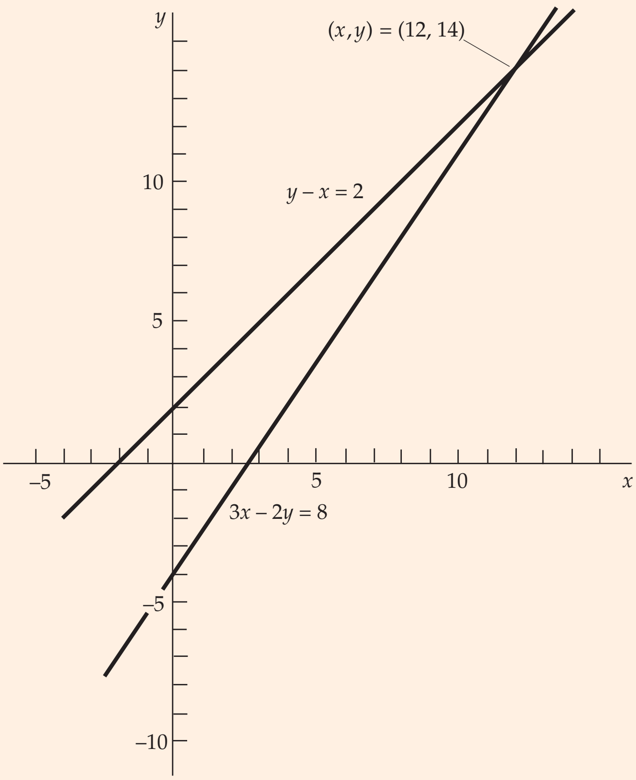

FIGURE M-2 Graph of Equations M-2 and M-3. At the point where the lines intersect, the values of x and y satisfy both equations.

PRACTICE PROBLEMS

7. True or false: $xy = 4$ is a linear equation.
8. At time $t = 0.0\text{ s}$, the position of a particle moving along the x axis at a constant velocity is $x = 3.0\text{ m}$. At $t = 2.0\text{ s}$, the position is $x = 12.0\text{ m}$. Write a linear equation showing the relation of x to t.
9. Solve the following pair of simultaneous equations for x and y:

$$\frac{5}{4}x + \frac{1}{3}y = 30$$
$$y - 5x = 20$$

M-5 QUADRATIC EQUATIONS AND FACTORING

A **quadratic equation** is an equation of the form $ax^2 + bxy + cy^2 + ex + fy + g = 0$, where x and y are variables and a, b, c, e, f, and g are constants. In each term of the equation the powers of the variables are integers that sum to 2, 1, or 0. The designation *quadratic equation* usually applies to an equation of one variable that can be written in the standard form

$$ax^2 + bx + c = 0 \qquad \text{M-4}$$

where a, b, and c are constants. The quadratic equation has two solutions or **roots**—values of x for which the equation is true.

FACTORING

We can solve some quadratic equations by **factoring.** Very often terms of an equation can be grouped or organized into other terms. When we factor terms, we look for multipliers and multiplicands—which we now call **factors**—that will yield two or more new terms as a product. For example, we can find the roots of the quadratic equation $x^2 - 3x + 2 = 0$ by factoring the left side, to get $(x - 2)(x - 1) = 0$. The roots are $x = 2$ and $x = 1$.

Factoring is useful for simplifying equations and for understanding the relationships between quantities. You should be familiar with the multiplication of the factors $(ax + by)(cx + dy) = acx^2 + (ad + bc)xy + bdy^2$.

You should readily recognize some typical factorable combinations:

1. Common factor: $2ax + 3ay = a(2x + 3y)$
2. Perfect square: $x^2 - 2xy + y^2 = (x - y)^2$ (If the expression on the left side of a quadratic equation in standard form is a perfect square, the two roots will be equal.)
3. Difference of squares: $x^2 - y^2 = (x + y)(x - y)$

Also, look for factors that are prime numbers (2, 5, 7, etc.) because these factors can help you factor and simplify terms quickly. For example, the equation $98x^2 - 140 = 0$ can be simplified because 98 and 140 share the common factor 2. That is, $98x^2 - 140 = 0$ becomes $2(49x^2 - 70) = 0$, so we have $49x^2 - 70 = 0$.

This result can be further simplified because 49 and 70 share the common factor 7. Thus, $49x^2 - 70 = 0$ becomes $7(7x^2 - 10) = 0$, so we have $7x^2 - 10 = 0$.

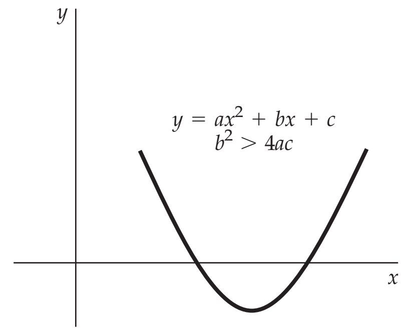

FIGURE M-3 Graph of y versus x when $y = ax^2 + bx + c$ for the case $b^2 > 4ac$. The two values of x for which $y = 0$ satisfy the quadratic equation (Equation M-4).

THE QUADRATIC FORMULA

Not all quadratic equations can be solved by factoring. However, *any* quadratic equation in the standard form $ax^2 + bx + c = 0$ can be solved by the **quadratic formula,**

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a} = -\frac{b}{2a} \pm \frac{1}{2a}\sqrt{b^2 - 4ac} \qquad \text{M-5}$$

When b^2 is greater than $4ac$, there are two solutions corresponding to the + and − signs. Figure M-3 shows a graph of y versus x where $y = ax^2 + bx + c$. The curve, a **parabola,** crosses the x axis twice. (The simplest representation of a parabola in (x, y) coordinates is an equation of the form $y = ax^2 + bx + c$.) The two roots of this equation are the values for which $y = 0$; that is, they are the x *intercepts.*

When b^2 is less than $4ac$, the graph of y versus x does not intersect the x axis, as is shown in Figure M-4; there are still two roots, but they are not real numbers (see the discussion of complex numbers beginning on page M-19). When $b^2 = 4ac$, the graph of y versus x is tangent to the x axis at the point $x = -b/2a$; the two roots are each equal to $-b/2a$.

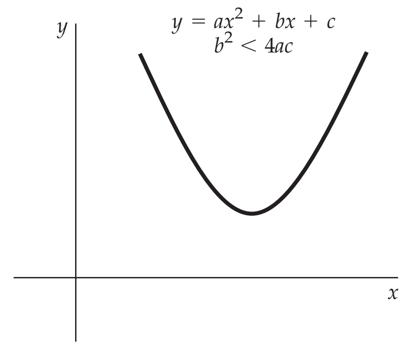

FIGURE M-4 Graph of y versus x when $y = ax^2 + bx + c$ for the case $b^2 < 4ac$. In this case, there are no real values for x for which $y = 0$.

Example M-5 Factoring a Second-Degree Polynomial

Factor the expression $6x^2 + 19xy + 10y^2$.

PICTURE We examine the coefficients of the terms to see whether the expression can be factored without resorting to more advanced methods. Remember that the multiplication $(ax + by)(cx + dy) = acx^2 + (ad + bc)xy + bdy^2$.

SOLVE

1. The coefficient of x^2 is 6 which can be factored two ways: $ac = 6$
   $3 \cdot 2 = 6$ or $6 \cdot 1 = 6$
2. The coefficient of y^2 is 10 which can also be factored two ways: $bd = 10$
   $5 \cdot 2 = 10$ or $10 \cdot 1 = 10$

3. List the possibilities for a, b, c, and d in a table. Include a column for $ad + bc$.
   If $a = 3$, then $c = 2$, and vice versa. In addition, if $a = 6$, then $c = 1$, and vice versa. For each value of a there are four values for b.

a	b	c	d	$ad + bc$
3	5	2	2	16
3	2	2	5	19
3	10	2	1	23
3	1	2	10	32
2	5	3	2	19
2	2	3	5	16
2	10	3	1	32
2	1	3	10	23
6	5	1	2	17
6	2	1	5	32
6	10	1	1	16
6	1	1	10	61
1	5	6	2	32
1	2	6	5	17
1	10	6	1	61
1	1	6	10	16

4. Find a combination such that $ad + bc = 19$. As you can see from the table there are two such combinations, and each gives the same results:

$$ad + bc = 19$$
$$3 \cdot 5 + 2 \cdot 2 = 19$$

5. Use the combination in the second row of the table to factor the expression in question:

$$6x^2 + 19xy + 10y^2 = (3x + 2y)(2x + 5y)$$

CHECK As a check, expand $(3x + 2y)(2x + 5y)$.

$$(3x + 2y)(2x + 5y) = 6x^2 + 15xy + 4xy + 10y^2 = 6x^2 + 19xy + 10y^2$$

The combination in the fifth row of the table also gives the step-4 result.

PRACTICE PROBLEMS

10. Show that the combination in the fifth row of the table also gives the step-4 result.
11. Factor $2x^2 - 4xy + 2y^2$.
12. Factor $2x^4 + 10x^3 + 12x^2$.

M-6 EXPONENTS AND LOGARITHMS

EXPONENTS

The notation x^n stands for the quantity obtained by multiplying x times itself n times. For example, $x^2 = x \cdot x$ and $x^3 = x \cdot x \cdot x$. The quantity n is called the **power,** or the **exponent,** of x (the **base**). Listed below are some rules that will help you simplify terms that have exponents.

1. When two powers of x are multiplied, the exponents are added:

$$(x^m)(x^n) = x^{m+n} \qquad \text{M-6}$$

   Example: $x^2x^3 = x^{2+3} = (x \cdot x)(x \cdot x \cdot x) = x^5$.

2. Any number (except 0) raised to the 0 power is defined to be 1:

$$x^0 = 1 \qquad \text{M-7}$$

3. Based on rule 2,

$$x^n x^{-n} = x^0 = 1$$

$$x^{-n} = \frac{1}{x^n} \qquad \text{M-8}$$

4. When two powers are divided, the exponents are subtracted:

$$\frac{x^n}{x^m} = x^n x^{-m} = x^{n-m} \qquad \text{M-9}$$

5. When a power is raised to another power, the exponents are multiplied:

$$(x^n)^m = x^{nm} \qquad \text{M-10}$$

6. When exponents are written as fractions, they represent the roots of the base. For example,

$$x^{1/2} \cdot x^{1/2} = x$$

so

$$x^{1/2} = \sqrt{x} \qquad (x > 0)$$

Example M-6 Simplifying a Quantity That Has Exponents

Simplify $\frac{x^4 x^7}{x^8}$.

PICTURE According to rule 1, when two powers of x are multiplied, the exponents are added. Rule 4 states that when two powers are divided, the exponents are subtracted.

SOLVE

1. Simplify the numerator $x^4\,x^7$ using rule 1. $\quad x^4\,x^7 = x^{4+7} = x^{11}$
2. Simplify $\frac{x^{11}}{x^8}$ using rule 4: $\quad \frac{x^{11}}{x^8} = x^{11}\,x^{-8} = x^{11-8} = x^3$

CHECK Use the value $x = 2$ to determine if your answer is correct.

$$\frac{2^4 2^7}{2^8} = 2^3 = 8$$

$$\frac{2^4 2^7}{2^8} = \frac{(16)(128)}{256} = \frac{2048}{256} = 8$$

PRACTICE PROBLEMS

13. $(x^{1/18})^9 =$
14. $x^6 x^0 =$

LOGARITHMS

Any positive number can be expressed as some power of any other positive number except one. If y is related to x by $y = a^x$, then the number x is said to be the **logarithm** of y to the **base** a, and the relation is written

$$x = \log_a y$$

Thus, logarithms are *exponents*, and the rules for working with logarithms correspond to similar laws for exponents. Listed below are some rules that will help you simplify terms that have logarithms.

1. If $y_1 = a^n$ and $y_2 = a^m$, then

$$y_1 y_2 = a^n a^m = a^{n+m}$$

Correspondingly,

$$\log_a y_1 y_2 = \log_a a^{n+m} = n + m = \log_a a^n + \log_a a^m = \log_a y_1 + \log_a y_2 \qquad \text{M-11}$$

It then follows that

$$\log_a y^n = n \log_a y \qquad \text{M-12}$$

2. Because $a^1 = a$ and $a^0 = 1$,

$$\log_a a = 1 \qquad \text{M-13}$$

and

$$\log_a 1 = 0 \qquad \text{M-14}$$

There are two bases in common use: logarithms to base 10 are called **common logarithms,** and logarithms to base e (where $e = 2.718\ldots$) are called **natural logarithms.**

In this text, the symbol ln is used for natural logarithms and the symbol log, without a subscript, is used for common logarithms. Thus,

$$\log_e x = \ln x \quad \text{and} \quad \log_{10} x = \log x \qquad \text{M-15}$$

and $y = \ln x$ implies

$$x = e^y \qquad \text{M-16}$$

Logarithms can be changed from one base to another. Suppose that

$$z = \log x \qquad \text{M-17}$$

Then

$$10^z = 10^{\log x} = x \qquad \text{M-18}$$

Taking the natural logarithm of both sides of Equation M-18, we obtain

$$z \ln 10 = \ln x$$

Substituting $\log x$ for z (see Equation M-17) gives

$$\ln x = (\ln 10)\log x \qquad \text{M-19}$$

Example M-7 Converting Between Common Logarithms and Natural Logarithms

The steps leading to Equation M-19 show that, in general, $\log_b x = (\log_b a)\log_a x$, and thus that conversion of logarithms from one base to another requires only multiplication by a constant. Describe the mathematical relation between the constant for converting common logarithms to natural logarithms and the constant for converting natural logarithms to common logarithms.

PICTURE We have a general mathematical formula for converting logarithms from one base to another. We look for the mathematical relation by exchanging a for b and vice versa in the formula.

SOLVE

1. You have a formula for converting logarithms from base a to base b: $\log_b x = (\log_b a)\log_a x$
2. To convert from base b to base a, exchange all a for b and vice versa: $\log_a x = (\log_a b)\log_b x$
3. Divide both sides of the equation in step 1 by $\log_a x$: $\dfrac{\log_b x}{\log_a x} = \log_b a$
4. Divide both sides of the equation in step 2 by $(\log_a b)\log_a x$: $\dfrac{1}{\log_a b} = \dfrac{\log_b x}{\log_a x}$
5. The results show that the conversion factors $\log_b a$ and $\log_a b$ are reciprocals of one other: $\dfrac{1}{\log_a b} = \log_b a$

CHECK For the value of $\log_{10} e$, your calculator will give 0.43429. For ln 10, your calculator will give 2.3026. Multiply 0.43429 by 2.3026; you will get 1.0000.

PRACTICE PROBLEMS

15. Evaluate $\log_{10} 1000$.
16. Evaluate $\log_2 5$

M-7 GEOMETRY

The properties of the most common **geometric figures**—bounded shapes in two or three dimensions whose lengths, areas, or volumes are governed by specific ratios—are a basic analytical tool in physics. For example, the characteristic ratios within triangles give us the laws of *trigonometry* (see the next section of this tutorial), which in turn give us the theory of vectors, essential in analyzing motion in two or more dimensions. Circles and spheres are essential for understanding, among other concepts, angular momentum and the probability densities of quantum mechanics.

BASIC FORMULAS IN GEOMETRY

Circle The ratio of the circumference of a circle to its diameter is a number π, which has the approximate value

$$\pi = 3.141\,592$$

The circumference C of a circle is thus related to its diameter d and its radius r by

$$C = \pi d = 2\pi r \qquad \text{circumference of circle} \qquad \text{M-20}$$

The area of a circle is (Figure M-5)

$$A = \pi r^2 \qquad \text{area of circle} \qquad \text{M-21}$$

Parallelogram The area of a parallelogram is the base b times the height h (Figure M-6):

$$A = bh$$

The area of a triangle is one-half the base times the height (Figure M-7)

$$A = \frac{1}{2}bh$$

Sphere A sphere of radius r (Figure M-8) has a surface area given by

$$A = 4\pi r^2 \qquad \text{surface area of sphere} \qquad \text{M-22}$$

and a volume given by

$$V = \frac{4}{3}\pi r^3 \qquad \text{volume of sphere} \qquad \text{M-23}$$

Cylinder A cylinder of radius r and length L (Figure M-9) has surface area (not including the end faces) of

$$A = 2\pi rL \qquad \text{surface of cylinder} \qquad \text{M-24}$$

and volume of

$$V = \pi r^2 L \qquad \text{volume of cylinder} \qquad \text{M-25}$$

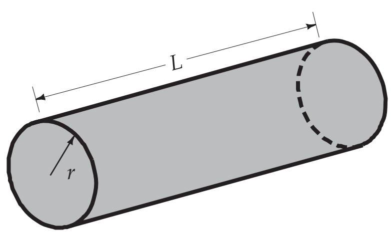

FIGURE M-9 Surface area (not including the end faces) and the volume of a cylinder.

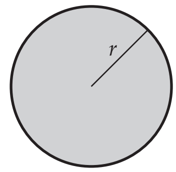

FIGURE M-5 Area of a circle.

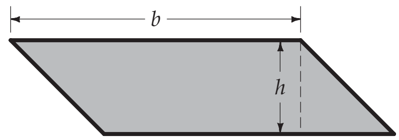

FIGURE M-6 Area of a parallelogram.

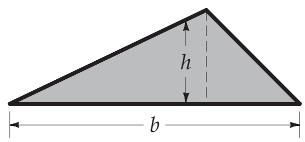

FIGURE M-7 Area of a triangle.

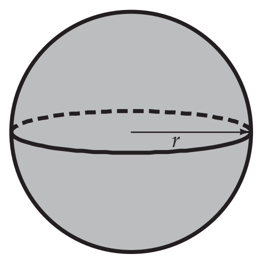

FIGURE M-8 Surface area and volume of a sphere.

Example M-8 Calculating the Mass of a Spherical Shell

An aluminum spherical shell has an outer diameter of 40.0 cm and an inner diameter of 39.0 cm. Find the volume of the aluminum in this shell.

PICTURE The volume of the aluminum in the spherical shell is the volume that remains when we subtract the volume of the inner sphere having $d_i = 2r_i = 39.0$ cm from the volume of the outer sphere having $d_o = 2r_o = 40.0\text{ cm}$.

SOLVE

1. Subtract the volume of the sphere of radius r_i from the volume of the sphere of radius r_o: $V = \frac{4}{3}\pi r_o^3 - \frac{4}{3}\pi r_i^3 = \frac{4}{3}\pi(r_o^3 - r_i^3)$
2. Substitute 20.0 cm for r_o and 19.5 cm for r_i: $V = \frac{4}{3}\pi[(20.0\text{ cm})^3 - (19.5\text{ cm})^3] = \boxed{2.45 \times 10^3\text{ cm}^3}$

CHECK The volume of the shell is expected to be the same order of magnitude as the volume of a hollow cube with an outside edge length of 40.0 cm and an inside edge length of 39.0 cm. The volume of such a hollow cube is $(40.0\text{ cm})^3 - (39.0\text{ cm})^3 = 4.68 \times 10^3\text{ cm}^3$. The step-2 result meets the expectation that the volume of the shell is the same order of magnitude as the volume of the hollow cube.

PRACTICE PROBLEMS

17. Find the ratio between the volume V and the surface A of a sphere of radius r.
18. What is the area of a cylinder that has a radius that is 1/3 its length?

M-8 TRIGONOMETRY

Trigonometry, which gets its name from Greek roots meaning "triangle" and "measure," is the study of some important mathematical functions, called **trigonometric functions.** These functions are most simply defined as ratios of the sides of right triangles. However, these right-triangle definitions are of limited use because they are valid only for angles between zero and 90°. However, the validity of the right-triangle definitions can be extended by defining the trigonometric functions in terms of the ratio of the coordinates of points on a circle of unit radius drawn centered at the origin of the xy plane.

In physics, we first encounter trigonometric functions when we use vectors to analyze motion in two dimensions. Trigonometric functions are also essential in the analysis of any kind of periodic behavior, such as circular motion, oscillatory motion, and wave mechanics.

ANGLES AND THEIR MEASURE: DEGREES AND RADIANS

The size of an angle formed by two intersecting straight lines is known as its **measure.** The standard way of finding the measure of an angle is to place the angle so that its **vertex,** or point of intersection of the two lines that form the angle, is at the center of a circle located at the origin of a graph that has Cartesian coordinates and one of the lines extends rightward on the positive x axis. The distance traveled *counterclockwise* on the circumference from the positive x axis to reach the intersection of the circumference with the other line defines the measure of the angle. (Traveling clockwise to the second line would simply give us a negative measure; to illustrate basic concepts, we position the angle so that the smaller rotation will be in the counterclockwise direction.)

The most familiar unit for expressing the measure of an angle is the **degree,** which equals 1/360 of the full distance around the circumference of the circle. For greater precision, or for smaller angles, we either show degrees plus minutes (′)

and seconds (″), with 1′ = 1°/60 and 1″ = 1′/60 = 1°/3600; or show degrees as an ordinary decimal number.

For scientific work, a more useful measure of an angle is the **radian** (rad). Again, place the angle with its vertex at the center of a circle and measure counterclockwise rotation around the circumference. The measure of the angle in radians is then defined as the length of the circular arc from one line to the other divided by the radius of the circle (Figure M-10). If s is the arc length and r is the radius of the circle, the angle θ measured in radians is

$$\theta = \frac{s}{r} \qquad \text{M-26}$$

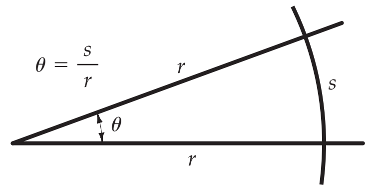

FIGURE M-10 The angle θ in radians is defined to be the ratio s/r, where s is the arc length intercepted on a circle of radius r.

Because the angle measured in radians is the ratio of two lengths, it is dimensionless. The relation between radians and degrees is

$$360° = 2\pi \text{ rad}$$

or

$$1 \text{ rad} = \frac{360°}{2\pi} = 57.3°$$

Figure M-11 shows some useful relations for angles.

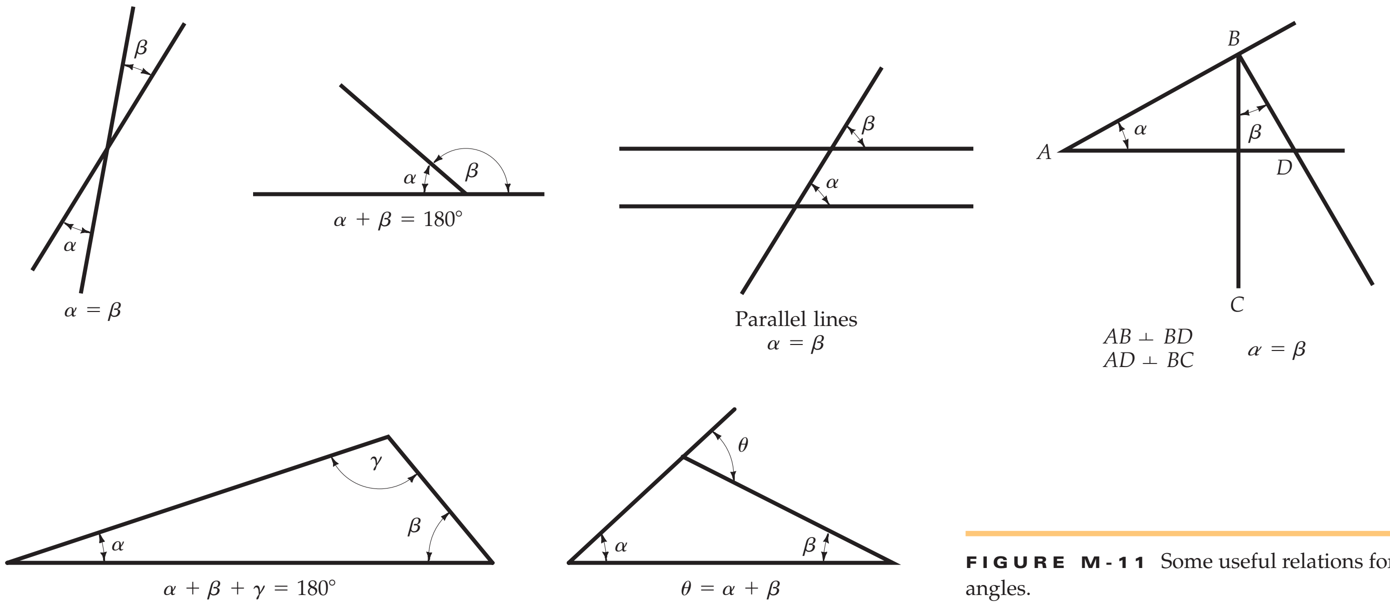

FIGURE M-11 Some useful relations for angles.

THE TRIGONOMETRIC FUNCTIONS

Figure M-12 shows a right triangle formed by drawing the line BC perpendicular to AC. The lengths of the sides are labeled a, b, and c. The right-triangle definitions of the trigonometric functions $\sin\theta$ (the **sine**), $\cos\theta$ (the **cosine**), and $\tan\theta$ (the **tangent**) for an acute angle θ are

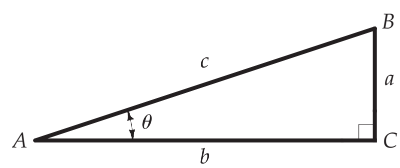

FIGURE M-12 A right triangle with sides of length a and b and a hypotenuse of length c.

$$\sin\theta = \frac{a}{c} = \frac{\text{Opposite side}}{\text{Hypotenuse}} \qquad \text{M-27}$$

$$\cos\theta = \frac{b}{c} = \frac{\text{Adjacent side}}{\text{Hypotenuse}} \qquad \text{M-28}$$

$$\tan\theta = \frac{a}{b} = \frac{\text{Opposite side}}{\text{Adjacent side}} = \frac{\sin\theta}{\cos\theta} \qquad \text{M-29}$$

(**Acute angles** are angles whose positive rotation around the circumference of a circle measures less than 90°, or $\pi/2$.) Three other trigonometric functions—the

secant (sec), the **cosecant** (csc), and the **cotangent** (cot), defined as the reciprocals of these functions—are

$$\sec\theta = \frac{c}{b} = \frac{1}{\cos\theta} \qquad \text{M-30}$$

$$\csc\theta = \frac{c}{a} = \frac{1}{\sin\theta} \qquad \text{M-31}$$

$$\cot\theta = \frac{b}{a} = \frac{1}{\tan\theta} = \frac{\cos\theta}{\sin\theta} \qquad \text{M-32}$$

The angle θ, whose sine is x, is called the arcsine of x, and is written $\sin^{-1} x$. That is, if

$$\sin\theta = x$$

then

$$\theta = \arcsin x = \sin^{-1} x \qquad \text{M-33}$$

The arcsine is the inverse of the sine. The inverse of the cosine and tangent are defined similarly. The angle whose cosine is y is the arccosine of y. That is, if

$$\cos\theta = y$$

then

$$\theta = \arccos y = \cos^{-1} y \qquad \text{M-34}$$

The angle whose tangent is z is the arctangent of z. That is, if

$$\tan\theta = z$$

then

$$\theta = \arctan z = \tan^{-1} z \qquad \text{M-35}$$

TRIGONOMETRIC IDENTITIES

We can derive several useful formulas, called **trigonometric identities,** by examining relationships between the trigonometric functions. Equations M-30 through M-32 list three of the most obvious identities, formulas expressing some trigonometric functions as reciprocals of others. Almost as easy to discern are identities derived from the **Pythagorean theorem,**

$$a^2 + b^2 = c^2 \qquad \text{M-36}$$

(Figure M-13 illustrates a graphic proof of the theorem.) Simple algebraic manipulation of Equation M-36 gives us three more identities. First, if we divide each term in Equation M-36 by c^2, we obtain

$$\frac{a^2}{c^2} + \frac{b^2}{c^2} = 1$$

or, from the definitions of $\sin\theta$ (which is a/c) and $\cos\theta$ (which is b/c)

$$\sin^2\theta + \cos^2\theta = 1 \qquad \text{M-37}$$

Similarly, we can divide each term in Equation M-36 by a^2 or b^2 and obtain

$$1 + \cot^2\theta = \csc^2\theta \qquad \text{M-38}$$

and

$$1 + \tan^2\theta = \sec^2\theta \qquad \text{M-39}$$

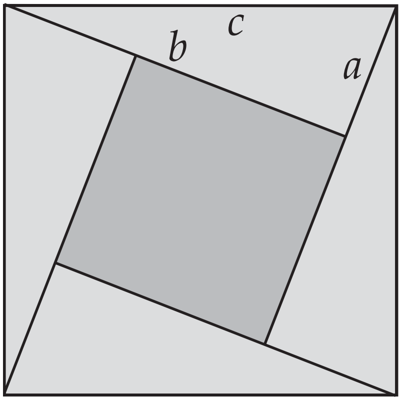

FIGURE M-13 When this figure was first published, the letters were absent and it was accompanied by the single word "Behold!" Using the drawing, establish the Pythagorean theorem ($a^2 + b^2 = c^2$).

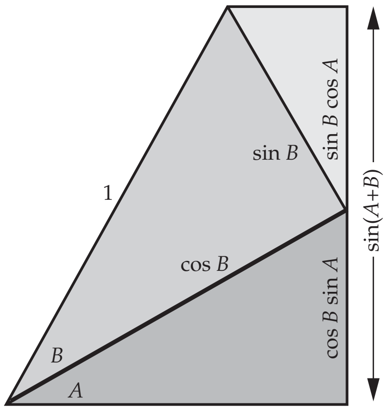

FIGURE M-14 Using this drawing, establish the identity $\sin(A + B) = \sin A \cos B + \cos A \sin B$. You can also use it to establish the identity $\cos(A + B) = \cos A \cos B - \sin A \sin B$. Try it.

Table M-2 Trigonometric Identities

$$\sin(A \pm B) = \sin A \cos B \pm \cos A \sin B$$

$$\cos(A \pm B) = \cos A \cos B \mp \sin A \sin B$$

$$\tan(A \pm B) = \frac{\tan A \pm \tan B}{1 \mp \tan A \tan B}$$

$$\sin A \pm \sin B = 2 \sin\left[\frac{1}{2}(A \pm B)\right]\cos\left[\frac{1}{2}(A \mp B)\right]$$

$$\cos A + \cos B = 2 \cos\left[\frac{1}{2}(A + B)\right]\cos\left[\frac{1}{2}(A - B)\right]$$

$$\cos A - \cos B = 2 \sin\left[\frac{1}{2}(A + B)\right]\sin\left[\frac{1}{2}(B - A)\right]$$

$$\tan A \pm \tan B = \frac{\sin(A \pm B)}{\cos A \cos B}$$

$$\sin^2\theta + \cos^2\theta = 1; \sec^2\theta - \tan^2\theta = 1; \csc^2\theta - \cot^2\theta = 1$$

$$\sin 2\theta = 2 \sin\theta \cos\theta$$

$$\cos 2\theta = \cos^2\theta - \sin^2\theta = 2\cos^2\theta - 1 = 1 - 2\sin^2\theta$$

$$\tan 2\theta = \frac{2\tan\theta}{1 - \tan^2\theta}$$

$$\sin\frac{1}{2}\theta = \pm\sqrt{\frac{1 - \cos\theta}{2}}; \cos\frac{1}{2}\theta = \pm\sqrt{\frac{1 + \cos\theta}{2}}; \tan\frac{1}{2}\theta = \pm\sqrt{\frac{1 - \cos\theta}{1 + \cos\theta}}$$

Table M-2 lists these last three and many more trigonometric identities. Notice that they fall into four categories: functions of sums or differences of angles, sums or differences of squared functions, functions of double angles (2θ), and functions of half angles $\left(\frac{1}{2}\theta\right)$. Notice that some of the formulas contain paired alternatives, expressed with the signs $\pm$ and $\mp$; in such formulas, remember to always apply the formula with either all the "upper" or all the "lower" alternatives. Figure M-14 shows a graphic proof of the first two sum-of-angle identities.

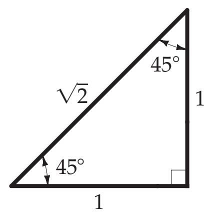

FIGURE M-15 An isosceles right triangle.

SOME IMPORTANT VALUES OF THE FUNCTIONS

Figure M-15 is a diagram of an *isosceles* right triangle (an isosceles triangle is a triangle with two equal sides), from which we can find the sine, cosine, and tangent of 45°. The two acute angles of this triangle are equal. Because the sum of the three angles in a triangle must equal 180° and the right angle is 90°, each acute angle must be 45°. For convenience, let us assume that the equal sides each have a length of 1 unit. The Pythagorean theorem gives us a value for the hypotenuse of

$$c = \sqrt{a^2 + b^2} = \sqrt{1^2 + 1^2} = \sqrt{2} \text{ units}$$

We calculate the values of the functions as follows:

$$\sin 45^\circ = \frac{a}{c} = \frac{1}{\sqrt{2}} = 0.707 \quad \cos 45^\circ = \frac{b}{c} = \frac{1}{\sqrt{2}} = 0.707 \quad \tan 45^\circ = \frac{a}{b} = \frac{1}{1} = 1$$

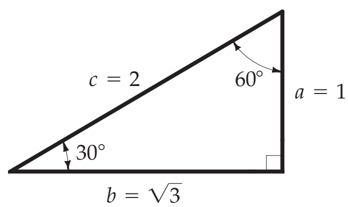

FIGURE M-16 A 30°–60° right triangle.

Another common triangle, a 30°–60° right triangle, is shown in Figure M-16. Because this particular right triangle is in effect half of an *equilateral triangle* (a 60°–60°–60° triangle, or a triangle having three equal sides and three equal angles), we can see that the sine of 30° must be exactly 0.5 (Figure M-17). The equilateral triangle must have all sides equal to c, the hypotenuse of the 30°–60° right triangle. Thus, side a is one-half the length of the hypotenuse, and so

$$\sin 30^\circ = \frac{1}{2}$$

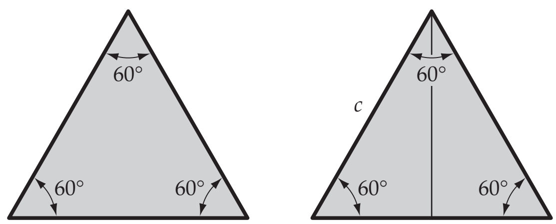

FIGURE M-17 (a) An equilateral triangle. (b) An equilateral triangle that has been bisected to form two 30°–60° right triangles.

To find the other ratios within the 30–60° right triangle, let us assign a value of 1 to the side opposite the 30° angle. Then

$$c = \frac{1}{0.5} = 2 \qquad b = \sqrt{c^2 - a^2} = \sqrt{2^2 - 1^2} = \sqrt{3}$$

$$\cos 30° = \frac{b}{c} = \frac{\sqrt{3}}{2} = 0.866 \qquad \tan 30° = \frac{a}{b} = \frac{1}{\sqrt{3}} = 0.577$$

$$\sin 60° = \frac{b}{c} = \cos 30° = 0.866 \qquad \cos 60° = \frac{a}{c} = \sin 30° = \frac{1}{2}$$

$$\tan 60° = \frac{b}{a} = \frac{\sqrt{3}}{1} = 1.732$$

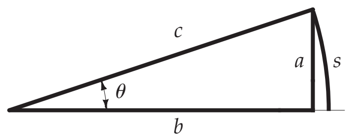

FIGURE M-18 For small angles, $\sin\theta = a/c$, $\tan\theta = a/b$, and the angle $\theta = s/c$ are all approximately equal.

SMALL-ANGLE APPROXIMATION

For small angles, the length a is nearly equal to the arc length s, as can be seen in Figure M-18. The angle $\theta = s/c$ is therefore nearly equal to $\sin\theta = a/c$:

$$\sin\theta \approx \theta \qquad \text{for small values of } \theta \qquad \text{M-40}$$

Similarly, the lengths c and b are nearly equal, so $\tan\theta = a/b$ is nearly equal to both θ and $\sin\theta$ for small values of θ:

$$\tan\theta \approx \sin\theta \approx \theta \qquad \text{for small values of } \theta \qquad \text{M-41}$$

Equations M-40 and M-41 hold only if θ is measured in radians. Because $\cos\theta = b/c$, and because these lengths are nearly equal for small values of θ, we have

$$\cos\theta \approx 1 \qquad \text{for small values of } \theta \qquad \text{M-42}$$

Figure M-19 shows graphs of θ, $\sin\theta$, and $\tan\theta$ versus θ for small values of θ. If accuracy of a few percent is needed, small-angle approximations can be used only for angles of about a quarter of a radian (or about 15°) or less. Below this value, as the angle becomes smaller, the approximation $\theta \approx \sin\theta \approx \tan\theta$ is even more accurate.

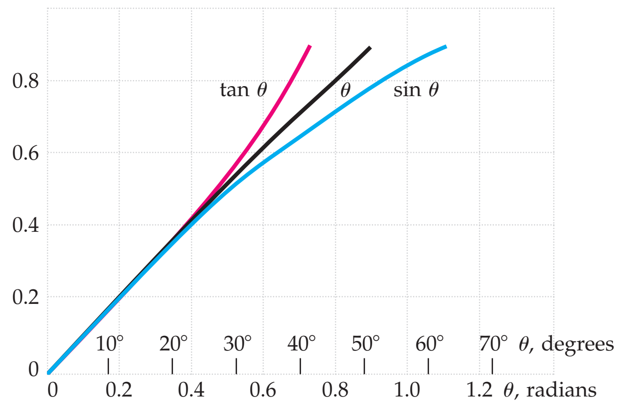

FIGURE M-19 Graphs of $\tan\theta$, θ, and $\sin\theta$ versus θ for small values of θ.

TRIGONOMETRIC FUNCTIONS AS FUNCTIONS OF REAL NUMBERS

So far we have illustrated the trigonometric functions as properties of angles. Figure M-20 shows an *obtuse* angle with its vertex at the origin and one side along the x axis. The trigonometric functions for a "general" angle such as this are defined by

$$\sin\theta = \frac{y}{c} \qquad \text{M-43}$$

$$\cos\theta = \frac{x}{c} \qquad \text{M-44}$$

$$\tan\theta = \frac{y}{x} \qquad \text{M-45}$$

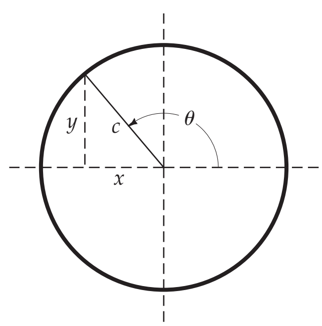

FIGURE M-20 Diagram for defining the trigonometric functions for an obtuse angle.

It is important to remember that values of x to the left of the vertical axis and values of y below the horizontal axis are negative; c in the figure is always regarded as positive. Figure M-21 shows plots of the general sine, cosine, and tangent functions versus θ. The sine function has a period of 2π rad. Thus, for any value of θ, $\sin(\theta + 2\pi) = \sin\theta$, and so forth. That is, when an angle changes by 2π rad, the function returns to its original value. The tangent function has a

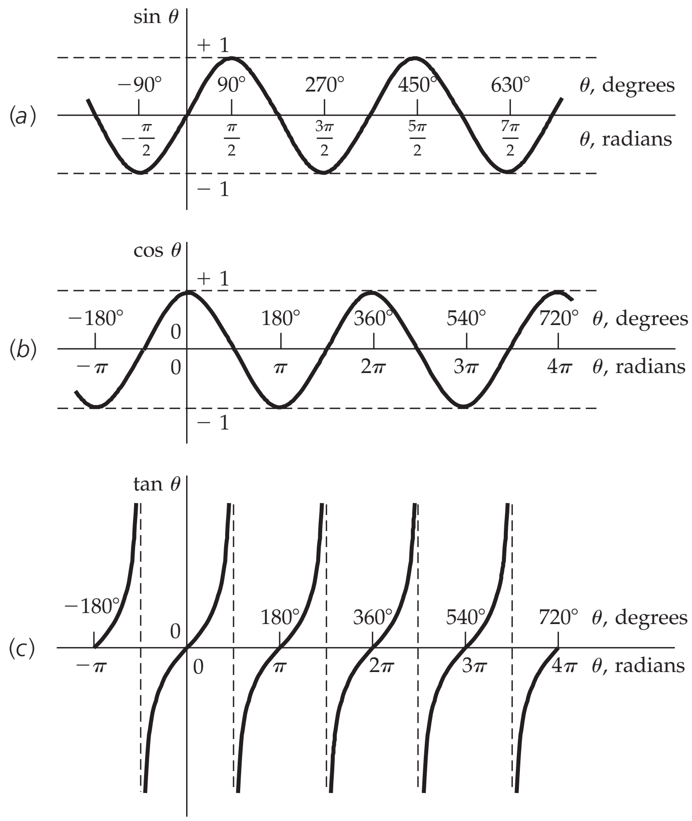

FIGURE M-21 The trigonometric functions $\sin\theta$, $\cos\theta$, and $\tan\theta$ versus θ.

period of π rad. Thus, $\tan(\theta + \pi) = \tan\theta$, and so forth. Some other useful relations are

$$\sin(\pi - \theta) = \sin\theta \qquad \text{M-46}$$

$$\cos(\pi - \theta) = -\cos\theta \qquad \text{M-47}$$

$$\sin(\tfrac{1}{2}\pi - \theta) = \cos\theta \qquad \text{M-48}$$

$$\cos(\tfrac{1}{2}\pi - \theta) = \sin\theta \qquad \text{M-49}$$

Because the radian is dimensionless, it is not hard to see from the plots in Figure M-21 that the trigonometric functions are functions of all real numbers. The functions can also be expressed as power series in θ. The series for $\sin\theta$ and $\cos\theta$ are

$$\sin\theta = \theta - \frac{\theta^3}{3!} + \frac{\theta^5}{5!} - \frac{\theta^7}{7!} + \cdots \qquad \text{M-50}$$

$$\cos\theta = 1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \frac{\theta^6}{6!} + \cdots \qquad \text{M-51}$$

When θ is small, good approximations are obtained using only the first few terms in the series.

Example M-9 Cosine of a Sum

Using the suitable trigonometric identity from Table M-2, find $\cos(135° + 22°)$. Give your answer in four significant figures.

PICTURE As long as all angles are given in degrees, there is no need to convert to radians, because all operations are numerical values of the functions. Be sure, however, that your calculator is in degree mode. The suitable identity is $\cos(A \pm B) = \cos A \cos B \mp \sin A \sin B$, where the upper signs are appropriate.

SOLVE

1. Write the trigonometric identity for the cosine of a sum, with $A = 135°$ and $B = 22°$:

$$\cos(135° + 22°) = (\cos 135°)(\cos 22°) - (\sin 135°)(\sin 22°)$$

2. Using a calculator, find cos 135°, sin 135°, cos 22°, and sin 22°:

$\cos 135° = -0.7071$ $\quad \sin 135° = 0.7071$
$\cos 22° = 0.9272$ $\quad \sin 22° = 0.3746$

3. Enter the values in the formula and calculate the answer:

$$\cos(135° + 22°) = (-0.7071)(0.9272) - (0.7071)(0.3746) = -0.9205$$

CHECK The calculator shows that the $\cos(135° + 22°) = \cos(157°) = -0.9205$.

PRACTICE PROBLEMS

19. Find $\sin\theta$ and $\cos\theta$ for the right triangle shown in Figure M-12 in which $a = 4$ cm and $b = 7$ cm. What is the value for θ?
20. Find $\sin\theta$ where $\theta = 8.2°$. Is your answer consistent with the small-angle approximation?

M-9 THE BINOMIAL EXPANSION

A **binomial** is an expression consisting of two terms joined by a plus sign or a minus sign. The **binomial theorem** states that a binomial raised to a power can be written, or *expanded*, as a series of terms. If we raise the binomial $(1 + x)$ to a power n, the binomial theorem takes the form

$$(1 + x)^n = 1 + nx + \frac{n(n-1)}{2!}x^2 + \frac{n(n-1)(n-2)}{3!}x^3 + \cdots \qquad \text{M-52}$$

The series is valid for any value of n if $|x|$ is less than 1. The binomial expansion is very useful for approximating algebraic expressions, because when $|x| < 1$, the higher-order terms in the sum are small. (The order of a term is the power of x in the term. Thus, the terms explicitly shown in Equation M-52 are of order 0, 1, 2, and 3.) The series is particularly useful in situations where $|x|$ is small compared with 1; then each term is *much* smaller than the previous term and we can drop all but the first two or three terms in the expansion. If $|x|$ is much less than 1, we have

$$(1 + x)^n \approx 1 + nx, \qquad |x| \ll 1 \qquad \text{M-53}$$

The binomial expansion is used in deriving many formulas of calculus that are important in physics. A well-known use in physics of the approximation in Equation M-53 is the proof that relativistic kinetic energy reduces to the classic formula when the velocity of a particle is very small compared with the velocity of light c.

Example M-10 Using the Binomial Expansion to Find a Power of a Number

Use Equation M-53 to find an approximate value for the square root of 101.

PICTURE The number 101 readily suggests a binomial, namely, $(100 + 1)$. To approximate the answer using the binomial expansion, we must manipulate the expression to get a binomial consisting of 1 and a term less than 1.

SOLVE

1. Write $(101)^{1/2}$ to give an expression $(1 + x)^n$ in which x is much less than 1:

$$(101)^{1/2} = (100 + 1)^{1/2} = (100)^{1/2}(1 + 0.01)^{1/2} = 10(1 + 0.01)^{1/2}$$

2. Use Equation M-53 with $n = \frac{1}{2}$ and $x = 0.01$ to expand $(1 + 0.01)^{1/2}$:

$$(1 + 0.01)^{1/2} = 1 + \tfrac{1}{2}(0.01) + \frac{\frac{1}{2}\left(-\frac{1}{2}\right)}{2}(0.01)^2 + \cdots$$

3. Because $|x| \ll 1$, we expect the magnitude of terms of order 2 and higher to be significantly smaller than the magnitude of the first-order term. Approximate the binomial (1) by keeping only the zeroth and first-order terms, and (2) by keeping only the first 3 terms:

Keeping only the zeroth and first-order terms gives

$$(1 + 0.01)^{1/2} \approx 1 + \tfrac{1}{2}(0.01) = 1 + 0.005\,000\,0$$
$$= 1.005\,000\,0$$

Keeping only the zeroth, first-, and second-order terms gives

$$(1 + 0.01)^{1/2} \approx 1 + \tfrac{1}{2}(0.01) + \frac{\tfrac{1}{2}(-\tfrac{1}{2})}{2}(0.01)^2$$
$$\approx 1 + 0.005\,000\,0 - 0.000\,012\,5$$
$$= 1.004\,987\,5$$

4. Substitute these results into the equation in step 1:

Keeping only the zeroth and first-order terms gives

$$(101)^{1/2} = 10(1 + 0.01)^{1/2} \approx \boxed{10.050\,000}$$

Keeping only the zeroth, first-, and second-order terms gives

$$(101)^{1/2} = 10(1 + 0.01)^{1/2} \approx \boxed{10.049\,875}$$

CHECK We therefore expect our answer to be correct to within about 0.001%. The value of $(101)^{1/2}$, to eight figures, is 10.049 876. This differs from 10.050 000 by 0.000 124, or about one part in 10^5, and differs from 10.049 875 by about one part in 10^7.

PRACTICE PROBLEMS For the following, calculate the answer keeping the zeroth and first-order terms in the binomial series (Equation M-53), find the answer using your calculator, and show the percentage discrepancy between the two values:

21. $(1 + 0.001)^{-4}$
22. $(1 - 0.001)^{40}$

M-10 COMPLEX NUMBERS

Real numbers are all numbers, from $-\infty$ to $+\infty$, that can be *ordered*. We know that, given two real numbers, one is always equal to, greater than, or less than the other. For example, $3 > 2$, $1.4 < \sqrt{2} < 1.5$, and $3.14 < \pi < 3.15$. A number that *cannot* be ordered is $\sqrt{-1}$; we cannot measure the size of this number, and so it makes no sense to say, for example, that $3 \times \sqrt{-1}$ is greater than or less than $2 \times \sqrt{-1}$. The earliest mathematicians who dealt with numbers containing $\sqrt{-1}$ referred to these numbers as *imaginary* numbers because they could not be used to measure or count something. In mathematics the symbol i is used to represent $\sqrt{-1}$.

Equation M-5, the quadratic formula, applies to equations of the form

$$ax^2 + bx + c = 0$$

The formula shows that there are no real roots when $b^2 < 4ac$. There are, however, still two roots. Each root is a number containing two terms: a real number, and a multiple of $i = \sqrt{-1}$. The multiple of i is called an **imaginary number,** and i is called the **unit imaginary.**

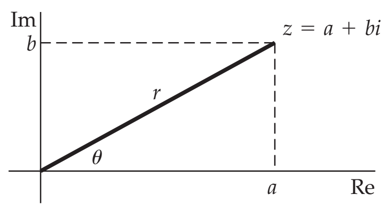
A general **complex number** z can be written

$$z = a + bi \qquad \text{M-54}$$

where a and b are real numbers. The quantity a is called the real part of z, or Re(z), and the quantity b is called the imaginary part of z, or Im(z). We can represent a complex number z as a point in a plane, called the complex plane, as shown in Figure M-22, where the x axis is the **real axis** and the y axis is the **imaginary axis.** We can also use the relations $a = r\cos\theta$ and $b = r\sin\theta$ from Figure M-22 to write the complex number z in **polar coordinates** (a system in which a point is designated by the counterclockwise angle of rotation θ and the distance r in the direction of θ):

$$z = r\cos\theta + ir\sin\theta \qquad \text{M-55}$$

where $r = \sqrt{a^2 + b^2}$ is called the **magnitude** of z.



$$z = a + bi$$
$$= r\cos\theta + (r\sin\theta)i$$
$$= r(\cos\theta + i\sin\theta)$$

FIGURE M-22 Representation of a complex number in a plane. The real part of the complex number is plotted along the horizontal axis, and the imaginary part is plotted along the vertical axis.

When complex numbers are added or subtracted, the real and imaginary parts are added or subtracted separately:

$$z_1 + z_2 = (a_1 + ib_1) + (a_2 + ib_2) = (a_1 + a_2) + i(b_1 + b_2) \qquad \text{M-56}$$

However, when two complex numbers are multiplied, each part of one number is multiplied by each part of the other number:

$$\begin{aligned} z_1 z_2 &= (a_1 + ib_1)(a_2 + ib_2) = a_1a_2 + i^2b_1b_2 + i(a_1b_2 + a_2b_1) \\ &= a_1a_2 - b_1b_2 + i(a_1b_2 + a_2b_1) \end{aligned} \qquad \text{M-57}$$

where we have used $i^2 = -1$.

The **complex conjugate** z^* of the complex number z is that number obtained by replacing i with $-i$ when writing z. If $z = a + ib$, then

$$z^* = (a + ib)^* = a - ib \qquad \text{M-58}$$

(When a quadratic equation has complex roots, the roots are **conjugate complex numbers,** in the form $a \pm bi$.) The product of a complex number and its complex conjugate equals the square of the magnitude of the number:

$$zz^* = (a + ib)(a - ib) = a^2 + b^2 = r^2 \qquad \text{M-59}$$

A particularly useful function of a complex number is the exponential $e^{i\theta}$. Using an expansion for e^x, we have

$$e^{i\theta} = 1 + i\theta + \frac{(i\theta)^2}{2!} + \frac{(i\theta)^3}{3!} + \frac{(i\theta)^4}{4!} + \cdots$$

Using $i^2 = -1$, $i^3 = -i$, $i^4 = +1$, and so forth, and separating the real parts from the imaginary parts, this expansion can be written

$$e^{i\theta} = \left(1 - \frac{\theta^2}{2!} + \frac{\theta^4}{4!} - \cdots\right) + i\left(\theta - \frac{\theta^3}{3!} + \cdots\right)$$

Comparing this result with Equations M-50 and M-51, we can see that

$$e^{i\theta} = \cos\theta + i\sin\theta \qquad \text{M-60}$$

Using this result, we can express a general complex number as an exponential:

$$z = a + ib = r\cos\theta + ir\sin\theta = re^{i\theta} \qquad \text{M-61}$$

If $z = x + iy$, where x and y are real variables, then z is called a **complex variable.**

COMPLEX VARIABLES IN PHYSICS

Complex variables are often used in formulas describing AC circuits: the impedance of a capacitor or an inductor includes a real part (the resistance) and an imaginary part (the reactance). (There are alternative ways, however, of analyzing AC circuits—such as rotating vectors called *phasors*—that do not require assigning imaginary values.) Complex variables are also important in the study of harmonic waves through Fourier analysis and synthesis. The time-dependent Schrödinger equation contains a complex-valued function of position and time.

Example M-11 Finding a Power of a Complex Number

Calculate $(1 + 3i)^4$ by using the binomial expansion.

PICTURE The expression is of the form $(1 + x)^n$. Because n is a positive integer, the expansion is valid for any value of x, and all terms, other than those of order n or lower must equal zero.

SOLVE

1. Write out the expansion of $(1 + 3i)^4$ to show the terms up through the fouth-order term:

$$1 + 4\cdot 3i + \frac{4(3)}{2!}(3i)^2 + \frac{4(3)(2)}{3!}(3i)^3 + \frac{4(3)(2)(1)}{4!}(3i)^4$$

2. Evaluate each term, remembering that $i^2 = -1$, $i^3 = -i$, and $i^4 = +1$: $1 + 12i - 54 - 108i + 81$

3. Show the result in the form $a + bi$: $(1 + 3i)^4 = \boxed{28 - 96i}$

CHECK We can solve the problem algebraically to show that the answer is correct. We first square $(1 + 3i)$ and then square the result, to get $(1 + 3i)^4$:

$$(1 + 3i)^2 = 1 \cdot 1 + 2 \cdot 1 \cdot 3i + (3i)^2 = 1 + 6i - 9 = -8 + 6i$$
$$(-8 + 6i)^2 = (-8)(-8) + 2(-8)(6i) + (6i)^2 = 64 - 96i - 36 = 28 - 96i$$

PRACTICE PROBLEMS Express in the form $a + bi$:

23. $e^{i\pi}$

24. $e^{i\pi/2}$

M-11 DIFFERENTIAL CALCULUS

Calculus is the branch of mathematics that allows us to deal with instantaneous rates of change of functions and variables. From the equation of a function—say, x as a function of t—we can always find x for a particular t, but with the methods of calculus you can go much further. You can know where x will have certain properties, such as a maximum or a minimum value, without having to try endless values of t. With calculus, if given the proper data, you can find, for example, the location of maximum stress on a beam, or the velocity or position of a falling object at a time t, or the energy a falling object has acquired at the time of impact. The principles of calculus are derived from examining functions at the infinitesimal level—analyzing how, say, x will change when the change in t becomes vanishingly small. We start with **differential calculus,** in which we determine the *limit* of the rate of change of x with respect to t as the change in t becomes closer and closer to zero.

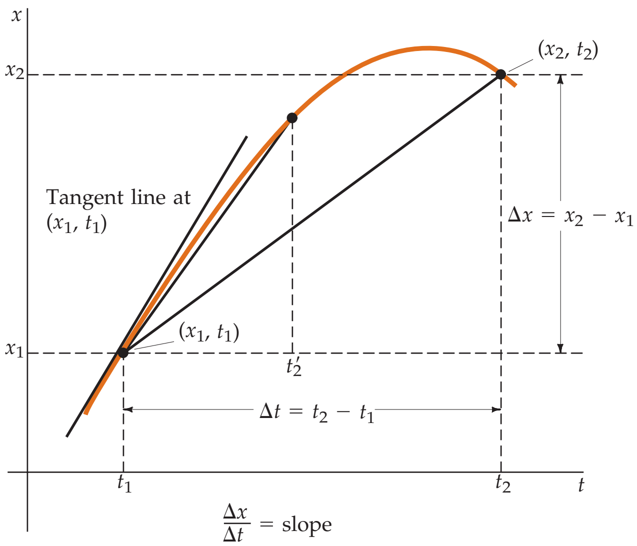


FIGURE M-23 Graph of a typical function $x(t)$. The points (x_1, t_1) and (x_2, t_2) are connected by a straight line. The slope of this line is $\Delta x/\Delta t$. As the time interval beginning at t_1 is decreased, the slope for that interval approaches the slope of the line tangent to the curve at time t_1, which is the derivative of x with respect to t.

Figure M-23 is a graph of x versus t for a typical function $x(t)$. At a particular value $t = t_1$, x has the value of x_1, as indicated. At another value t_2, x has the value x_2. The change in t, $t_2 - t_1$, is written $\Delta t = t_2 - t_1$; and the corresponding change in x is written $\Delta x = x_2 - x_1$. The ratio $\Delta x/\Delta t$ is the slope of the straight line connecting (x_1, t_1) and (x_2, t_2). If we take the limit as t_2 approaches t_1 (as Δt approaches zero) the slope of the line connecting (x_1, t_1) and (x_2, t_2) approaches the slope of the line that is tangent to the curve at the point (x_1, t_1). The slope of this tangent line is equal to the **derivative** of x with respect to t and is written dx/dt:

$$\frac{dx}{dt} = \lim_{\Delta t \to 0} \frac{\Delta x}{\Delta t} \qquad \text{M-62}$$

(When we find the derivative of a function, we say that we are **differentiating** the function; and the very small "dx" and "dt" elements are called **differentials** of x and t, respectively.) The derivative of a function of t is another function of t. If x is a constant and does not change, the graph of x versus t is a horizontal line with zero slope. The derivative of a constant is thus zero. In Figure M-24, x is not constant but is proportional to t:

$$x = Ct$$

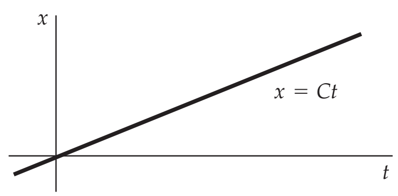

FIGURE M-24 Graph of the linear function $x = Ct$. This function has a constant slope C.

This function has a constant slope equal to C. Thus the derivative of Ct is C. Table M-3 lists some properties of derivatives and the derivatives of some particular functions that occur often in physics. It is followed by comments aimed at making these properties and rules clearer. More detailed discussion can be found in most calculus textbooks.

Table M-3 Properties of Derivatives and Derivatives of Particular Functions

Linearity

1. The derivative of a constant C times a function $f(t)$ equals the constant times the derivative of the function:

$$\frac{d}{dt}[Cf(t)] = C\frac{df(t)}{dt}$$

2. The derivative of a sum of functions equals the sum of the derivatives of the functions:

$$\frac{d}{dt}[f(t) + g(t)] = \frac{df(t)}{dt} + \frac{dg(t)}{dt}$$

Chain rule

3. If f is a function of x and x is in turn a function of t, the derivative of f with respect to t equals the product of the derivative of f with respect to x and the derivative of x with respect to t:

$$\frac{d}{dt}f(x(t)) = \frac{df}{dx}\frac{dx}{dt}$$

Derivative of a product

4. The derivative of a product of functions $f(t)g(t)$ equals the first function times the derivative of the second plus the second function times the derivative of the first:

$$\frac{d}{dt}[f(t)g(t)] = f(t)\frac{dg(t)}{dt} + g(t)\frac{df(t)}{dt}$$

Reciprocal derivative

5. The derivative of t with respect to x is the reciprocal of the derivative of x with respect to t, assuming that neither derivative is zero:

$$\frac{dt}{dx} = \left(\frac{dx}{dt}\right)^{-1} \quad \text{if} \quad \frac{dt}{dx} \neq 0 \quad \text{and} \quad \frac{dx}{dt} \neq 0$$

Derivatives of particular functions

6. If C is a constant, then $dC/dt = 0$.

7. $\dfrac{d(t^n)}{dt} = nt^{n-1}$ If n is constant.

8. $\dfrac{d}{dt}\sin \omega t = \omega \cos \omega t$ If ω is constant.

9. $\dfrac{d}{dt}\cos \omega t = -\omega \sin \omega t$ If ω is constant.

10. $\dfrac{d}{dt}\tan \omega t = \omega \sin^2 \omega t$ If ω is constant.

11. $\dfrac{d}{dt}e^{bt} = be^{bt}$ If b is constant.

12. $\dfrac{d}{dt}\ln bt = \dfrac{1}{t}$ If b is constant.

COMMENTS ON RULES 1 THROUGH 5

Rules 1 and 2 follow from the fact that the limiting process is linear. We can understand rule 3, the chain rule, by multiplying $\Delta f/\Delta t$ by $\Delta x/\Delta x$ and noting that as Δt approaches zero, Δx also approaches zero. That is,

$$\lim_{\Delta t\to 0}\frac{\Delta f}{\Delta t} = \lim_{\Delta t\to 0}\left(\frac{\Delta f}{\Delta t}\frac{\Delta x}{\Delta x}\right) = \lim_{\Delta t\to 0}\left(\frac{\Delta f}{\Delta x}\frac{\Delta x}{\Delta t}\right) = \left(\lim_{\Delta x\to 0}\frac{\Delta f}{\Delta x}\right)\left(\lim_{\Delta t\to 0}\frac{\Delta x}{\Delta t}\right) = \frac{df}{dx}\frac{dx}{dt}$$

where we have used that the limit of the product is equal to product of the limits.

Rule 4 is not immediately apparent. The derivative of a product of functions is the limit of the ratio

$$\frac{f(t+\Delta t)g(t+\Delta t) - f(t)g(t)}{\Delta t}$$

If we add and subtract the quantity $f(t+\Delta t)g(t)$ in the numerator, we can write this ratio as

$$\frac{f(t+\Delta t)g(t+\Delta t) - f(t+\Delta t)g(t) + f(t+\Delta t)g(t) - f(t)g(t)}{\Delta t}$$
$$= f(t+\Delta t)\left[\frac{g(t+\Delta t)-g(t)}{\Delta t}\right] + g(t)\left[\frac{f(t+\Delta t)-f(t)}{\Delta t}\right]$$

As Δt approaches zero, the terms in square brackets become $dg(t)/dt$ and $df(t)/dt$, respectively, and the limit of the expression is

$$f(t)\frac{dg(t)}{dt} + g(t)\frac{df(t)}{dt}$$

Rule 5 follows directly from the definition:

$$\frac{dx}{dt} = \lim_{\Delta t\to 0}\frac{\Delta x}{\Delta t} = \lim_{\Delta x\to 0}\left(\frac{\Delta t}{\Delta x}\right)^{-1} = \left(\frac{dt}{dx}\right)^{-1}$$

COMMENTS ON RULE 7

We can obtain this important result using the binomial expansion. We have

$$f(t) = t^n$$
$$f(t+\Delta t) = (t+\Delta t)^n = t^n\left(1+\frac{\Delta t}{t}\right)^n$$
$$= t^n\left[1 + n\frac{\Delta t}{t} + \frac{n(n-1)}{2!}\left(\frac{\Delta t}{t}\right)^2 + \frac{n(n-1)(n-2)}{3!}\left(\frac{\Delta t}{t}\right)^3 + \cdots\right]$$

Then

$$f(t+\Delta t) - f(t) = t^n\left[n\frac{\Delta t}{t} + \frac{n(n-1)}{2!}\left(\frac{\Delta t}{t}\right)^2 + \cdots\right]$$

and

$$\frac{f(t+\Delta t)-f(t)}{\Delta t} = nt^{n-1} + \frac{n(n-1)}{2!}t^{n-2}\Delta t + \cdots$$

The next term omitted from the last sum is proportional to $(\Delta t)^2$, the following to $(\Delta t)^3$, and so on. Each term except the first approaches zero as Δt approaches zero. Thus

$$\frac{df}{dt} = \lim_{\Delta x\to 0}\frac{f(t+\Delta t)-f(t)}{\Delta t} = nt^{n-1}$$

COMMENTS ON RULES 8 TO 10

We first write $\sin\omega t = \sin\theta$ with $\theta = \omega t$ and use the chain rule,

$$\frac{d\sin\theta}{dt} = \frac{d\sin\theta}{d\theta}\frac{d\theta}{dt} = \omega\frac{d\sin\theta}{d\theta}$$

We then use the trigonometric formula for the sine of the sum of two angles θ and $\Delta\theta$:

$$\sin(\theta + \Delta\theta) = \sin \Delta\theta \cos \theta + \cos \Delta\theta \sin \theta$$

Because $\Delta\theta$ is to approach zero, we can use the small-angle approximations

$$\sin \Delta\theta \approx \Delta\theta \qquad \text{and} \qquad \cos \Delta\theta \approx 1$$

Then

$$\sin(\theta + \Delta\theta) \approx \Delta\theta \cos \theta + \sin \theta$$

and

$$\frac{\sin(\theta + \Delta\theta) - \sin \theta}{\Delta\theta} \approx \cos \theta$$

Similar reasoning can be applied to the cosine function to obtain rule 9.

Rule 10 is obtained by writing $\tan \theta = \sin \theta/\cos \theta$ and applying rule 4 along with rules 8 and 9:

$$\begin{aligned}\frac{d}{dt}(\tan \theta) &= \frac{d}{dt}(\sin \theta)(\cos \theta)^{-1} = \sin \theta \frac{d}{dt}(\cos \theta)^{-1} + \frac{d(\sin \theta)}{dt}(\cos \theta)^{-1} \\ &= \sin \theta(-1)(\cos \theta)^{-2}(-\sin \theta) + (\cos \theta)(\cos \theta)^{-1} \\ &= \frac{\sin^2 \theta}{\cos^2 \theta} + 1 = \tan^2 \theta + 1 = \sec^2 \theta\end{aligned}$$

To obtain rule 10, let $\theta = \omega t$ and use the chain rule.

COMMENTS ON RULE 11

Again we use the chain rule

$$\frac{de^\theta}{dt} = \frac{b\, de^\theta}{b\, dt} = b\frac{de^\theta}{d(bt)} = b\frac{de^\theta}{d\theta} \qquad \text{with} \qquad \theta = bt$$

and the series expansion for the exponential function:

$$e^{\theta + \Delta\theta} = e^\theta e^{\Delta\theta} = e^\theta\left[1 + \Delta\theta + \frac{(\Delta\theta)^2}{2!} + \frac{(\Delta\theta)^3}{3!} + \cdots\right]$$

Then

$$\frac{e^{\theta + \Delta\theta} - e^\theta}{\Delta\theta} = e^\theta + e^\theta\frac{\Delta\theta}{2!} + e^\theta\frac{(\Delta\theta)^2}{3!} + \cdots$$

As $\Delta\theta$ approaches zero, the right side of this equation approaches e^θ.

COMMENTS ON RULE 12

Let

$$y = \ln bt$$

Then

$$e^y = bt \Rightarrow t = \frac{1}{b}e^y$$

Then, using rule 11, we obtain

$$\frac{dt}{dy} = \frac{1}{b}e^y \therefore \frac{dt}{dy} = t$$

Then, using rule 5, we obtain

$$\frac{dy}{dt} = \left(\frac{dt}{dy}\right)^{-1} = \frac{1}{t}$$

SECOND- AND HIGHER-ORDER DERIVATIVES; DIMENSIONAL ANALYSIS

Once we have differentiated a function, we can differentiate the resulting derivative as long as terms remain to differentiate. A function such as $x = e^{bt}$ can be differentiated indefinitely: $dx/dt = be^{bt}$ (this function differentiates to give b^2e^{bt}, and so on).

Consider velocity and acceleration. We can define velocity as the rate of change of position of a particle, or dx/dt, and acceleration as the rate of change of velocity, or the *second* derivative of x with respect to t, written dx^2/dt^2. If a particle moves at a constant velocity, then dx/dt will equal a constant. The acceleration, however, will be zero: having constant velocity is the same as having no acceleration, and the derivative of a constant is zero. Now consider a falling object, subject to the constant acceleration of gravity: the velocity itself will be time-dependent, so the *second* derivative, dx^2/dt^2, will be a constant.

The *physical dimensions* of a derivative with respect to a variable are those that would result if the original function of the variable were divided by a value of the variable. For example, the dimension of an equation in which one term is x (for position) is that of length (L); the dimensions of the derivative of x with respect to time t are those of velocity (L/T), and the dimensions of dx^2/dt^2 are those of acceleration (L/T^2).

Example M-12 Position, Velocity, and Acceleration

Find the first and the second derivative of $x = \frac{1}{2}at^2 + bt + c$, where a, b, and c are constants. The function gives the position (in m) of a particle in one dimension, where t is the time (in s), a is acceleration (in m/s^2), b is velocity (in m/s) at a time $t = 0$, and c is the position (in m) of the particle at $t = 0$.

PICTURE Both the first and the second derivatives are sums of terms; for each differentiation we take the derivative of each term separately and add the results.

SOLVE

1. To find the first derivative, first compute the derivative of the first term:
$$\frac{d(\frac{1}{2}at^2)}{dt} = \left(\frac{1}{2}a\right)2t^1 = at$$

2. Compute the first derivative of the second and third terms:
$$\frac{d(bt)}{dt} = b, \qquad \frac{d(c)}{dt} = 0$$

3. Add these results:
$$\frac{dx}{dt} = at + b$$

4. To compute the second derivative, repeat the process for the result in step 3:
$$\frac{d^2x}{dt^2} = a + 0 = a$$

CHECK The physical dimensions show that the answer is plausible. The original function is an equation for position; all terms are in meters—the units of t^2 and t cancel the units of s^2 and s in the constants a and b, respectively. In the function for dx/dt, all terms are similarly in m/s: the constant c has differentiated to zero, and the unit for t cancels one of the units for s in the constant a. In the function for dx^2/dt^2, only the acceleration constant remains; as expected, its dimensions are L/T^2.

PRACTICE PROBLEMS

25. Find dy/dx for $y = \frac{5}{8}x^3 - 24x - \frac{5}{8}$.

26. Find dy/dt for $y = ate^{bt}$, where a and b are constants.

SOLVING DIFFERENTIAL EQUATIONS USING COMPLEX NUMBERS

A **differential equation** is an equation in which the derivatives of a function appear as variables. It is an equation in which the variables are related to each other through their derivatives. Consider an equation of the form

$$a\frac{d^2x}{dt^2} + b\frac{dx}{dt} + cx = A\cos\omega t \qquad \text{M-63}$$

that represents a physical process, such as a damped harmonic oscillator driven by a sinusoidal force, or a series *RLC* combination being driven by a sinusoidal potential drop. Although each of the parameters in Equation M-63 is a real number, the time-dependent cosine term suggests that we might find the steady-state solution to this equation by introducing complex numbers. We first construct the "parallel" equation

$$a\frac{d^2y}{dt^2} + b\frac{dy}{dt} + cy = A\sin\omega t \qquad \text{M-64}$$

Equation M-64 has no physical meaning of its own, and we have no interest in solving it. However, it is of use in solving Equation M-63. After multiplying through Equation M-64 by the unit imaginary i, we add Equation M-64 and Equation M-63 to obtain

$$\left(a\frac{d^2x}{dt^2} + ai\frac{d^2y}{dt^2}\right) + \left(b\frac{dx}{dt} + bi\frac{dy}{dt}\right) + (cx + ciy) = A\cos\omega t + Ai\sin\omega t$$

We next combine terms to get

$$a\frac{d^2(x+iy)}{dt^2} + b\frac{d(x+iy)}{dt} + c(x+iy) = A(\cos\omega t + i\sin\omega t) \qquad \text{M-65}$$

which is valid because the derivative of a sum is equal to the sum of the derivatives. We simplify our result by defining $z = x + iy$ and by using the identity $e^{i\omega t} = \cos\omega t + i\sin\omega t$. Substituting these into Equation M-65, we obtain

$$a\frac{d^2z}{dt^2} + b\frac{dz}{dt} + cz = Ae^{i\omega t} \qquad \text{M-66}$$

which we now solve for z. Once z is obtained, we can solve for x using $x = \text{Re}(z)$.

Because we are looking only for the steady-state solution for Equation M-65, we can assume its solution is of the form $x = x_0\cos(\omega t - \phi)$, where ϕ is a constant. This is equivalent to assuming that the solution to Equation M-66 is of the form $z = \eta e^{i\omega t}$, where η, pronounced eta (like beta without the b), is a constant complex number. Then $dz/dt = i\omega z$, $d^2z/dt^2 = -\omega^2 z$, and $e^{i\omega t} = z/\eta$. Substituting these into Equation M-65 gives

$$-a\omega^2 z + i\omega bz + cz = A\frac{z}{\eta}$$

Dividing both sides of this equation by z and solving for η gives

$$\eta = \frac{A}{-a\omega^2 + i\omega b + c}$$

Expressing the denominator in polar form gives

$$(-a\omega^2 + c) + i\omega b = \sqrt{(-a\omega^2 + c)^2 + \omega^2 b^2}\, e^{i\phi}$$

where $\tan\phi = \omega^2 b^2/(-a\omega^2 + c)$. Thus,

$$\eta = \frac{A}{\sqrt{(-a\omega^2 + c)^2 + \omega^2 b^2}}e^{-i\phi}$$

so

$$z = \eta e^{i\omega t} = \frac{A}{\sqrt{(-a\omega^2 + c)^2 + \omega^2 b^2}} e^{i(\omega t - \phi)}$$

$$= \frac{A}{\sqrt{(-a\omega^2 + c)^2 + \omega^2 b^2}}[\cos(\omega t - \phi) + i\sin(\omega t - \phi)] \qquad \text{M-67}$$

It follows that

$$x = \mathrm{Re}(z) = \frac{A}{\sqrt{(-a\omega^2 + c)^2 + \omega^2 b^2}}\cos(\omega t - \phi) \qquad \text{M-68}$$

THE EXPONENTIAL FUNCTION

An **exponential function** is a function of the form a^{bx}, where $a > 0$ and b are constants. The function is usually written as e^{cx}, where c is constant.

When the rate of change of a quantity is proportional to the quantity itself, the quantity increases or decreases exponentially, depending on the sign of the proportionality constant. An example of an *exponentially* decreasing function is nuclear decay. If N is the number of radioactive nuclei at some time, then the change dN in some very small time interval dt will be proportional to N and to dt:

$$dN = -\lambda N\, dt$$

where λ is the *decay constant* (not to be confused with the decay rate dN/dt, which decreases exponentially). The function N satisfying this equation is

$$N = N_0 e^{-\lambda t} \qquad \text{M-69}$$

where N_0 is the value of N at time $t = 0$. Figure M-25 shows N versus t. A characteristic of exponential decay is that N decreases by a constant factor in a given time interval. The time interval for N to decrease to half its original value is its *half-life* $t_{1/2}$. The half-life is obtained from Equation M-69 by setting $N = \frac{1}{2}N_0$ and solving for the time. This gives

$$t_{1/2} = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda} \qquad \text{M-70}$$

An example of *exponential increase* is population growth. If the number of organisms is N, the change in N after a very small time interval dt is given by

$$dN = +\lambda N\, dt$$

where λ is now the *growth constant*. The function N satisfying this equation is

$$N = N_0 e^{\lambda t} \qquad \text{M-71}$$

(Note the change of sign in the exponent.) A graph of this function is shown in Figure M-26. An exponential increase can be characterized by a doubling time T_2, which is related to λ by

$$T_2 = \frac{\ln 2}{\lambda} = \frac{0.693}{\lambda} \qquad \text{M-72}$$

Very often, we know population growth as an annual percentage increase and wish to calculate the doubling time. In this case, we find T_2 (in years) from the equation

$$T_2 = \frac{69.3}{r} \qquad \text{M-73}$$

where r is the percent per year. For example, if the population increases by 2 percent per year, the population will double every $69.3/2 \approx 35$ years. Table M-4 lists some useful relations for exponential and logarithmic functions.

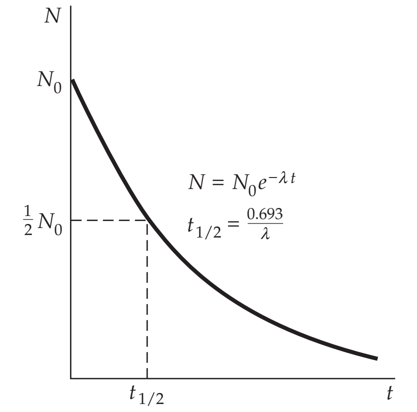

FIGURE M-25 Graph of N versus t when N decreases exponentially. The time $t_{1/2}$ is the time it takes for N to decrease by one-half.

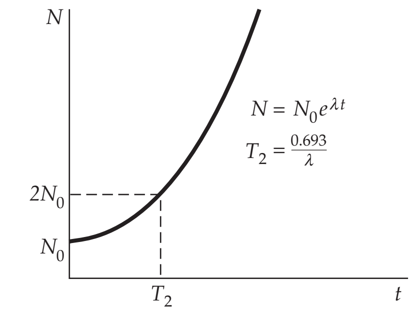

FIGURE M-26 Graph of N versus t when N increases exponentially. The time T_2 is the time it takes for N to double.

Table M-4 Exponential and Logarithmic Functions

$e = 2.718\,28$

$e^0 = 1$

If $y = e^x$, then $x = \ln y$.

$e^{\ln x} = x$

$e^x e^y = e^{(x+y)}$

$(e^x)^y = e^{xy} = (e^y)^x$

$\ln e = 1; \ln 1 = 0$

$\ln xy = \ln x + \ln y$

$\ln \frac{x}{y} = \ln x - \ln y$

$\ln e^x = x; \ln a^x = x \ln a$

$\ln x = (\ln 10)\log x$

$\quad = 2.30\,26 \log x$

$\log x = (\log e)\ln x = 0.434\,29 \ln x$

$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} = \ldots$

$\ln(1 + x) = x - \frac{x^2}{2} + \frac{x^3}{3} - \frac{x^4}{4}$

Example M-13 Radioactive Decay of Cobalt-60

The half-life of cobalt-60 (^{60}Co) is 5.27 y. At $t = 0$ you have a sample of ^{60}Co that has a mass equal to 1.20 mg. At what time t (in years) will 0.400 mg of the sample of ^{60}Co have decayed?

PICTURE When we derived the half-life in exponential decay, we set $N/N_0 = 1/2$. In this example, we are to find the time at which two-thirds of a sample remains, and so the ratio N/N_0 will be 0.667.

SOLVE

1. Express the ratio N/N_0 as an exponential function: $$\frac{N}{N_0} = 0.667 = e^{-\lambda t}$$
2. Take the reciprocal of both sides: $$\frac{N_0}{N} = 1.50 = e^{\lambda t}$$
3. Solve for t: $$t = \frac{\ln 1.50}{\lambda} = \frac{0.405}{\lambda}$$
4. The decay constant is related to the half-life by $\lambda = (\ln 2)/t_{1/2}$ (Equation M-70). Substitute $(\ln 2)/t_{1/2}$ for λ and evaluate the time: $$t = \frac{\ln 1.5}{\ln 2} t_{1/2} = \frac{\ln 1.5}{\ln 2} \times 5.27\text{ y} = 3.08\text{ y}$$

CHECK It takes 5.27 y for the mass of a sample of ^{60}Co to decrease to 50 percent of its initial mass. Thus, we expect it to take less than 5.27 y for the sample to lose 33.3 percent of its mass. Our step-4 result of 3.08 y is less than 5.27 y, as expected.

PRACTICE PROBLEMS

27. The discharge time constant τ of a capacitor in an RC circuit is the time in which the capacitor discharges to e^{-1} (or 0.368) times its charge at $t = 0$. If $\tau = 1$ s for a capacitor, at what time t (in seconds) will it have discharged to 50.0% of its initial charge?
28. If the coyote population in your state is increasing at a rate of 8.0% a decade and continues increasing at the same rate indefinitely, in how many years will it reach 1.5 times its current level?

M-12 INTEGRAL CALCULUS

Integration can be considered the inverse of differentiation. If a function $f(t)$ is *integrated*, a function $F(t)$ is found for which $f(t)$ is the derivative of $F(t)$ with respect to t.

THE INTEGRAL AS AN AREA UNDER A CURVE; DIMENSIONAL ANALYSIS

The process of finding the area under a curve on the graph illustrates integration. Figure M-27 shows a function $f(t)$. The area of the shaded element is approximately $f_i\,\Delta t_i$, where f_i is evaluated anywhere in the interval Δt_i. This approximation is highly accurate if Δt_i is very small. The total area under some stretch of the curve is found by summing all the area elements it covers and taking the limit as each Δt_i approaches zero. This limit is called the **integral** of f over t and is written

$$\int f\,dt = \text{area}_i = \lim_{\Delta t_i \to 0} \sum_i f_i \Delta t_i \qquad \text{M-74}$$

The *physical dimensions* of an integral of a function $f(t)$ are found by multiplying the dimensions of the *integrand* (the function being integrated) and the dimensions of the integration variable t. For example, if the integrand is a velocity function

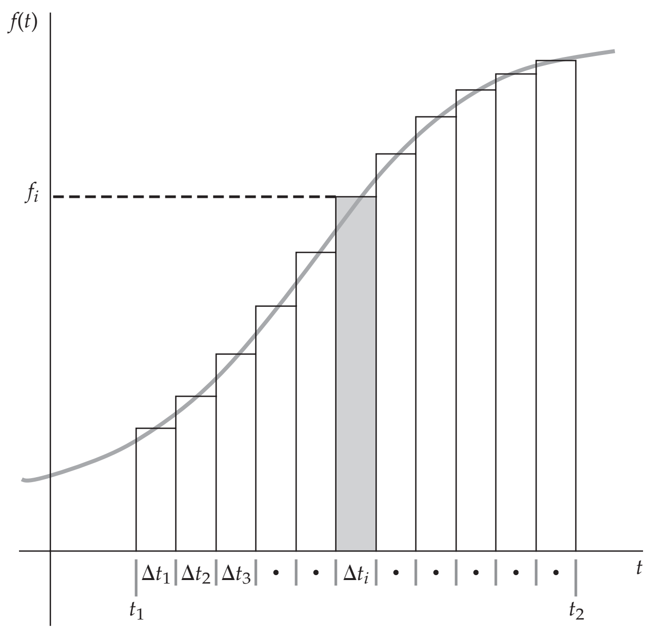

FIGURE M-27 A general function $f(t)$. The area of the shaded element is approximately $f_i\Delta t_i$, where f_i is evaluated anywhere in the interval.

$v(t)$ (dimensions L/T) and the integration variable is time t), the dimension of the integral is $\mathrm{L} = (\mathrm{L/T}) \times \mathrm{T}$. That is, the dimensions of the integral are those of velocity times time.

Let

$$y = \int_{t_1}^{t} f\,dt \qquad \text{M-75}$$

The function y is the area under the f-versus-t curve from t_1 to a general value t. For a small interval Δt, the change in the area Δy is approximately $f\,\Delta t$:

$$\Delta y \approx f\,\Delta t$$

$$f \approx \frac{\Delta y}{\Delta t}$$

If we take the limit as Δt approaches 0, we can see that f is the derivative of y:

$$f = \frac{dy}{dt} \qquad \text{M-76}$$

INDEFINITE INTEGRALS AND DEFINITE INTEGRALS

When we write

$$y = \int f\,dt \qquad \text{M-77}$$

we are showing y as an **indefinite integral** of f over t. To evaluate an indefinite integral, we find the function y whose derivative is f. Because that function could contain a constant term that differentiated to zero, we include as our final term a **constant of integration** C. If we are integrating the function over a known segment—such as t_1 to t_2 in Figure M-27—we can find a **definite integral,** eliminating the unknown constant C:

$$\int_{t_1}^{t_2} f\,dt = y(t_2) - y(t_1) \qquad \text{M-78}$$

Table M-5 lists some important integration formulas. More extensive lists of integration formulas can be found in any calculus textbook or by searching for "table of integrals" on the Internet.

Table M-5 Integration Formulas[†]

1. $\int A\,dt = At$
2. $\int At\,dt = \frac{1}{2}At^2$
3. $\int At^n\,dt = A\frac{t^{n+1}}{n+1}, \quad n \neq -1$
4. $\int At^{-1}\,dt = A\ln|t|$
5. $\int e^{bt}\,dt = \frac{1}{b}e^{bt}$
6. $\int \cos\omega t\,dt = \frac{1}{\omega}\sin\omega t$
7. $\int \sin\omega t\,dt = -\frac{1}{\omega}\cos\omega t$
8. $\int_0^\infty e^{-ax}\,dx = \frac{1}{a}$
9. $\int_0^\infty e^{-ax^2}\,dx = \frac{1}{2}\sqrt{\frac{\pi}{a}}$
10. $\int_0^\infty xe^{-ax^2}\,dx = \frac{2}{a}$
11. $\int_0^\infty x^2e^{-ax^2}\,dx = \frac{1}{4}\sqrt{\frac{\pi}{a^3}}$
12. $\int_0^\infty x^3e^{-ax^2}\,dx = \frac{4}{a^2}$
13. $\int_0^\infty x^4e^{-ax^2}\,dx = \frac{3}{8}\sqrt{\frac{\pi}{a^5}}$

† In these formulas, A, b, and ω are constants. In formulas 1 through 7, an arbitrary constant C can be added to the right side of each equation. The constant a is greater than zero.

Example M-14 Integrating Equations of Motion

A particle is moving at a constant acceleration a. Write a formula for position x at time t given that the position and velocity are x_0 and v_0 at time $t = 0$.

PICTURE Velocity v is the derivative of x with respect to time t, and acceleration is the derivative of v with respect to t. We should be able to write a function $x(t)$ by performing two integrations.

SOLVE

1. Integrate a with respect to t to find the v as a function of t. The a can be factored from the integrand because a is constant:

$$v = \int a\,dt = a\int dt$$

$$v = at + C_1$$

where C_1 represents a times the constant of integration.

2. The velocity $v = v_0$ when $t = 0$

$$v_0 = 0 + C_1 \Rightarrow C_1 = v_0$$

so $v = v_0 + at$

3. Integrate v with respect to t to find x as a function of t:

$$x = \int v\,dt = \int (v_0 + at)\,dt = \int v_0\,dt + \int at\,dt$$

$$x = v_0 \int dt + a \int t\,dt = v_0 t + \tfrac{1}{2}at^2 + C_2$$

where C_2 represents the combined constants of integration.

4. The position $x = x_0$ when $t = 0$

$$x_0 = 0 + 0 + C_2$$

so $\quad x = x_0 + v_0 t + \tfrac{1}{2}at^2$

CHECK Differentiate the step-4 result twice to get the acceleration

$$v = \frac{dx}{dt} = \frac{d}{dt}(x_0 + v_0 t + \tfrac{1}{2}at^2) = 0 + v_0 + at$$

$$a = \frac{dv}{dt} = \frac{d}{dt}(v_0 + at) = a$$

23 (*d*)

25 (*a*) False, (*b*) True, (*c*) True, (*d*) False, (*e*) True

27 Assume the $+x$ direction is east and the $+y$ direction is north. Then

(*a*)

Path	Direction of Velocity Vector
AB	North
BC	Northeast
CD	East
DE	Southeast
EF	South

(*b*)

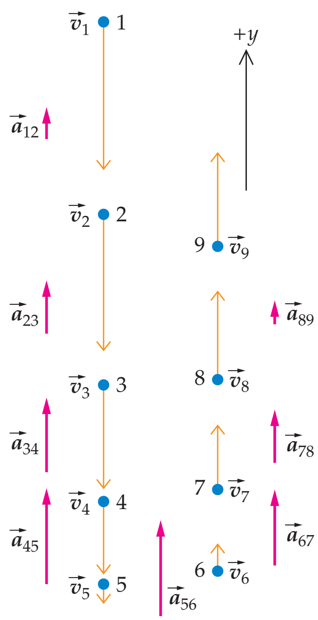
Path	Direction of Acceleration Vector
AB	North
BC	Southeast
CD	0
DE	Southwest
EF	North

(*c*) The magnitude of the acceleration is larger on DE than on BC.

29 The droplet leaving the bottle has the same horizontal velocity as the ship. During the time the droplet is in the air, it is also moving horizontally with the same velocity as the rest of the ship. Because of this, it falls into the vessel, which has the same horizontal velocity. Because you have the same horizontal velocity as the ship does, you see things as if the ship were standing still.

31 (*a*) True, (*b*) False, (*c*) False, (*d*) True

33 (*a*)



i	v_y (m/s)	Δv_y (m/s)	a_{ave} (m/s^2)
1	−0.78		
2	−0.69	0.09	1.8
3	−0.55	0.14	2.8
4	−0.35	0.20	4.0

Chapter 4

1 Yes, there are forces acting on it. They are the same as those that would act on it if it were sitting on your table at home.

3 In the limo you hold one end of the string and suspend the object from the other end. If the string remains vertical, the reference frame of the limo is an inertial reference frame. No, you cannot determine the limo's velocity

5 No. Predicting the direction of the subsequent motion requires additional information.

7 The mass of the probe is constant. However, the solar system will attract the probe with a gravitational force.

9 You and the elevator could be either descending and slowing or ascending and speeding up. In both cases your apparent weight is greater than your actual weight.

11 The most significant force in our everyday world is gravity. It literally keeps us on or near the ground. The other most relevant force is the electromagnetic force. It provides "the glue" to hold solids together and make them rigid. It is of great importance in electric circuits.

13 (*a*) Normal force, contact type, (*b*) Normal, contact, (*c*) Normal, contact, (*d*) Normal, contact, (*e*) Gravitational, action-at-a-distance
The two normal forces that the two blocks exert on each other and the two normal forces that the table and the bottom block exert on each other

15 When the plate is sitting on the floor, the normal force F_n acting upward on it is exerted by the floor and is the same size as the gravitational force F_g on the plate. Hence, the plate does not accelerate. However, to slow the plate down as it hits the floor requires that $F_n > F_g$ (or $F_n \gg F_g$, if the

floor is hard and the plate slows quickly). A large normal force exerted on delicate china can easily break it.

17 (*a*) The normal force of the block on the sprinter, in the forward direction.
(*b*) The frictional force by the ice on the puck, in the opposite direction to the velocity.
(*c*) The gravitation force by Earth on the ball, in the downward direction.
(*d*) The force by the stretched bungee cord on the jumper, in the upward direction.

19 (*a*) (2) 100 N, (*b*) Their accelerations are the same. (*c*) The directions of their acceleration are the same.

Chapter 5

1 Static and kinetic frictional forces are responsible for the accelerations. If the coefficient of static friction between the truck bed and the object is sufficiently large, then the object will not slip on the truck bed. The larger the acceleration of the truck, the larger the coefficient of static friction that is needed to prevent slipping.

3 (*d*)

5 (*c*)

7 As the spring is extended, the force exerted by the spring on the block increases. Once that force exceeds the maximum value of the force of static friction, the block will slip. As it does, it will shorten the length of the spring, decreasing the force that the spring exerts. The force of kinetic friction then slows the block to a stop, which starts the cycle over again.

9 (*a*), (*b*), and (*c*)

11 Block 1 will hit the pulley before block 2 hits the wall.

13 Air drag is proportional to the density of air and to the cross-sectional area of the object. On a warm day the air is less dense. The air is also less dense at high altitudes. Pointing his hands results in less area being presented to air drag forces and, hence, reduces them. Rounded and sleek clothing has the same effect as pointing his hands.

15 (*c*)

17 (*a*) The drag force is proportional to the area presented and some power of the speed.The drag force on the feather initially is larger because the feather presents a larger area than does the pebble. As the pebble gains speed the drag force on it increases. The drag force on the pebble eventually exceeds the drag force on the feather because the drag force on the feather cannot exceed the gravitational force on the feather.

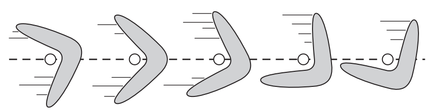
(*b*) Terminal speed is much higher for the pebble than for the feather. The acceleration of the pebble will remain high until its speed approaches its terminal speed.

19 $a_{cm} = (m_1/(m_1 + m_2))a_1$

21 The friction of the road on the tire causes the car to slow down

23 The center of mass moves downward

25 The acceleration of the center of mass is zero.



27 (*a*) M/T, kg/s, (*b*) M/L, kg/m, (*c*) ML/T^2, (*d*) 57 m/s, (*e*) 87 m/s

29 $\mu_s \approx 1.4$. This is probably not such a good idea. Tires on asphalt or concrete have a maximum coefficient of static friction of about 1.

31 (*b*)

33 (*a*) 15 N, (*b*) 12 N

35 500 N

37 (*a*) 5.9 m/s^2, (*b*) 76 m

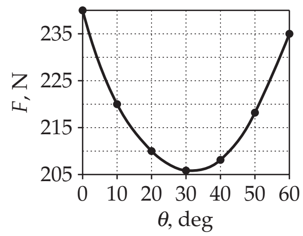
49 (*a*) 2.7 m/s^2, (*b*) 10 s

51 (*a*) 0.96 m/s^2, (*b*) 0.18 N

53 (*a*) The static-frictional force opposes the motion of the object, and the maximum value of the static-frictional force is proportional to the normal force F_N. The normal force is equal to the weight minus the vertical component F_y of the force F. Keeping the magnitude F constant while increasing θ from zero results in a decrease in F_y and thus a corresponding decrease in the maximum static-frictional force, f_{max}. The object will begin to move if the horizontal component F_x of the force F exceeds f_{max}. An increase in θ results in a decrease in F_x. As θ increases from 0, the decrease in F_N is larger than the decrease in F_x, so the object is more and more likely to slip. However, as θ approaches 90°, F_x approaches zero and no movement will be initiated. If F is large enough and if θ increases from 0, then at some value of θ, the block will start to move.

(*b*)



From the graph, we can see that the minimum value for F occurs when $\theta \approx 32°$.

57 (*a*) 0.24, (*b*) 1.4 m/s^2

Chapter 8

5 The momentum of the bullet–gun system is initially zero. After firing, the bullet's momentum is directed west. Momentum conservation requires that the system's total momentum does not change, so the gun's momentum must be directed east. Kinetic energy is not conserved.

7 In a way, the rocket does need something to push upon. It pushes the exhaust in one direction, and the exhaust pushes it in the opposite direction. However, the rocket does not push against the air.

9 Think of someone pushing a box across a floor. Her push on the box is equal but opposite to the push of the box on her, but the action and reaction forces act on *different objects*. Newton's second law states that the sum of the forces acting on the box equals the rate of change of momentum of the box. This sum does not include the force of the box on her.

11 Hovering in midair while tossing objects violates the conservation of linear momentum! To throw something forward requires being pushed backward. Superheroes are not depicted as experiencing this backward motion that is predicted by conservation of linear momentum. This action does not violate conservation of energy.

13 The road. (The frictional force by the road on the tire causes the car to slow down.)

15 About 10^4

17 (*a*) False, (*b*) True, (*c*) True, (*d*) True

19 (*a*) The loss of kinetic energy is the same in both cases. (*b*) The situation in which the two objects have oppositely directed velocities.

21 (*b*)

23 The water is changing direction when it rounds the corner in the nozzle. Therefore, the nozzle must exert a force on the stream of water to change its momentum, and from Newton's third law, the water exerts an equal but opposite force on the nozzle. This requires a net force in the direction of the momentum change.

25 In the center-of-mass frame the two velocities are equal and opposite, both before and after the collision. In addition, the speed of each puck is the same before and after the collision. The direction of the velocity of each puck changes by some angle during the collision.

27 The downward force of lunar gravity and the upward thrust provided by the rocket combustion products.

29 Think of the sail facing the fan (like the sail on a square rigger might), and think of the stream of air molecules hitting the sail. Imagine that they bounce off the sail elastically—their net change in momentum is then roughly twice the change in momentum that they experienced going through the fan. Thus the change in momentum of the air is backward, so to conserve momentum of the air–fan–boat system the change in momentum of the fan–boat system will be forward.

5 (*a*) L is doubled, (*b*) L is doubled

7 False. A high diver going from a tucked to a layout position.

9 (*e*)

11 The hardboiled egg is solid inside, so everything rotates with a uniform angular speed. By contrast, when you start an uncooked egg spinning, the yolk will not immediately spin with the shell, and when you stop it from spinning the yolk will continue to spin for a while.

13 (*a*)

15 (*a*) The plane tends to veer to the right. The change in angular momentum $\Delta\vec{L}_{prop}$ for the propeller is up, so the net torque $\vec{\tau}$ on the propeller is up as well. The propeller must exert an equal but opposite torque on the plane. This downward torque exerted by the prop on the plane tends to cause a downward change in the angular momentum of the plane. This means the plane tends to rotate clockwise as viewed from above.
(*b*) The plane tends to veer downward. The change in angular momentum $\Delta\vec{L}_{prop}$ for the propeller is to the right,

so the net torque $\vec{\tau}$ on the propeller is toward the right as well. The propeller must exert an equal but opposite torque on the plane. This leftward directed torque exerted by the prop on the plane tends to cause a leftward-directed change in angular momentum for the plane. This means the plane tends to rotate clockwise as viewed from the right.

17 (*a*) Your kinetic energy decreases. Increasing your moment of inertia I while conserving your angular momentum L decreases your kinetic energy $K = L^2/(2I)$.
(*b*) Extending your arms out to the side increases your moment of inertia, and decreases your angular speed. The angular momentum of the system is unchanged.

19 About 4 rev/s

Chapter R

1 In the reference frame of the car both events occur at the same location (the location of the car). Thus, your friend's watch measures the proper time between the two events.

3 Yes. Let the initial frame of reference be frame 1. In frame 1 let L be the distance between the events, let T be the time between the events, and let the $+x$ direction be the direction of event B relative to event A. Next, calculate the value of L/T. If L/T is less than c, then consider the two events in a reference frame 2, a frame moving at speed $v = L/T$ in the $+x$ direction. In frame 2 both events occur at the same location.

5 Yes.

53 In 100 lifetimes, $d \approx 6600$ km or approximately one Earth radius. This relatively short distance should convince your classmate that the origin of the muons that are observed on Earth is within our atmosphere, and that they certainly are not from the Sun.

55 (*a*) 4.50 km/s, (*b*) 0.334 μs

57 (*a*) 0.75*c*, (*b*) 5.0 ft, (*c*) No. In your rest frame, the back end of the ladder will clear the door before the front end hits the wall of the shed, while in Ernie's rest frame, the front end will hit the wall of the shed while the back end has yet to clear the door.

Chapter 11

1 (*a*) False, (*b*) True, (*c*) True, (*d*) False

3 Earth is closest to the Sun during winter in the northern hemisphere. This is the time of fastest orbital speed. Summer would be the time for minimum orbital speed.

5 To obtain the mass M of Venus you need to measure the period T and semi-major axis a of the orbit of one of the satellites, substitute the measured values into $T^2/a^3 = 4\pi^2/(GM)$ (Kepler's third law) and solve for M.

7 (*d*)

9 (*b*)

11 (*b*)

13 You should fire the rocket in a direction to oppose the orbital motion of the satellite. As the satellite gets closer to Earth after the burn, the potential energy will decrease. However, the total mechanical energy will decrease due to the frictional drag forces transforming mechanical energy into thermal energy. The kinetic energy will increase until the satellite enters the atmosphere where the drag forces slow its motion.

15 At a point inside the sphere a distance r from its center, the gravitational field strength is directly proportional to the amount of mass within a distance r from the center, and inversely proportional to the square of the distance r from the center. The mass within a distance r from the center is proportional to the cube of r. Thus, the gravitational field strength is directly proportional to r.

17 $M_{\text{galaxy}} = 1.08 \times 10^{11}\, M_S$

19 About 3.0 km

21 (*a*) 6.28×10^{-4} rad/s, 2.78 h, (*b*) $L_J = 1.93 \times 10^{43}\ \text{kg}\cdot\text{m}^2/\text{s}$, $L_S = 7.85 \times 10^{42}\ \text{kg}\cdot\text{m}^2/\text{s}$, 0.70%, (*c*) $T_{\text{Sun}} = 3.64$ h, $T_{\text{Sun}} = 1.30T_{\text{max}}$

35 Your weight would be ten times your weight on Earth.

37 2.27×10^4 m/s

39 (*a*) 1.4, (*b*) It is farther from the Sun than Earth. Kepler's third law $[T^2 = Cr^3_{\text{av}}]$ tells us that longer orbital periods together with larger orbital radii means slower orbital speeds, so the speed of objects orbiting the Sun decreases with distance from the Sun. The average orbital speed of Earth, given by $v = 2\pi r_{\text{ES}}/T_{\text{ES}}$, is approximately 30 km/s. Because the given maximum speed of the asteroid is only 20 km/s, the asteroid is further from the Sun.

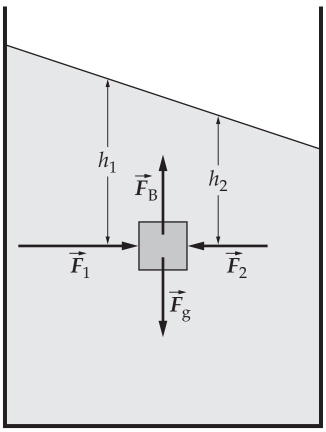
Chapter 13

1 (*e*)
3 (*c*)
5 Pressure increases approximately 1 atm every 10 m of depth. To breathe requires creating a pressure of less than 1 atm in your lungs. At the surface you can do this easily, but not at a depth of 10 m.
7 (*b*)
9 False. The buoyant force on a submerged object depends on the weight of the displaced fluid, which, in turn, depends on the volume of the displaced fluid. Because the bricks have the same volume, they will displace the same volume of water.
11 Because the pressure increases with depth, the object will be compressed and its density will increase as its volume decreases. Thus, the object will sink to the bottom.
13



The pictorial representation shows the glass and an element of water in the middle of the glass. As is readily established by a simple demonstration, the surface of the water is not level while the glass is accelerated, showing that there is a pressure gradient (a difference in pressure) due to the differing depths ($h_1 > h_2$, and hence, $F_1 > F_2$) of water on the two sides of the element of water. This pressure gradient results in a net force on the element of water, as shown in the figure. The upward buoyant force is equal in magnitude to the downward gravitational force.
15 (*c*)
17 The mounding around entrance 1 will cause the streamlines to curve concave downward over the entrance. An upward pressure gradient produces the downward centripetal force. This means there is a lowering of the pressure at entrance 1. No such lowering occurs over entrance 2, so the pressure there is higher than the pressure at entrance 1. The air circulates in entrance 2 and out entrance 1. It has been demonstrated that enough air will circulate inside the tunnel even with the slightest breeze outside.

Chapter 14

1 (*a*) False, (*b*) True, (*c*) True
3 (*a*)
5 (*c*)
7 (*c*)
9 Neglecting the mass of the spring in your calculations results in your using a value for the mass of the oscillating system that is smaller than its actual value. Hence, your calculated value for the period will be smaller than the actual period of the system and the calculated value for the frequency, which is the reciprocal of the period, will be higher than the actual value.

Because the total energy of the oscillating system depends solely on the amplitude of its motion and on the stiffness of the spring, it is independent of the mass of the system, and so neglecting the mass of the spring would have no effect on your calculation of the system's total energy.

Chapter 15

1 The speed of a transverse wave on a uniform rope increases with increasing tension. The waves on the rope move faster as they move up because the tension increases due to the weight of the rope below.

3 (*b*)

5 The resonant (standing-wave) frequencies on a string are inversely proportional to the square root of the linear density of the string ($f = \sqrt{F_T/\mu}/\lambda$). Thus, extremely high frequencies (which might otherwise require very long strings) can be accommodated on relatively short strings if the strings are linearly denser than the high-frequency strings. High frequencies are not a problem, as they utilize short strings anyway.

7 (*c*)

9 There was only one explosion. Sound travels faster in water than air. Abel heard the sound wave in the water first, then, surfacing, heard the sound wave traveling through the air, which took longer to reach him.

5 (*a*)

7 3.0 m

9 (*b*)

11 (*a*)

13 You could measure the lowest resonant frequency f and the length L of the pipe. Assuming the end corrections are negligible, the wavelength equals $4L$ if the pipe is stopped at one end, and is $2L$ if the pipe is open at both ends. Then use $v = f\lambda$ to find the speed of sound at the ambient temperature. Finally, use $v = \sqrt{\gamma RT/M}$ (Equation 15-5), where $\gamma = 1.4$ for a diatomic gas such as air, M is the molar mass of air, R is the universal gas constant, and T is the absolute temperature, to estimate the temperature of the air.

15 (*a*) No, (*b*) Yes

17 Standing sound waves are produced in the air columns above the water. The resonance frequency of the air columns depends on the length of the air column, which depends on how much water is in the glass.

19 The wavelength is determined mostly by the size of the resonant cavity of the mouth; the frequency of sounds he makes is equal to the wave speed divided by the wavelength. Because $v_{He} > v_{air}$ (see Equation 15-5), the resonance frequency is higher if helium is the gas in the cavity.

21 If you do not hear even one beat for the entire time the string and the tuning fork are vibrating, you can be sure that their frequencies, while not exactly the same, are very close. If the sounds of the vibrating string and the tuning fork last for 10 s, it follows that the beat frequency is less than 0.1 Hz. Hence the frequencies of the vibrating string and the tuning fork are within 0.1 Hz of each other.

23 3. The estimated frequencies agree with the observed frequencies to within 14%.

53 (*a*) 71.5 Hz, (*b*) 5.00 kHz, (*c*) 71

55 452 Hz. Ideally, the pipe should expand so that v/L, where L is the length of the pipe, is independent of temperature.

57 (*a*) 40.0 cm, (*b*) 480 N, (*c*) You should place your finger 9.2 cm from the scroll bridge.

59 (*a*) 75 Hz, (*b*) 5th and 6th, (*c*) 2.0 m

61 (*a*) 0.574 g/m, (*b*) $\mu_E = 1.29$ g/m, $\mu_A = 2.91$ g/m, $\mu_D = 2.91$ g/m, $\mu_G = 6.57$ g/m

63 (*a*) The two sounds produce a beat because the third harmonic of the A string equals the second harmonic of the E string, and the original frequency of the E string is slightly greater than 660 Hz. (*b*) 662 Hz

65 (*a*) Because the frequency is fixed, the wavelength depends only on the tension on the string. This is true because the only parameter that can affect the wave speed on the string is the tension on the string. The tension on the string is provided by the weight hanging from its end. Given that the length of the string is fixed, only certain wavelengths can resonate on the string. Thus, because only certain wavelengths are allowed, only certain wave speeds will work. This, in turn, means that only certain tensions, and therefore weights, will work.
(*b*) Higher frequency modes on the same length of string results in shorter wavelengths. To accomplish this without changing frequency, you need to reduce the wave speed. This is accomplished by reducing the tension in the string. Because the tension is provided by the weight on the end of the string, you must reduce the weight.
(*d*) $w_1 = 19.2$ N, $w_2 = 4.80$ N, $w_3 = 2.13$ N

67 (*a*) $\Delta t = N/f_0$, (*b*) $\lambda \approx \Delta x/N$, (*c*) $k = 2\pi N/\Delta x$, (*d*) N is uncertain because the waveform dies out gradually rather than stopping abruptly at some time; hence, where the pulse starts and stops is not well defined.

Chapter 17

1 (*a*) False, (*b*) False, (*c*) True

3 Mert's room was colder.

5 From the ideal-gas law, we have $P = nRT/V$, and V/T is the slope of the line from the origin to the point (T, V) on the graph. During the process the slope of the line from the origin to (T, V) continuously decreases, so the pressure continuously increases.

7 (*d*)

9 The average kinetic energies are equal. The ratio of their rms speeds is equal to the square root of the reciprocal of the ratio of their molecular masses.

11 False

13 It does not matter.

15 (*b*)

17 The rms speed is always somewhat greater than the speed of sound. However, it is only the component of the molecular velocities in the direction of propagation that is relevant to this issue. In addition, in a gas the mean free path is greater than the average intermolecular distance.

19 If the volume decreases the pressure increases because more molecules hit a unit of area of the walls in a given time. This happens because the number of molecules per unit volume increases as the volume decreases.

21 The average molecular speed of He gas at 300 K is about 1.4 km/s, so a significant fraction of He molecules have speeds in excess of Earth's escape velocity (11.2 km/s). Thus, they "leak" away into space. Over time, the He content of the atmosphere decreases to almost nothing.

23 About 1.2 kg/m^3

25 (*a*) 3600 K, (*b*) 230 K, (*c*) Because hydrogen is lighter than air, it rises to the top of the atmosphere. Because the temperature is high there, a greater fraction of the molecules reach escape speed. (*d*) 160 K, 10 K. Because g is less on the moon, the escape speed is lower. Thus, a larger percentage of the molecules are moving at escape speed.

27 (*a*) 1.23 km/s, (*b*) 310 m/s, (*c*) 264 m/s, (*d*) Because v_e is greater than v_{rms} for O_2, CO_2, and H_2, all three gases should be found on Jupiter.

29 (*a*) 2×10^{11} atm, (*b*) $v_{\text{rms protons}} = 5 \times 10^5$ m/s,

$v_{\text{rms electrons}} = 2 \times 10^7$ m/s

31 1×10^{-4} g

(*b*) 54.9 torr, (*c*) 3.70×10^3 K

41 $-40.0°C = -40.0°F$

43 $-183°C$, $-297°F$

45 (*a*) $R_0 = 3.91 \times 10^{-3}$ K, $B = 3.94 \times 10^3$ K, (*b*) 1.31 kΩ, (*c*) −389 Ω/K, −4.33 Ω/K, (*d*) The thermistor has greater sensitivity at lower temperatures.

47 1.79 mol, 1.08×10^{24} molecules

49 −83 *glips*

51 (*a*) 3.7×10^3 mol, (*b*) 60 mol

53 11.1 atm

55 (*a*) Air will be less dense when its water-vapor content is higher. (*b*) 18 g

57 1.1 kN

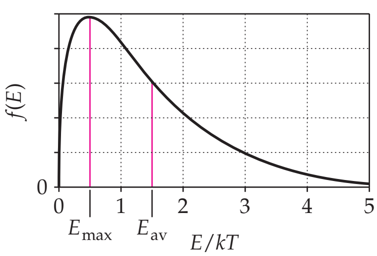
59 (*a*) 0.28 km/s, (*b*) 0.87 km/s. The rms speed of argon atoms is slightly less than one-third the rms speed of helium atoms.

61 5.0×10^5 m/s, 2.1×10^{-16} J

65 $K/\Delta U = 7.9 \times 10^4$

69 (*a*) $E_{\text{peak}} = \frac{1}{2}kT$, $E_{\text{peak}} = \frac{1}{3}E_{\text{av}}$

(*b*)



$E_{\max}$ is the most probable energy

(*c*) The graph rises from zero to the peak much more rapidly than it falls off to the right of the peak. Because the distribution is so strongly skewed to the right of the peak, the outlying molecules with relatively high energies pull the average $(3kT/2)$ far to the right of the most probable value $(kT/2)$.

71 (*a*) 1.2×10^2 K, (*b*) 2.4×10^2 K, (*c*) 1.4 atm

73 (*a*) To escape from the surface of a droplet of water, molecules must have enough translational kinetic energy to overcome the attractive forces from their neighbors. Therefore the molecules that escape will be those that are moving faster, leaving the slower molecules behind. The slower molecules have less kinetic energy, so the temperature of the droplet, which is proportional to the average translational kinetic energy per molecule, decreases.
(*b*) As long as the temperature is not too high, the molecules that evaporate from a surface will be only those with the most extreme speeds, at the high-energy "tail" of the Maxwell–Boltzmann distribution. Within this part of the distribution, increasing the temperature only slightly can greatly increase the percentage of molecules with speeds above a certain threshold. For example, suppose that we set an initial threshold at $E = 5kT_1$, then imagine increasing the temperature by 10%, so $T_2 = 1.1T_1$. At the threshold, the ratio of the new energy distribution to the old one is

$$\frac{F(T_2)}{F(T_1)} = \left(\frac{T_1}{T_2}\right)e^{-E/KT_2}e^{+E/kT_1} = (1.1)^{-3/2}\,e^{-5/1.1}e^5 = 1.365$$

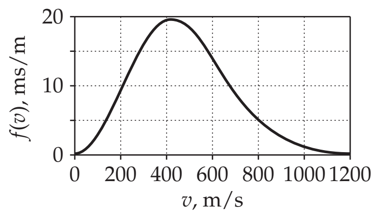
an increase of almost 37%.

75 110 mol of H_2, 55 mol of O_2

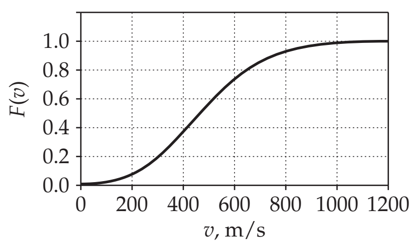
77 $4m$

79 (*a*) 142 ms, (*b*) 146 ms

81 (*a*)



(*b*) As the temperature is increased, the graph spreads out horizontally and gets shorter vertically. More precisely, the horizontal position of the peak moves to the right in proportion to the square root of the temperature, while the height of the peak drops by the same factor, preserving the total area under the graph (which must be 1.0, the total probability of a molecule having any velocity between zero and infinity).
(*c*) A graph of $F(v)$ for nitrogen at 300 K follows. Each number in column C of the spreadsheet [shown in Part (*a*)] is approximately equal to the integral of $f(v)$ from zero up to the corresponding v value. This integral represents the probability of a molecule having a speed greater than or equal to this value of v.

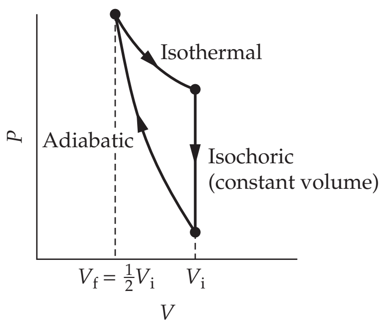


$F(v) = \int_0^v f(v')dv'$

(*d*) About 7%. Note that this value is consistent with the graph of $F(v)$ shown immediately above.
(*e*) A little under 14%.

Chapter 18

1 (*e*)
3 (*c*)
5 (*a*)
7 (*c*)
9 Yes. $\Delta E_{\text{int}} = Q_{\text{in}} + W_{\text{on}}$. If the gas does work at the same rate that it absorbs heat, its internal energy will remain constant.
11 Particles that attract each other have more potential energy the farther apart they are. In a real gas the molecules exert weak attractive forces on each other. These forces increase the internal potential energy during an expansion. An increase in potential energy means a decrease in kinetic energy, and a decrease in kinetic energy means a decrease in translational kinetic energy. Thus, there is a decrease in temperature.
13 Particles that repel each other have more potential energy the closer together they are. The repulsive forces decrease the internal potential energy during an expansion. A decrease in potential energy means an increase in kinetic energy, and an increase in kinetic energy means an increase in translational kinetic energy. Thus, there is an increase in temperature.
15 (*a*)
17 (*a*) False, (*b*) False, (*c*) True, (*d*) True, (*e*) True, (*f*) True
19 (*d*)
21 During a reversible adiabatic process, PV^{γ} is constant, where $\gamma > 1$, and during an isothermal processes, PV is constant. Thus the pressure rise during the compression is greater than the pressure drop during the expansion. The final process could be a constant volume process during which heat is absorbed from the system. A constant-volume cooling will decrease the pressure and return the gas to its original state.



23 The temperature decreases.

Chapter 19

1 (*c*)

3 (*a*)

5 The COP is defined so as to be a measure of the effectiveness of the device. For a refrigerator or air conditioner, the important quantity is the heat transferred from the already colder interior, Q_c. For a heat pump, the idea is to focus on the heat transferred into the warm interior of the house, Q_h.

7 Increasing the temperature of the steam increases its energy content. In addition, it increases the Carnot efficiency, and generally increases the efficiency of any heat engine.

9 A Carnot-cycle refrigerator is more efficient when the temperatures are close together because it requires less work to extract heat from an already cold interior if the temperature of the exterior is close to the temperature of the interior of the refrigerator. A Carnot-cycle heat engine is more efficient when the temperature difference is large because then more work is done by the engine for each unit of heat absorbed from the hot reservoir.

11 (*c*)

13 (*d*)

15 The cycle is that of the Otto engine (see Figure 19-3).

Chapter 20

1 The glass bulb warms and expands first, before the mercury warms and expands.

3 Water expands greatly as it freezes. If a sealed glass bottle full of water is placed in a freezer, as the water freezes there will be no room for the expansion to take place. The bottle will be broken.

5 The strip will curl more tightly.

7 (*c*)

9 (*a*) With increasing altitude, P decreases; from curve OC, the temperature T of the liquid–gas interface decreases as the pressure decreases, so the boiling temperature decreases. Likewise, from curve OB, the melting temperature increases with increasing altitude.

(*b*) Boiling at a lower temperature means that the cooking time will have to be increased.

11 At very low pressures and temperatures, carbon dioxide can exist only as a solid or gas (or vapor above the gas). The atmosphere of Mars is 95 percent carbon dioxide. Mars, on average, is warm enough so that the atmosphere is mostly gaseous carbon dioxide. The polar regions are cold enough to enable solid carbon dioxide (dry ice) to exist, even at the low pressure.

13 (*a*)

59 (*a*) 0.70 cm/h, (*b*) 12 d

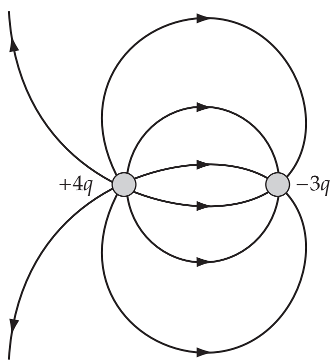
Chapter 21

1 The net charge on large objects is always very close to zero. Hence the most obvious force is the gravitational force.

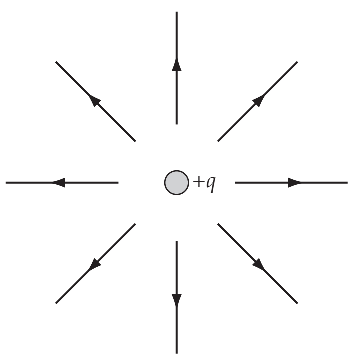
3 (*a*) Coulomb's law is only valid for point particles. The paper bits cannot be modeled as point particles because the paper bits become polarized.

(*b*) No, the attraction does not depend on the sign of the charge on the comb. The induced charge on the paper that is closest to the comb is always opposite in sign to the charge on the comb, and thus the net force on the paper is always attractive.

5 (*a*)

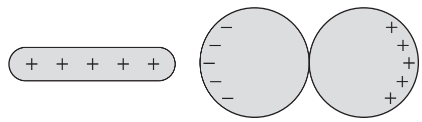


(*b*)



7 Assume that the rod has a negative charge. When the charged rod is brought near the aluminum foil, it induces a redistribution of charges with the side nearer the rod becoming positively charged, and so the ball of foil swings toward the rod. When it touches the rod, some of the negative charge is transferred to the foil, which, as a result, acquires a net negative charge and is now repelled by the rod.

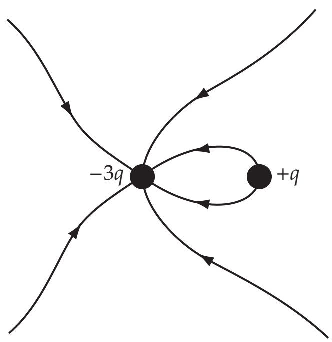
9 (*a*) On the sphere near the positively charged rod, the induced charge is negative and near the rod. On the other sphere, the net charge is positive and on the side far from the rod. This is shown in the diagram.



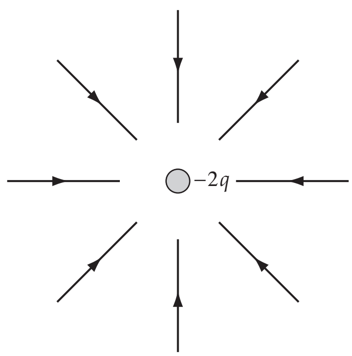
(*b*) When the spheres are separated and far apart and the rod has been removed, the induced charges are distributed uniformly over each sphere. The charge distributions are shown in the diagram.

11 (*a*) False, (*b*) True, (*c*) False, (*d*) Possibly, (*e*) False, (*f*) True

13 (*a*)



(*b*)



15 The dipole moment rotates back and forth in oscillatory motion. The dipole moment gains angular speed as it rotates toward the direction of the electric field, and loses angular speed as it rotates away from the direction of the electric field.

17

	1	2	3
(*a*)	down	up	up
(*b*)	up	right	left
(*c*)	down	up	up
(*d*)	down	up	up

Figure 21-23 shows the electric field due to a single dipole, where the dipole moment is directed toward the right. The electric field due two a pair of dipoles can be obtained by superposing the two electric fields.

19 Because the can is grounded, the presence of the negatively charged plastic rod induces a positive charge on it. The positive charges induced on the can are attracted, via the Coulomb interaction, to the negative charges on the plastic rod. Unlike charges attract, so the can will roll toward the rod.

21 5.0×10^{12} electrons

23 4.82×10^7 C

25 (*a*) 2.60 h, (*b*) 2.1×10^{-13} W

27 $\vec{F}_1 = (1.5 \times 10^{-2}\text{ N})\hat{i}$

29 A distance equal to $0.41L$ from the -2.9-μC charge on the side away from the 4.0-μC charge.

31 $\vec{F}_3 = -(8.65\text{ N})\hat{j}$

33 $\vec{F}_1 = (0.90\text{ N})\hat{i} + (1.8\text{ N})\hat{j}$, $\vec{F}_2 = (-1.3\text{ N})\hat{i} - (1.2\text{ N})\hat{j}$, $\vec{F}_3 = (0.4\text{ N})\hat{i} - (0.64\text{ N})\hat{j}$

(*c*) $v = \sqrt{8\left(1 - \sqrt{2/3}\right)}\sqrt{\dfrac{kqQ}{am}} = 1.21\sqrt{\dfrac{kqQ}{am}}$

85 $4.6 \times 10^{-14}\text{ m} = 46$ fm

87 (*b*) 52 μm/s

Chapter 22

1 The resultant field is directed along the dashed line, pointing away from the intersection of the two sides of the L-shaped object. This can be seen by dividing each leg of the object into 10 (or more) equal segments and then drawing the electric field on the dashed line due to the charges on each pair of segments that are equidistant from the intersection of the legs.

3 (*a*) True (assuming there are no charges inside the shell), (*b*) True, (*c*) False

5 (*a*) False, (*b*) True

7 (*a*) False, (*b*) False, (*c*) True, (*d*) False, (*e*) True

9 (*a*) radially inward, (*b*) radially outward, (*c*) radially inward

11 (*a*) radially inward, (*b*) radially inward, (*c*) The field is zero.

13 (*a*) 18 nC, (*b*) 26 N/C, (*c*) 4.4 N/C, (*d*) 2.6 mN/C, (*e*) This result is about 0.01% less than the exact value obtained in (*d*).

15 (*a*) 4.7×10^5 N/C, (*b*) 1.1×10^6 N/C, (*c*) 1.5×10^3 N/C (*d*) 1.5×10^3 N/C. This result agrees exactly, to two significant figures, with the result obtained in Part (*c*).

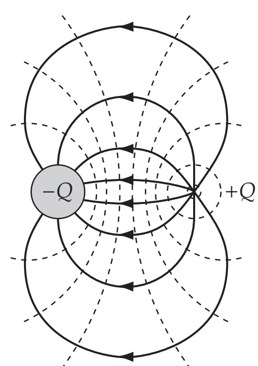
Chapter 23

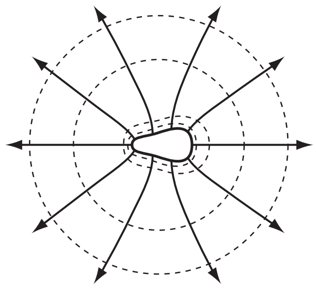
1 The proton is moving to a region of higher potential. The proton's electrostatic potential energy is increasing.

3 The electric field is zero throughout the region.

5



7



9 (*a*) 2, (*b*) 3

11 No. The local surface charge density is proportional to the normal component of the electric field, not the potential on the surface.

13 3.0×10^9 V

15 0.72 MeV

17 27 μC/m^2

19 (*a*) 4.49 kV, (*b*) 13.5 mJ

21 (*a*) -8.00 kV, (*b*) -24.0 mJ, (*c*) 24.0 mJ, (*d*) $V(x) = -(2.00 \text{ kV/m})x$

23 (*a*) 3.09×10^7 m/s, (*b*) 2.50 MV/m

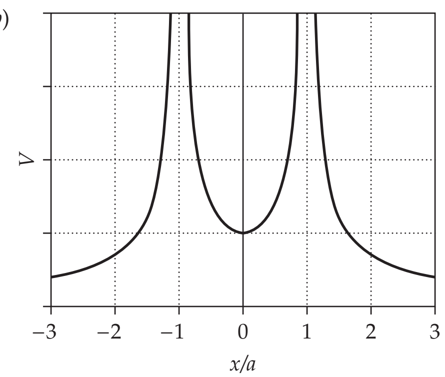
25 (*a*) $r = kzZe^2/K_i$, (*b*) 46 fm, 25 fm, (*c*) No. The distance of closest approach for a 5-MeV alpha particle found above (45.5 fm) is much larger than the 7 fm radius of a gold nucleus. Hence the scattering was solely the result of the inverse-square Coulomb force.

27 (*a*) 12.9 kV, (*b*) 7.55 kV, (*c*) 4.43 kV

29 (*a*) 135 kV (*b*) 95.3 kV (*c*) Because the two field points are equidistant from all points on the circle, the answers for Parts (*a*) and (*b*) would not change.

31 (*a*) $V(x) = kq\left(\dfrac{1}{|x-a|} + \dfrac{1}{|x+a|}\right)$,

(*b*)



33 (*b*) at points on the z axis

35 (*a*) positive, (*b*) 25.0 kV/m

37 (*a*) +668 nC, (*b*) 3.00 kV. The plane at $x = 2.00$ m is at the higher potential.

39 (*a*) $V(x) = kq\left(\dfrac{2}{\sqrt{x^2+a^2}} + \dfrac{1}{|x-a|}\right) \quad x \neq a$,

(*b*) $E_x(x) = \dfrac{2kqx}{(x^2+a^2)^{3/2}} + \dfrac{kq}{(x-a)^2} \quad x > a$,

$E_x(x) = \dfrac{2kqx}{(x^2+a^2)^{3/2}} - \dfrac{kq}{(a-x)^2} \quad x < a$

41 (*a*) 6.02 kV, (*b*) -12.7 kV, (*c*) -42.3 kV

43 ~3×10^{-5} C/m^2

45 $V_a - V_b = \dfrac{2kq}{L}\ln\left(\dfrac{b}{a}\right)$

47 $V_a - V_b = kq\left(\dfrac{1}{a} - \dfrac{1}{b}\right)$

49

Region	$x \le 0$	$0 \le x \le a$	$x \ge a$
Part (*a*)	$\dfrac{\sigma}{\epsilon_0}x$	0	$-\dfrac{\sigma}{\epsilon_0}(x-a)$
Part (*b*)	0	$-\dfrac{\sigma}{\epsilon_0}x$	0

51 (*a*) $V(x, 0) = \dfrac{kQ}{L}\ln\left(\dfrac{\sqrt{x^2 + \frac{1}{4}L^2} + \frac{1}{2}L}{\sqrt{x^2 + \frac{1}{4}L^2} - \frac{1}{4}L^2}\right)$

53 (*a*) $Q = \frac{1}{2}\pi\sigma_0 R^2$, (*b*) $V = \dfrac{2\pi k\sigma_0}{3R^2}\left((R^2 - 2z^2)\sqrt{z^2 + R^2} + 2z^3\right)$

55 (*a*) $V(x) = \dfrac{kQ}{L}\ln\left(\dfrac{x + \frac{1}{2}L}{x - \frac{1}{2}L}\right)$

57 (*a*) $dQ = \dfrac{3Q}{R^3}r'^2\,dr'$, (*b*) $dV = \dfrac{3kQ}{R^3}r'\,dr'$, (*c*) $V = \dfrac{3kQ}{2R^3}(R^2 - r^2)$,

(*d*) $dV = \left(\dfrac{3kQ}{R^3 r}\right)r'^2\,dr'$, (*e*) $V = \dfrac{kQ}{R^3}r^2$, (*f*) $V = \dfrac{kQ}{2R}\left(3 - \dfrac{r^2}{R^2}\right)$

61 (*a*) The equipotential surfaces are planes parallel to the charged planes. (*b*) The regions to either side of the two charged planes are equipotential regions, so any surface in either of these regions is an equipotential surface.

63 (*a*) 0.224 cm, closer to the wire, (*b*) 0.864 mm, (*c*) The distance between the 700 V and the 725 V equipotentials is 0.0966 mm. This closer spacing of these two equipotential surfaces was to be expected. Close to the central wire, two equipotential surfaces with the same difference in potential should be closer together to reflect the fact that the electric field strength is greater closer to the wire.

65 (*a*) 30.0 mJ, (*b*) -5.99 mJ, (*c*) -18.0 mJ

67 (*a*) 22.3 nC, (*b*) 22.3 μJ

69 $v = q\sqrt{\dfrac{6\sqrt{2}k}{ma}} = 2.91q\sqrt{\dfrac{k}{ma}}$

71 (*a*) 9.61×10^{-20} J, (*b*) 4.59×10^5 m/s, (*c*) Because $2K_{\text{i min}} > K_{\text{i escape}}$, the electron escapes from the proton with residual kinetic energy.

73 (*a*) $V(x) = \dfrac{2kq}{\sqrt{x^2+a^2}}$, (*b*) $\vec{E}(x) = \dfrac{2kqx}{(x^2+a^2)^{3/2}}\hat{\boldsymbol{i}}$

75 (*a*) $V(x, y) = \dfrac{\lambda}{2\pi\epsilon_0}\ln\left(\dfrac{\sqrt{(x-a)^2+y^2}}{\sqrt{(x+a)^2+y^2}}\right)$, $V(0, y) = 0$

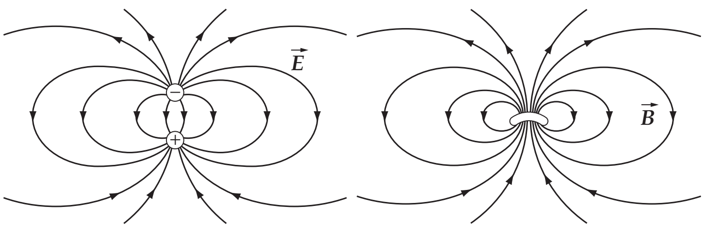
Chapter 27

1 Note that, while the two far fields (the fields far from the dipoles) are the same, the two near fields (the fields near to the dipoles) are not. At the center of the electric dipole, the electric field is antiparallel to the direction of the far field above and below the dipole, and at the center of the magnetic dipole, the magnetic field is parallel to the direction of the far field above and below the dipole. It is especially important to note that while the electric field lines begin and terminate on electric charges, the magnetic field lines are continuous, i.e., they form closed loops.



3 (*a*)

5 Both tell you about the respective fluxes through closed surfaces. In the electrical case, the flux is proportional to the net charge enclosed. In the magnetic case, the flux is always zero because there is no such thing as magnetic charge (a magnetic monopole). The source of the magnetic field is NOT the equivalent of electric charge; that is, it is NOT a thing called magnetic charge, but rather it is moving electric charges.

7 Clockwise

9 (*a*) True, (*b*) False, (*c*) True, (*d*) True

11 H_2, CO_2, and N_2 are diamagnetic ($\chi_m < 0$); O_2 is paramagnetic ($\chi_m > 0$).

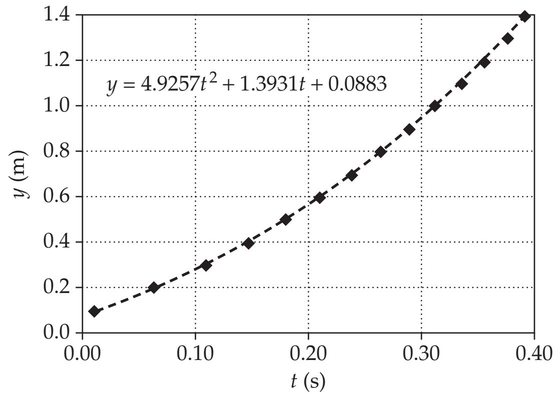
75 0.28 H

77 (*a*) As the magnet passes through a loop it induces an emf because of the changing flux through the loop. This allows the coil to "sense" when the magnet is passing through it. (*b*) One cannot use a cylinder made of conductive material because eddy currents induced in it by a falling magnet would slow the magnet. (*c*) As the magnet approaches the loop the flux increases, resulting in the negative voltage signal of increasing magnitude. When the magnet is passing a loop, the flux reaches a maximum value and then decreases, so the induced emf becomes zero and then positive. The instant at which the induced emf is zero is the instant at which the magnet is at the center of the loop.

(*d*)



$g = 9.85\ \text{m/s}^2$

79 (*a*) $E_r = -\frac{1}{2}r\mu_0 n I_0 \omega \cos \omega t \quad r < R$,

(*b*) $E_r = -\dfrac{\mu_0 n R^2 I_0 \omega}{2r}\cos \omega t \quad r > R$

Chapter 29

1 8.33 ms

3 (*b*)

5 (*c*)

7 Yes to both questions. (*a*) While the magnitude of the charge is accumulating on either plate of the capacitor, the capacitor absorbs power from the generator. (*b*) When the magnitude of the charge is on either plate of the capacitor is decreasing, it supplies power to the generator.

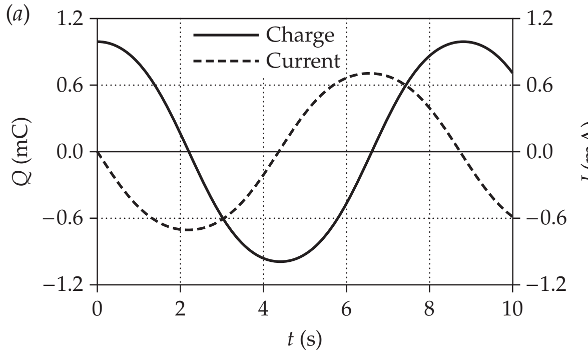
33 (*a*)



35 29.2 mH

37 (*a*) 0.33, (*b*) 27 Ω, (*c*) 0.20 H, (*d*) Because the circuit is inductive, the current lags the voltage. (*e*) 71°

39 0.397

41 (*a*) $I_{\text{rms}} = 6.23\ \text{A}$, $I_{R_L\,\text{rms}} = 2.80\ \text{A}$, $I_{L\,\text{rms}} = 5.53\ \text{A}$, (*b*) $I_{\text{rms}} = 3.28\ \text{A}$, $I_{R_L\,\text{rms}} = 2.94\ \text{A}$, $I_{L\,\text{rms}} = 1.46\ \text{A}$, (*c*) 50.2%, (*d*) 80.0%

43 60 V

45 (*a*) $\delta = \tan^{-1}\left[-\dfrac{1}{\omega RC}\right]$, (*b*) $\delta \to -90°$, (*c*) $\delta \to 0$,

(*d*) For very low driving frequencies, $X_C \gg R$ and so $\vec{V}_C$ effectively lags $\vec{V}_{\text{in}}$ by 90°. For very high driving frequencies, $X_C \ll R$ and so $\vec{V}_R$ is effectively in phase with $\vec{V}_{\text{in}}$.

51 (*b*) Note that, as $\omega \to 0$, $V_L \to V_{\text{peak}}$. This makes sense physically in that, for low frequencies, X_C is large and, therefore, a larger peak voltage will appear across it than appears across it for high frequencies. Note further that, as $\omega \to \infty$, $V_L \to 0$. This makes sense physically in that, for high frequencies, X_C is small and, therefore, a smaller peak voltage will appear across it than appears across it for low frequencies.

(*d*) $\int S_n\, dA = I^2R$

57 (*a*) 574 nm (*b*) The critical radius is an upper limit and so particles smaller than that radius will be blown out.

59 3.34 mN

Chapter 31

1 (*c*)

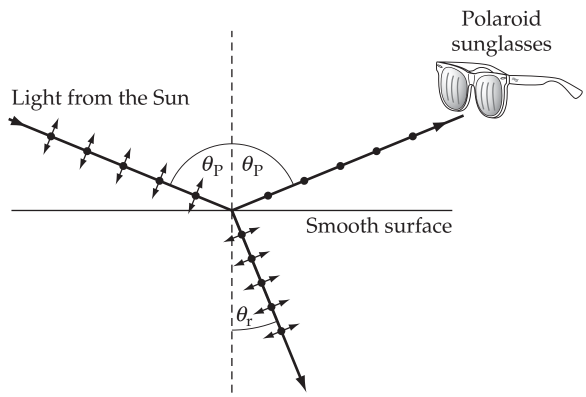
3 (*b*)

5 The decrease in the index of refraction n of the atmosphere with altitude results in refraction of the light from the Sun, bending it toward the normal to the surfaces on constant n (that is, toward the Earth). Consequently the Sun can be seen even after it is just below the horizon.

7 The path of least time is the path through point D.

9 In resonance absorption, the molecules respond to the frequency of the light through the Einstein photon relation $E = hf$. Neither the wavelength nor the frequency of the light within the eyeball depend on the index of refraction of the medium outside the eyeball. Thus, the color appears to be the same in spite of the fact that the wavelength has changed.

11



13 (*c*)

15 The population inversion between the state $E_{2\text{ Ne}}$ and the state 1.96 eV below it (see Figure 31-51) is achieved by inelastic collisions between neon atoms and helium atoms excited to the state $E_{2\text{ He}}$.

83 (*c*) 1.67°

Chapter 32

1 Yes. Note that a virtual image is "seen" because the eye focuses the diverging rays to form a real image on the retina. For example, you can photograph the virtual image of yourself in a flat mirror and get a perfectly good picture.

3 (*a*) False, (*b*) False, (*c*) True, (*d*) False

5 (*a*) The mirror will produce an upright image for all object distances.
(*b*) The mirror will produce a virtual image for all object distances.
(*c*) The mirror will produce an image that is smaller than the object for all object distances.
(*d*) The mirror will never produce an enlarged image.

7 (*b*)

9 (*d*)

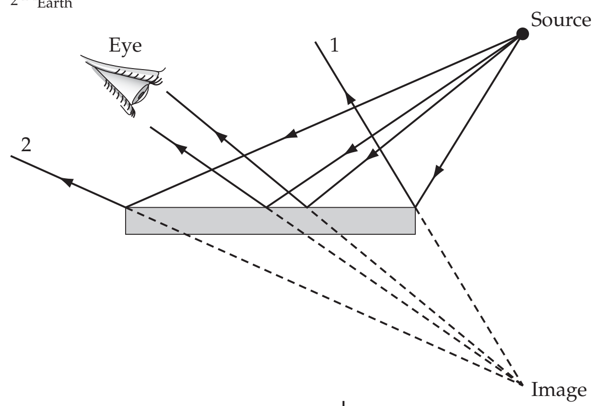
11 (*a*)

13 The muscles in the eye change the thickness of the lens and thereby change the focal length of the lens to accommodate objects at different distances. A camera lens, on the other hand, has a fixed focal length so that focusing is accomplished by varying the distance between the lens and the light-sensitive surface.

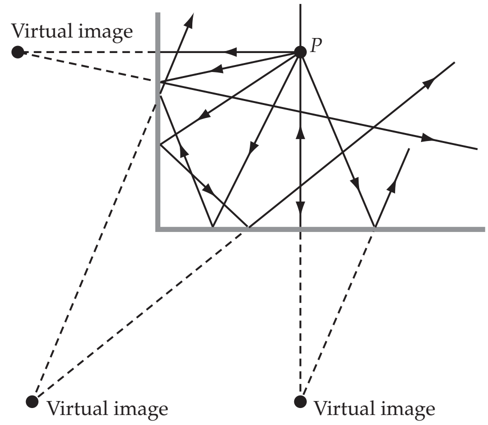
15 The objective lens of a microscope ordinarily produces an image that is larger than the object being viewed (see Figure 32-52), and that image is angularly magnified by the eyepiece. The objective lens of a telescope, on the other hand, ordinarily produces an image that is smaller than the object being viewed (see Figure 32-53), and that image is angularly magnified by the eyepiece. The telescope never produces a real image that is larger than the object.

17 $\frac{1}{2}R_{Earth}$

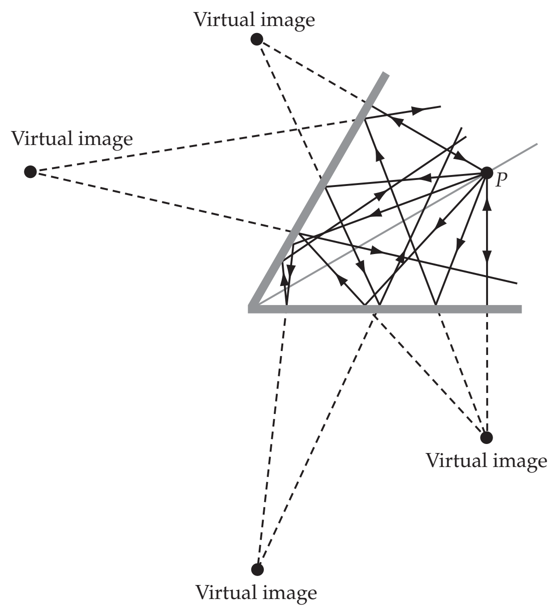
19



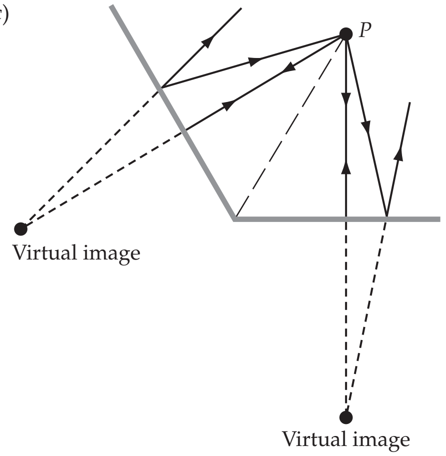
21 (*a*)



(*b*)



(*c*)



23 (*a*) For the mirror on the left, the location of the images to be 10 cm, 50 cm, 70 cm, and 110 cm behind the mirror on the left.
(*b*) For the mirror on the right, the location of the images to be 20 cm, 40 cm, 80 cm, and 100 cm behind the mirror on the right.
(*c*) The successive images are dimmer because the light travels farther to form them. The intensity falls of inversely with the square of the distance the light travels. In addition, at each reflection a small percentage of the light intensity is lost. Real mirrors are not 100% reflecting.

25 (*a*) 15 cm, 24 cm, undefined, −0.2 m,
(*b*) −0.28, −1.0, undefined, 3.0

27 (*a*) −9.9 cm, −8.0 cm, −6.0 cm, −4.8 cm,
(*b*) 0.18, 0.33, 0.50, 0.60

29 (*a*) concave, (*b*) 5.1 cm

31 The 3.7-cm-diameter image is 4.0 m in front of the mirror.

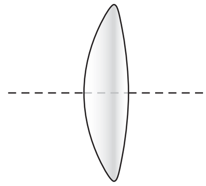
33 (*a*) −1.3 m, (*b*) convex

35 (*a*) $s' = -8.6$ cm, (*b*) 27 cm

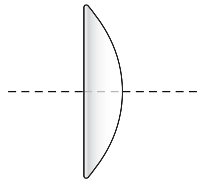
39 (*a*) 0.6 m, (*b*) −0.8 m, (*c*) The final image is inside the rod and 0.2 m from the surface whose radius of curvature is 8.00 cm and is virtual.

41 (*a*) −30 cm, (*b*) 22 cm from the lens and on the same side of the lens as the object, (*c*) 0.27, (*d*) virtual and upright

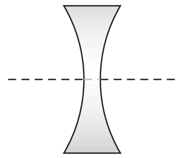
43 (*a*) 19 cm



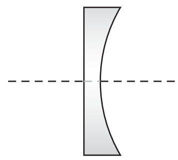
(*b*) 30 cm



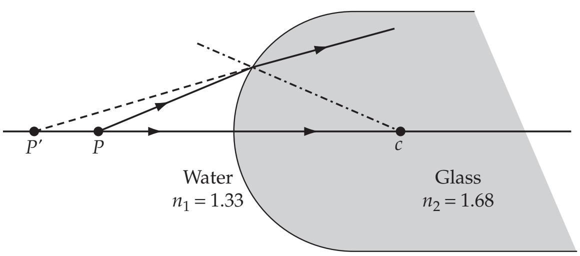
(*c*) −15 cm



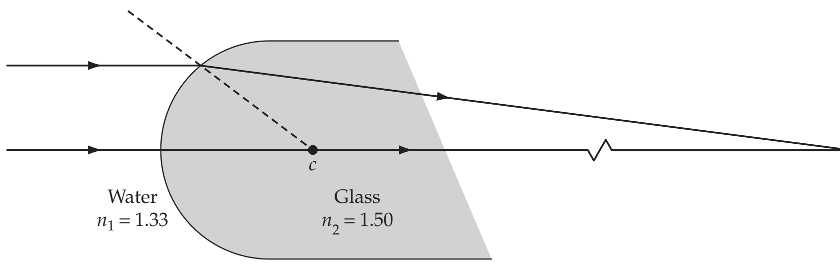
(*d*) −52 cm



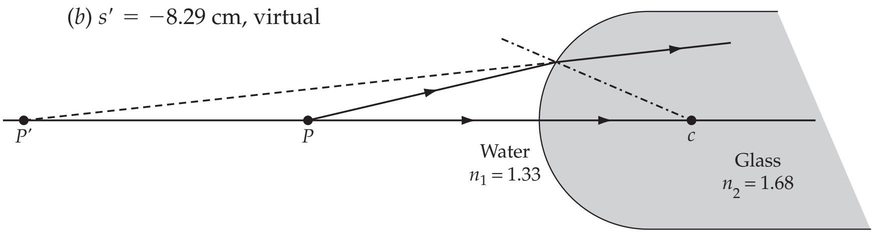
37 (*a*) $s' = -104$ cm, virtual



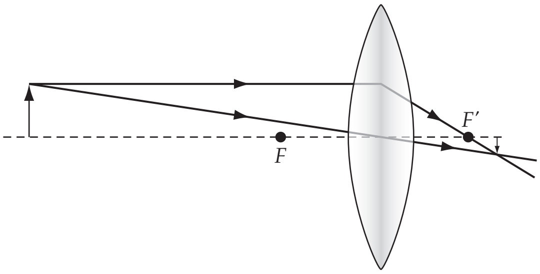
(*c*) $s' = 64$ cm, real



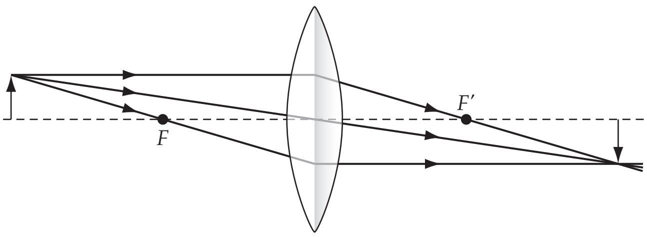
(*b*) $s' = -8.29$ cm, virtual



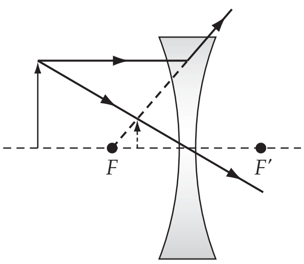
45 (*a*) $s' = 16.7$ cm, $y' = -2.00$ cm. Because $s' > 0$, the image is real and because $y'/y = -0.67$ cm, the image is inverted and diminished. These results confirm those obtained graphically. However, this ray diagram is not to scale.



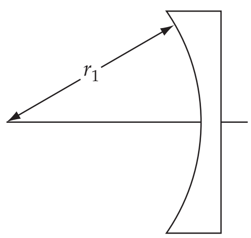
(*b*) $s' = 20.0$ cm, $y' = -3.00$ cm. Because $s' > 0$ the image is real. Because $y' = -3.00$ cm, the image is inverted and the same size as the object. These results confirm those obtained from the ray diagram.



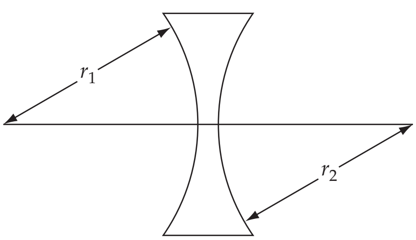
(*c*) $s' = -6.67$ cm, $y' = 1.00$ cm. Because $s' < 0$, the image is virtual. Because $y' = 1.00$ cm, the image is erect and about one-third the size of the object. These results are consistent with those obtained graphically.



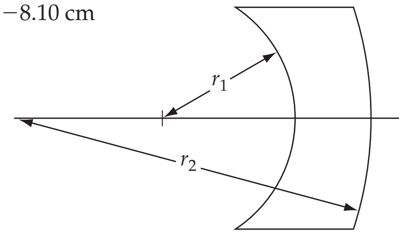
47 $r_1 = -16.2$ cm, $r_2 = \infty$,



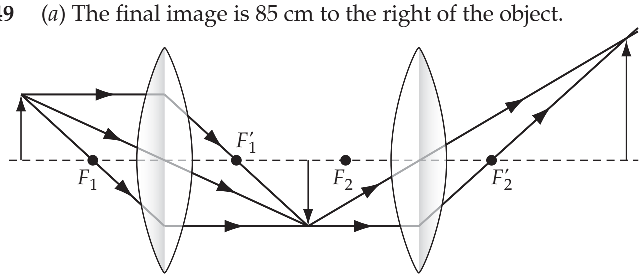
$r_1 = -32.4$ cm, $r_2 = 32.4$ cm,



$r_1 = -5.40$ cm, $r_2 = -8.10$ cm



49 (*a*) The final image is 85 cm to the right of the object.

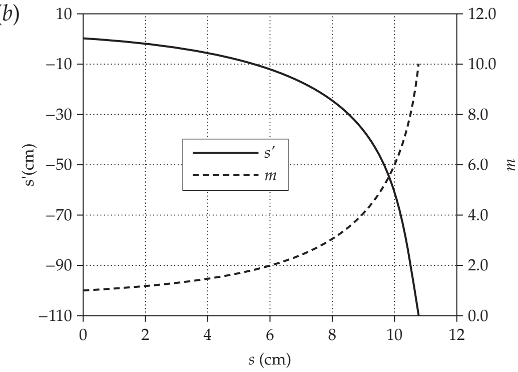


(*b*) Because $s_2' > 0$, the image is real, and because $m = m_1 m_2 = 2.0$, the image is erect and twice the size of the object.

(*c*) 2.0

51 (*b*) 3.70 m

53 (*a*) and (*b*)

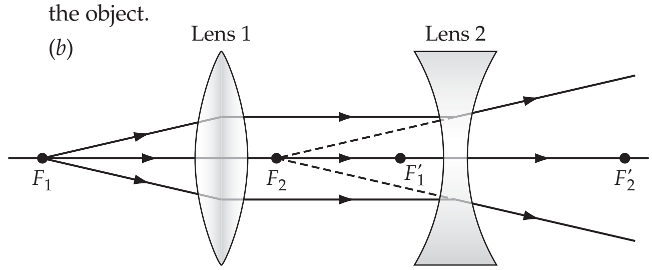


(*c*) The images are virtual and erect for this range of object distances.

(*d*) The equation for the vertical asymptote of the graph of s' versus s is $s = f$. This indicates, that as the object moves toward the second focal point, the magnitude of the image distance becomes large without limit. The equation for the vertical asymptote of the graph of m versus s is $s = f$. This indicates, that as the object moves toward the second focal point, the image becomes the large without limit. In addition, as s approaches zero s' approaches negative infinity and m approaches 1, so as the object moves toward the lens the image becomes the same size as the object and the magnitude of the image distance increases without limit.

55 (*a*) $s_2' = f_2 - 15.0$ cm, $m = m_2 = 1.00$. The final image is 20 cm from the object, virtual, erect, and the same size as the object.

(*b*)



59 (*a*) The final image is 18.7 cm to the right of the second lens. (*b*) −1.53 (*c*) Because $m < 0$, the image is inverted. Because $s'_2 > 0$, the image is real.

61 Reasons for the preference for reflectors include: (1) no chromatic aberrations, (2) less expensive to shape one side of a piece of glass than to shape both sides, (3) reflectors can be more easily supported from rear instead of edges, preventing sagging and focal length changes, and (4) support from rear makes larger sizes easier to handle.

63 −1.77 mm

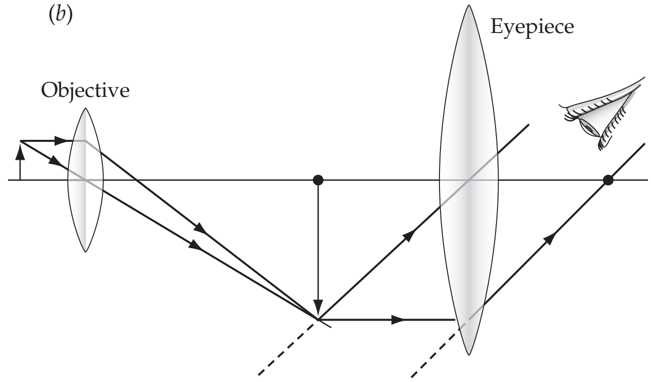
93 (*a*) The lens that has a focal length of 25 mm should be the objective. The two lenses should be separated by 210 mm. The angular magnification is −21.

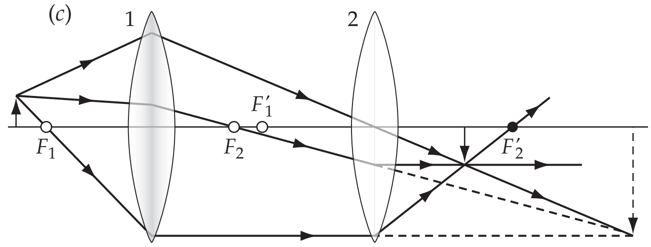
(*b*)



95 3.7 m

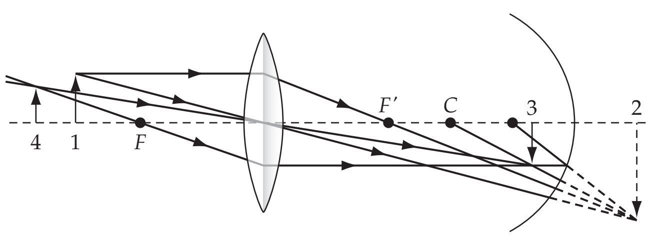
97 (*a*) 9.5 cm to the right of the second lens. (*b*) About 20% larger than the object and is inverted.

(*c*)



99 9.72 cm/s

101 (*a*) 18 cm from the lens, on the same side as the original object. (*b*) real and upright, (*c*) To see this image the eye must be to the left of image 4.



103 37 cm

105 (*a*) The final image is 13.2 cm to the left of the center of the ball. (*b*) Because s'_1 is undefined, no image is formed when the object is 20.0 cm to the left of the glass ball. (Alternatively, an image is formed an infinite distance to the left of the ball.)

Chapter 33

1 (*a*)

3 The thickness of the air space between the flat glass and the lens is approximately proportional to the square of d, the diameter of the ring. Consequently, the separation between adjacent rings is proportional to $1/d$.

5 Colors are observed when the light reflected from the front and back surfaces of the film interfere destructively for some wavelengths and constructively for other wavelengths. For this interference to occur, the phase difference between the light reflected from the front and back surfaces of the film must be constant. This means that twice the thickness of the film must be less than the coherence length of the light. The film is called a thin film if twice its thickness is less than the coherence length of the light.

17 The condition for the resolution of the two sources is given by Rayleigh's criterion: $\alpha_c = 1.22\,\lambda/D$ (Equation 33-25), where α_c is the critical angular separation, D is the diameter of the aperture, and λ is the wavelength of the light illuminating (or emitted by) the objects, in this case headlights, to be resolved. Because the diameter of the pupils of your eyes are larger at night, the critical angle is smaller at night, which means that at night you can resolve the light as coming from two distinct sources when they are at a greater distance.

1 Examination of Figure 36-4 indicates that as n increases, the spacing of adjacent energy levels decreases.

3 (*a*)

5 (*d*)

7 (*a*)

9 The energy of a bound isolated system that consists of two oppositely charged particles, such as an electron and a proton, depends only upon the principle quantum number n. For sodium, which consists of 12 charged particles, the energy of an $n = 3$ electron depends upon the degree to which the wave function of the electron penetrates the $n = 1$ and $n = 2$ electron shells. An electron in a 3s ($n = 3$, $\ell = 0$) state penetrates these shells to a greater degree than does an electron in a 3p ($n = 3$, $\ell = 1$) state, so a 3s electron has less energy (is more tightly bound) than is a 3p electron. In hydrogen, however, the wave function of an electron in the $n = 3$ shell cannot penetrate any other electron shells because no other electron shells exist. Thus, an electron in the 3s state in hydrogen has the same energy as an electron in the 3p state in hydrogen.

11 In conformity with the exclusion principle, the total number of electrons that can be accommodated in states of quantum number n is n^2 (see Problem 48). The fact that closed shells correspond to $2n^2$ electrons indicates that there is another quantum number that can have two possible values.

13 (*a*) phosphorus, (*b*) chromium

15 (*d*)

17 The optical spectrum of any atom is due to the configuration of its outer-shell electrons. Ionizing the next atom in the periodic table gives you an ion with the same number of outer-shell electrons, and almost the same nuclear charge. Hence, the spectra should be very similar.

Chapter 37

1 Because the center of charge of the positive Na ion does not coincide with the center of charge for the negative Cl ion, the NaCl molecule has a permanent dipole moment. Hence, it is a polar molecule.

3 Neon occurs naturally as Ne, not Ne_2. Neon is a noble gas. Atoms of noble gases have a closed shell electron configuration.

5 The diagram would consist of a nonbonding ground state with no vibrational or rotational states for ArF (similar to the upper curve in Figure 37-4) but for ArF* there should be a bonding excited state with a definite minimum with respect to internuclear separation and several vibrational states as in the excited state curve of Figure 37-13.

7 The effective force constant from Example 37-4 is 1.85×10^3 N/m. This value is about 25% larger than the given value of the force constant of the suspension springs on a typical automobile.

9 For H_2, the concentration of negative charge between the two protons holds the protons together. In the H_2^+ ion, there is only one electron that is shared by the two positive charges such that most of the electronic charge is again between the two protons. However, in the H_2^+ ion the negative charge between the protons is not as effective as the larger negative charge between them in the H_2 molecule, and the protons should be farther apart. The experimental values support this argument. For H_2, $r_0 = 0.074$ nm, while for H_2^+, $r_0 = 0.106$ nm.

11 For more than two atoms in the molecule, there will be more than just one frequency of vibration because more relative motions are possible. In advanced mechanics, these are known as normal modes of vibration.

13 $\ell \approx 2 \times 10^{30}$, $E_{0r} \approx 5 \times 10^{-65}$ J

15 0.947 nm

17 0.44 eV

19 You should agree. The potential energy curve is shown in the following diagram. The turning points for vibrations of energy E_1 and E_2 are at the values of r where the energies equal $U(r)$. The average value of r for the vibrational levels E_1 and E_2 are labeled $r_{1\,\text{av}}$ and $r_{2\,\text{av}}$. Note that the estimate of $r_{1\,\text{av}}$ is force midway between $r_{1\,\text{min}}$ and $r_{1\,\text{max}}$. The potential is like a special spring that has a greater force constant for compressions than it has for extensions. The period of a spring-and-mass oscillator is inversely proportional to the square root of the spring constant, so our "special spring" spends more time in extension than in compression. As a result, $r_{1\,\text{av}}$ will be greater than the equilibrium radius. This argument can be extended to explain why $r_{2\,\text{av}}$ is greater than $r_{1\,\text{av}}$. It is because the "force constant" for extension, which can be estimated by taking the average slope of the potential energy curve in the region to the right of the equilibrium position, is greater for $E = E_2$ than for $E = E_1$. It is also because the "force constant" for compression is greater for $E = E_2$ than for $E = E_1$. It follows that $r_{2\,\text{av}}$ is greater than $r_{1\,\text{av}}$. Because $r_{2\,\text{av}}$ is greater than $r_{1\,\text{av}}$, it follows that as the vibrational energy of a diatomic molecule increases, the average separation of the atoms of the molecule increases and, hence, the solid expands with heating.

Chapter 38

1 The energy lost by the electrons in collision with the ions of the crystal lattice appears as thermal energy throughout the crystal.

3 (*a*) potassium and nickel (*b*) 3.1 V

5 The resistivity of brass at 4 K is almost entirely due to the residual resistance (the resistance due to impurities and other imperfections of the crystal lattice). In brass, the zinc ions act as impurities in copper. In pure copper, the resistivity at 4 K is due to its residual resistance. The residual resistance is very low if the copper is very pure.

7 The resistivity of copper increases with increasing temperature; the resistivity of (pure) silicon decreases with increasing temperature because the number density of charge carriers increases.

9 (*b*)

11 The excited electron is the motion of the electron in the conduction band and contributes to the current. A hole is left in the valence band allowing the positive hole to move through the band, also the motion of the hole contributes to the current.

19 (*a*) −10.6 eV, (*b*) 2.83%

21 (*a*) 0.123 $\mu\Omega \cdot$m, (*b*) 70.7 n$\Omega \cdot$m

23 (*a*) $n_{Ag} = 5.86 \times 10^{22}$ electrons/cm^3
(*b*) $n_{Ag} = 5.90 \times 10^{22}$ electrons/cm^3. Both these results agree with the values in Table 38-1.

25 4.0

27 (*a*) 1.07×10^6 m/s (*b*) 1.39×10^6 m/s (*c*) 1.89×10^6 m/s

29 (*a*) 4.22 eV (*b*) 2.85 eV

31 (*a*) 5.90×10^{28} e/m^3, (*b*) 5.50 eV, (*c*) 212, (*d*) The ratio E_F/kT is equal to 212 at $T = 300$ K. The Fermi energy is the energy of the most energetic conduction electron when the crystal is at absolute zero. Because no two conduction electrons can occupy the same state, the Fermi energy is quite high compared with kT. The kT energy is the energy the average conduction electron would have when the crystal is at temperature T if the electrons did not obey the exclusion principle.

33 3.82×10^{10} N/m^2 = 3.77×10^5 atm

3 Generally, decay by α emission leaves the daughter nucleus neutron rich, i.e. above the line of stability. The daughter nucleus therefore tends to decay via β^- emission which converts a nuclear neutron to a proton.

5 It would make the dating unreliable because the current concentration of ^{14}C is not equal to that at some earlier time.

7 The probability for neutron capture by the fissionable nucleus is large only for slow (thermal) neutrons. The neutrons emitted during the fission process are fast (high energy) neutrons and must be slowed to thermal neutrons before they are likely to be captured by another fissionable nucleus.

37 About 15 g

39 7.0×10^8 y

41 (*a*) -0.764 MeV, (*b*) 3.27 MeV

43 (*a*) 0.156 MeV, (*b*) The masses given are for atoms, not nuclei, so the atomic masses are too large by the atomic number multiplied by the mass of an electron. For the given nuclear reaction, the mass of the carbon atom is too large by $6m_e$ and the mass of the nitrogen atom is too large by $7m_e$. Subtracting $6m_e$ from both sides of the reaction equation leaves an extra electron mass on the right. Not including the mass of the beta particle (electron) is mathematically equivalent to explicitly subtracting $1m_e$ from the right side of the equation.

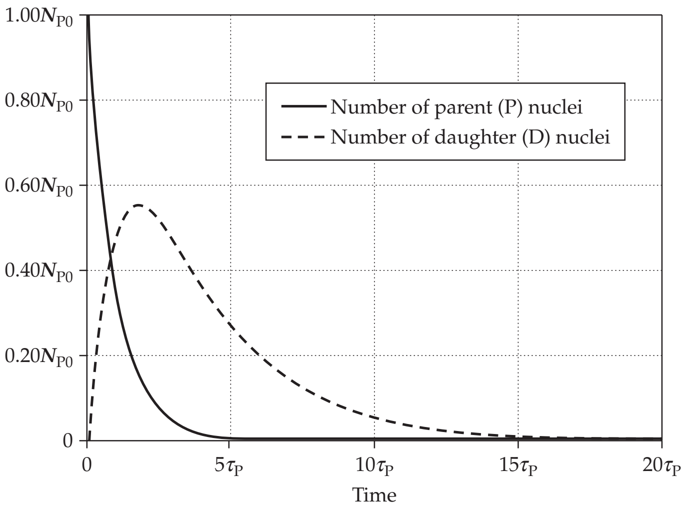
73 (*d*)



Chapter 41

1

Similarities	Differences
Baryons and mesons are hadrons, i.e., they participate in the strong interaction. Both are composed of quarks.	Baryons consist of three quarks and are fermions. Mesons consist of two quarks and are bosons. Baryons have baryon number +1 or −1. Mesons have baryon number 0.

3 A decay process involving the strong interaction has a very short lifetime ($\sim 10^{-23}$ s), whereas decay processes that proceed via the weak interaction have lifetimes of order 10^{-10} s.

5 False

7 No; from Table 41-3 it is evident that any quark–antiquark combination always results in an integral or zero charge.

9 (*a*) False, (*b*) True, (*c*) True

11 $\dfrac{F_{\text{em}}}{F_{\text{grav}}} = 1.24 \times 10^{36}$

13 (*a*) 279.2 MeV, (*b*) 1877 MeV, (*c*) 211.3 MeV

15 (*a*) Because $\Delta S = +1$, the reaction can proceed via the weak interaction, (*b*) Because $\Delta S = +2$, the reaction is not allowed, (*c*) Because $\Delta S = +1$, the reaction can proceed via the weak interaction.

17 (*a*) Because $\Delta S = +2$, the reaction is not allowed, (*b*) Because $\Delta S = +1$, the reaction can proceed via the weak interaction.

19 (*a*) K^0, (*b*) Σ^0 or Λ^0, (*c*) K^+

21

	Combination	B	Q	S	Hadron
(*a*)	*uud*	1	+1	0	p^+
(*b*)	*udd*	1	0	0	n
(*c*)	*uus*	1	+1	−1	Σ^+
(*d*)	*dds*	1	−1	−1	Σ^-
(*e*)	*uss*	1	0	−2	Ξ^0
(*f*)	*dss*	1	−1	−2	Ξ^-

23 From Table 41-3 we see that to satisfy the properties of charge number equal to +2 and strangeness, charm, topness, and bottomness all equal to zero, the quark combination must be *uuu*.

25 (*a*) $c\bar{d}$, (*b*) $\bar{c}d$

27 (*a*) *uds*, (*b*) $\bar{u}\,\bar{u}\,\bar{d}$, (*c*) *dds*

29 (*a*) *sss*, (*b*) *ssd*

31 $3.3 \times 10^8\, c \cdot \text{y}$

35 (*a*) Baryon number and lepton numbers are conserved quantities. A particle and its antiparticle must have baryon numbers that add to zero and lepton numbers that add to zero. Thus, for a particle and its antiparticle to be identical, its baryon number and all three of its lepton numbers must equal zero. This means it cannot be a lepton or a baryon, so it must be a meson. A particle and its antiparticle have the

complementary quark content. That is, if each quark in a particle is replaced by its antiquark, then the resulting entity is the antiparticle of the particle.
(b) The quark combination for the π^0 is a linear combination of $u\overline{u}$ and $d\overline{d}$ and the quark combination for the $\overline{\pi}^0$ is a linear combination of $\overline{u}u$ and $\overline{d}d$. The quark combination for the Ξ^0 is uss and that of the $\overline{\Xi}^0$ is $\overline{u}\,\overline{s}\,\overline{s}$.
(c) The π^0 is a meson with quark content of a linear combination of $u\overline{u}$ and $d\overline{d}$, so the π^0 is its own antiparticle. The Ξ^0 is a baryon. As is explained in the answer to Part (a), a baryon cannot be its own antiparticle.

37 (a) The u and $\overline{u}$ annihilate, resulting in the photons.
(b) Two or more photons are required to conserve linear momentum.

39 (a) π^+, (b) -815 MeV, (c) 1.98 GeV

41 (a) 38 MeV, (b) 6.72, (c) 5 MeV, 33 MeV

Physical Constants*

Atomic mass constant	$m_u = \frac{1}{12} m(^{12}\mathrm{C})$	$1\ \mathrm{u} = 1.660\,538\,86(28) \times 10^{-27}$ kg
Avogadro's number	N_A	$6.022\,1415(10) \times 10^{23}$ particles/mol
Boltzmann constant	$k = R/N_A$	$1.380\,6505(24) \times 10^{-23}$ J/K $8.617\,343(15) \times 10^{-5}$ eV/K
Bohr magneton	$m_B = e\hbar/(2m_e)$	$9.274\,009\,49(80) \times 10^{-24}$ J/T = $5.788\,381\,804(39) \times 10^{-5}$ eV/T
Coulomb constant	$k = 1/(4\pi\epsilon_0)$	$8.987\,551\,788\ldots \times 10^{9}\ \mathrm{N\cdot m^2/C^2}$
Compton wavelength	$\lambda_C = h/(m_e c)$	$2.426\,310\,238(16) \times 10^{-12}$ m
Fundamental charge	e	$1.602\,176\,53(14) \times 10^{-19}$ C
Gas constant	R	$8.314\,472(15)\ \mathrm{J/(mol\cdot K)}$ = $1.987\,2065(36)\ \mathrm{cal/(mol\cdot K)}$ = $8.205\,746(15) \times 10^{-2}\ \mathrm{L\cdot atm/(mol\cdot K)}$
Gravitational constant	G	$6.6742(10) \times 10^{-11}\ \mathrm{N\cdot m^2/kg^2}$
Mass of electron	m_e	$9.109\,3826(16) \times 10^{-31}$ kg = $0.510\,998\,918(44)\ \mathrm{MeV}/c^2$
Mass of proton	m_p	$1.672\,621\,71(29) \times 10^{-27}$ kg = $938.272\,029(80)\ \mathrm{MeV}/c^2$
Mass of neutron	m_n	$1.674\,927\,28(29) \times 10^{-27}$ kg = $939.565\,360(81)\ \mathrm{MeV}/c^2$
Magnetic constant (permeability of free space)	μ_0	$4\pi \times 10^{-7}\ \mathrm{N/A^2}$
Electric constant (permittivity of free space)	ϵ_0	$= 1/(\mu_0 c^2) = 8.854\,187\,817\ldots \times 10^{-12}\ \mathrm{C^2/(N\cdot m^2)}$
Planck's constant	h	$6.626\,0693(11) \times 10^{-34}\ \mathrm{J\cdot s}$ = $4.135\,667\,43(35) \times 10^{-15}\ \mathrm{eV\cdot s}$
	$\hbar = h/(2\pi)$	$1.054\,571\,68(18) \times 10^{-34}\ \mathrm{J\cdot s}$ = $6.582\,119\,15(56) \times 10^{-16}\ \mathrm{eV\cdot s}$
Speed of light	c	$2.997\,924\,58 \times 10^{8}$ m/s
Stefan-Boltzmann constant	σ	$5.670\,400(40) \times 10^{-8}\ \mathrm{W/(m^2\cdot K^4)}$

*The values for these and other constants can be found in Appendix B as well as on the Internet at http://physics.nist.gov/cuu/Constants/index.html. The numbers in parentheses represent the uncertainties in the last two digits. (For example, 2.044 43(13) stands for 2.044 43 ± 0.000 13.) Values without uncertainties are exact. Values with ellipses are exact (like the number π = 3.1415. . .), but are not completely specified.

Derivatives and Definite Integrals

$$\frac{d}{dx}\sin ax = a\cos ax \qquad \int_0^\infty e^{-ax}\,dx = \frac{1}{a} \qquad \int_0^\infty x^2 e^{-ax^2}\,dx = \frac{1}{4}\sqrt{\frac{\pi}{a^3}}$$

$$\frac{d}{dx}\cos ax = -a\sin ax \qquad \int_0^\infty e^{-ax^2}\,dx = \frac{1}{2}\sqrt{\frac{\pi}{a}} \qquad \int_0^\infty x^3 e^{-ax^2}\,dx = \frac{4}{a^2}$$

$$\frac{d}{dx}e^{ax} = ae^{ax} \qquad \int_0^\infty xe^{-ax^2}\,dx = \frac{2}{a} \qquad \int_0^\infty x^4 e^{-ax^2}\,dx = \frac{3}{8}\sqrt{\frac{\pi}{a^5}}$$

The a in the six integrals is a positive constant.

Vector Products

$\vec{A}\cdot\vec{B} = AB\cos\theta$ $\vec{A}\times\vec{B} = AB\sin\theta\,\hat{n}$ ($\hat{n}$ obtained using right-hand rule)

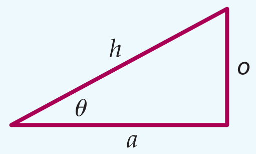
For additional data, see the following tables in the text.

Geometry and Trigonometry

$C = \pi d = 2\pi r$	definition of π
$A = \pi r^2$	area of circle
$V = \frac{4}{3}\pi r^3$	spherical volume
$A = \partial V/\partial r = 4\pi r^2$	spherical surface area
$V = A_{\text{base}} L = \pi r^2 L$	cylindrical volume
$A = \partial V/\partial r = 2\pi r L$	cylindrical surface area

$o = h \sin\theta$

$a = h \cos\theta$



$\sin^2\theta + \cos^2\theta = 1$

$\sin(A \pm B) = \sin A \cos B \pm \cos A \sin B$

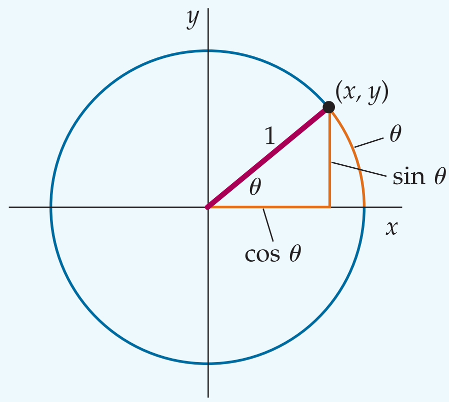
$\cos(A \pm B) = \cos A \cos B \mp \sin A \sin B$

$\sin A \pm \sin B = 2 \sin[\frac{1}{2}(A \pm B)] \cos[\frac{1}{2}(A \mp B)]$

$\sin\theta \equiv y$

$\cos\theta \equiv x$

$\tan\theta \equiv \dfrac{y}{x}$



If $|\theta| << 1$, then

$\cos\theta \approx 1$ and $\tan\theta \approx \sin\theta \approx \theta$ (θ in radians)

Quadratic Formula

If $ax^2 + bx + c = 0$, then $x = \dfrac{-b \pm \sqrt{b^2 - 4ac}}{2a}$

Binomial Expansion

If $|x| < 1$, then $(1 + x)^n =$

$$1 + nx + \frac{n(n-1)}{2!}x^2 + \frac{n(n-1)(n-2)}{3!}x^3 + \ldots$$

If $|x| << 1$, then $(1 + x)^n \approx 1 + nx$

Differential Approximation

If $\Delta F = F(x + \Delta x) - F(x)$ and if $|\Delta x|$ is small,

then $\Delta F \approx \dfrac{dF}{dx}\Delta x$.
